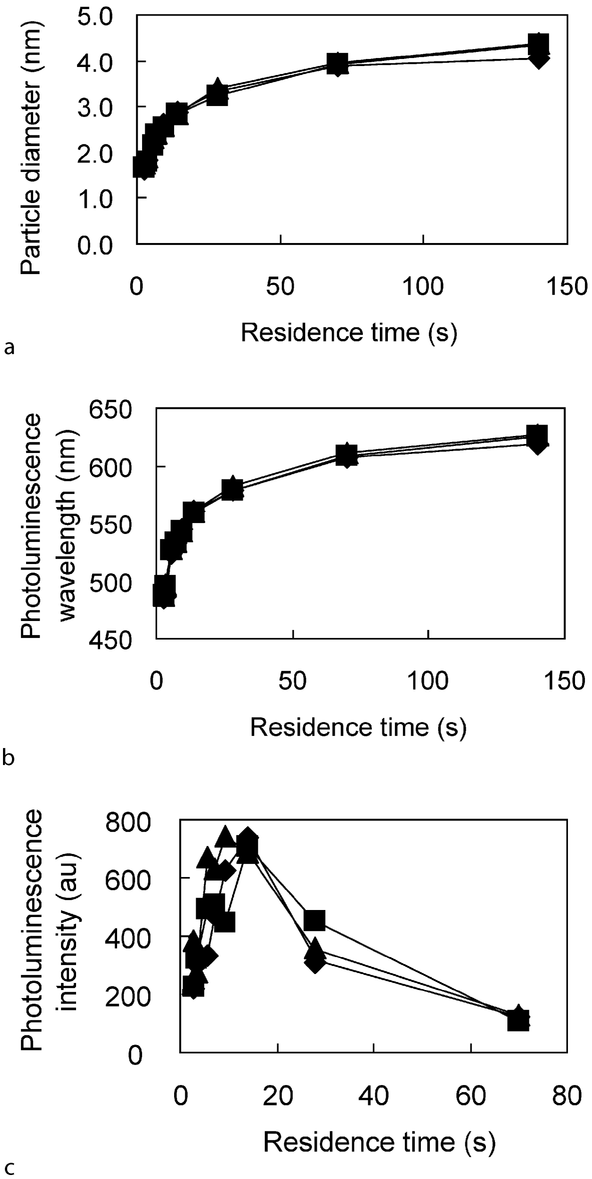
Nanoparticle Synthesis in Microreactors, Figure 4 Size and luminescence wavelength control of CdSe nanoparticles by a microreactor

was mainly used to obtain a stable interface for nanoparticle generation. It was reported that a thin mixed phase (∼1 nm) existed in the oil–water interface where the reaction mainly occurred. In this case, they utilized easily hydrolyzable titanium alkoxide as Ti source; however, the interface reaction made the reaction condition sufficiently slow. Here, they focused on the reaction field control rather than the control of reaction time. By using this method, a continuous synthesis of anatase-type TiO_2 nanoparticles, whose reproducible production is difficult in a batch system, became possible.

Method (c) was performed by Nakamura et al. of the same group as Wang. They utilized high temperature controllability of the microreactor. Here, they previously mixed all reaction solutions (reaction at room temperature was negligible) and heated to the reaction temperature to initiate particle generation. In the temperature-triggered reaction, it was easily possible to stop the reaction by quenching the reaction solution. The reaction time can be tuned by controlling the reactor volume and flow rate in an easy and exact fashion, and it was possible to tune the product particle size very easily (Fig. 4). Furthermore, they introduced inert gas bubbles into the reactor to obtain narrow residential time distribution. They also showed that the reproducibility of the reaction, when they used the identical reaction solution, was extremely high (Fig. 5a, b) [2], showing reproducible nucleation and growth process. The high reproducibility of the nucleation process, in particular, is not easy for a batch reactor. The fairly high reproducibility was also found in optical properties (Fig. 5c) [2]. They used a commercial quartz capillary tube as a microreactor. The tube had thin walls (a few tens of micrometers) and had high heat conductivity, and fabrication of the microreactor was easy.

These three reports have succeeded in showing the possibility of nanoparticle synthesis using a microreactor. Especially, method (c) showed that a dimension of time, which is not easy to control, can be controlled by space, which is much easier to control, for nanoparticle synthesis.

On the other hand, a segmented reaction solution like the one in method (c) can produce eddies in the solution



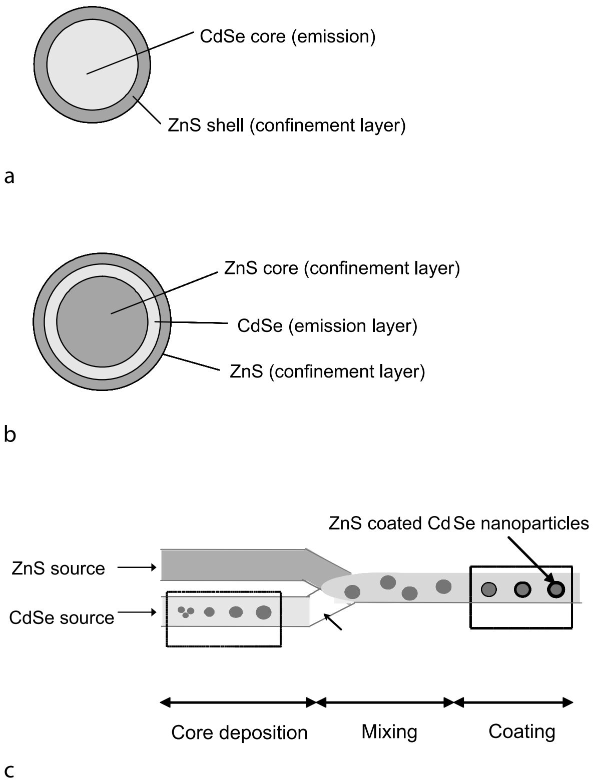
Nanoparticle Synthesis in Microreactors, Figure 5 Reproducibility of CdSe nanoparticle properties: (**a**) band edge peak location, (**b**) photoluminescence wavelength, (**c**) photoluminescence intensity

caused by the friction between channel wall and the solution. The eddies can stir the solution, mixing it rapidly at almost millisecond time scales.

In 2004, Shestopalov et al. [6] reported another method:

(d) Segmentation of reaction solution for rapid and sequential mixing of reaction solutions (Fig. 3d).

In this method, to stop the particle growth reaction, the authors rapidly mixed a capping agent (surfactant) which strongly coordinates the products and/or raw materials. (Diluting was also effective to quench the reaction.) This kind of method can control the growth time of the



Nanoparticle Synthesis in Microreactors, Figure 6 Schematic images of composite nanoparticles (**a, b**), and sequential mixing process for CdSe/ZnS composite nanoparticle synthesis (**c**)

order of a millisecond. As mentioned above, to control nanoparticle synthesis, it is important to control the reaction homogeneously in a sufficiently short time. Therefore, this kind of method is expected to be an excellent way to control the reaction condition of nanoparticles especially where strict reaction condition control is required.

Many works have since reported the expansion of applicability and optimization of operation, but still most of the work can be roughly categorized into the four methods above. Several kinds of processes are utilized in microreactors for nanoparticle synthesis, including organometallic route, sol–gel, supercritical, reduction, and polyol methods. Moreover, a wide range of materials including metal chalcogenides, multinary compounds, metal oxides, metals, and organic pigments are synthesized, showing the wide applicability of this method for various nanoparticle syntheses.

Composite Nanoparticle Synthesis Using a Microreactor

Composite structure of nanoparticles largely affects their properties, as can be seen in semiconductor nanoparti-

cles [1]. Therefore, if it is possible to control the structure of composite nanoparticles, it could be possible to provide a wide range of particles with high-valued properties. From this point of view, some works have reported the composite structure control of nanoparticles. Here, the high reaction controllability of microreactors is expected to be helpful for composite structures and property control.

Photoluminescence (PL) intensity of CdSe nanoparticles is improved drastically by a wide bandgap material coating like ZnS (Fig. 6a) [1]. However, PL wavelength shifts with coating layer thickness, and too great a thickness of the coating layer induces interfacial defects between the core and shell to reduce PL intensity. Therefore, in order to improve PL intensity by maintaining monochromaticity of luminescence spectra, control of coating layer thickness by maintaining a homogeneous amount of coating is necessary. Demonstrating this, Wang et al. utilized a microreactor to synthesize ZnS-coated CdSe (CdSe/ZnS), and showed that it was possible to increase the intensity by maintaining narrow PL intensity [7] (Fig. 7). This method can control only one condition (i. e., temperature, reaction time) by fixing other conditions. Therefore, optimization of reaction condition can be easily done. Furthermore, this method can be utilized in a multi-step method by sequential addition of raw materials (Fig. 6c).

In our group, we found it was possible to synthesize a nanoparticle, in which a CdSe inner shell was sandwiched between ZnS core and outer shell (QDQW structure nanoparticle; Fig. 6b), by sequential deposition of the ZnS core, then the CdSe shell, and finally the ZnS outer shell. The particle had a high quantum yield with blue PL, and furthermore it was possible to control bandgap and PL wavelength by controlling CdSe shell thickness which was controlled by the quantum size effect.

These results show the ability of a microreactor to control the composite structure as well as the size of nanoparticles. A segmentation flow was also reported for the synthesis of CdSe/CdS composite nanoparticles using a similar strategy [6].

Optimization and Analysis of Particle Growth Kinetics Using Microreactors

As described above, numerous kinds of nanoparticles and composite nanoparticles are being developed, and these require optimization of synthesis conditions. Actually, numerous reports on nanoparticle synthesis using microreactors discussed reaction condition optimization or its possibilities. Furthermore, analysis of nucleation and growth kinetics will be helpful for deeper understanding of the particle generation and further development or alterations of the synthesis method. The above-mentioned high reaction condition controllability and reproducibility of microreactors will benefit quick reaction analysis. For example, the flexible reaction time tuneability of microreactors can be used for particle growth analysis [2]. By this method, as shown in Fig. 8, CdSe nanocrystal synthesis was confirmed, and the growth kinetics fit a diffusion-limited growth formula

$$\mathrm{d}r/\mathrm{d}t = DV_\mathrm{m}\,(1/r + 1/d)\,(C_\mathrm{b} - C_\mathrm{e})$$

where D is the diffusion coefficient of the monomer, V_m is the molar volume of the monomer, r is the particle diameter, d is the thickness of the diffusion layer, C_b is the bulk concentration of the monomer, and C_e is the equilibrium concentration of the monomer at the particle surface.

It is worth mentioning that all of the sample for data shown in Fig. 8 was obtained in a 1-day experiment, and this plainly shows the advantage of a microreactor as a kinetics analyzer. Moreover, it was shown that synthesis conditions affect the particle number, which would be induced by nucleation frequency.

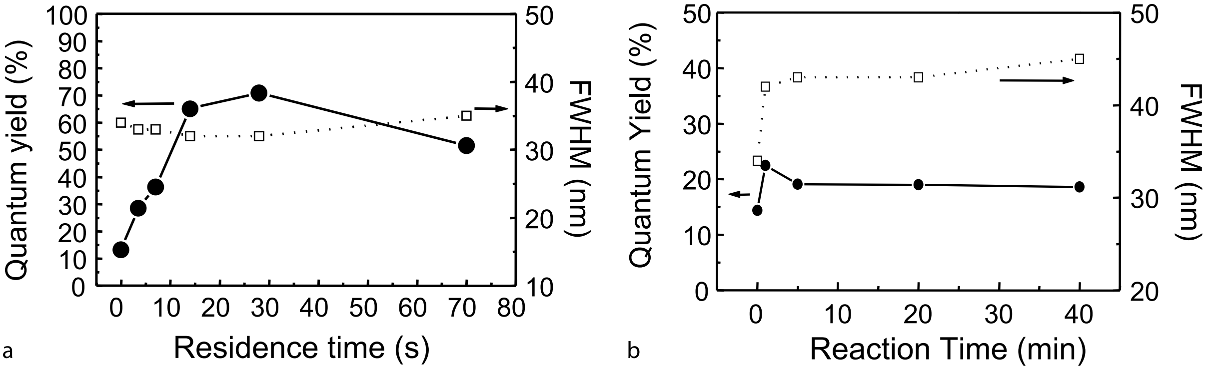
Additionally, on-line analysis can enhance the speed of reaction analysis. Therefore, reaction condition optimizations by microreactors are effective. For example, in a report in 2003, Chan et al. mixed previously heated Cd and Se source in a micromixer, and stopped the reaction by cooling and diluting. The properties of the product were determined on-line using a spectrometer, showing that online monitoring of the product properties was possible. Similarly, the on-line monitoring of properties of nanoparticles whose morphology offers optical properties (e. g., semiconductors) is straightforward. Other techniques like IR and Raman spectroscopy can be used on-line, and it is expected that these on-line methods will enhance new materials and process development for nanoparticle synthesis by microreactors.

N

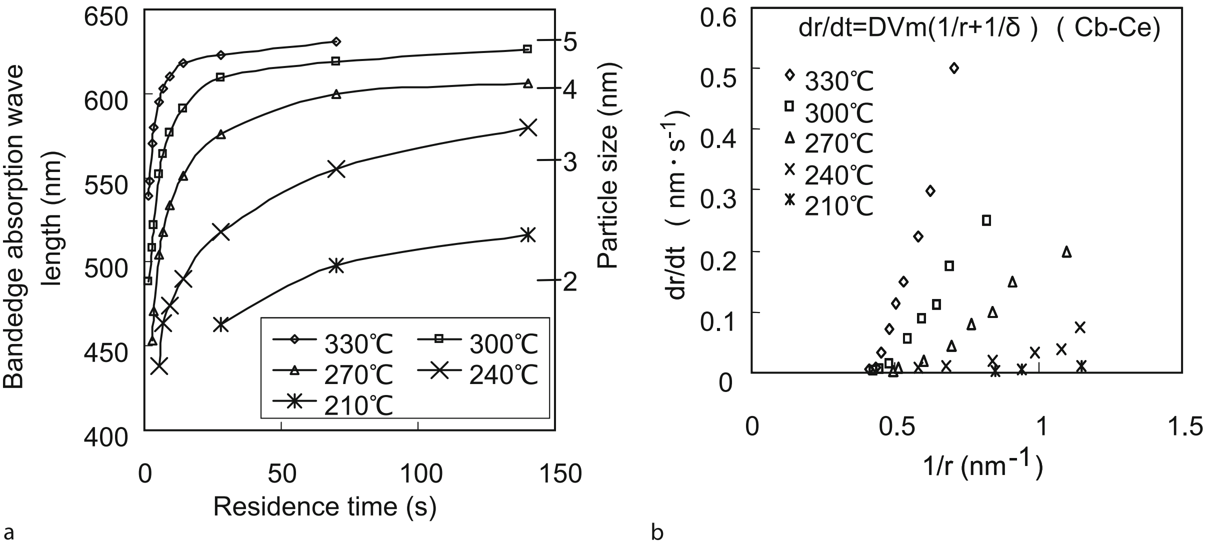
Problems in Nanoparticle Synthesis by Microreactors and their Solutions

The realization of industrial production of nanoparticles by microreactors still faces some problems, and several papers point out these problems and possible approaches to solve them.

One of the main problems is the scale of the reaction system. So far, with some exceptions, production rates of reactors are less than 1 ml/min. Therefore, the industrial production of nanoparticles requires piling up of the reactors or further optimization of the reactor design by maintaining the above outstanding features. For organic pigment nanoparticles, a pilot plant targeting 100 t/year has



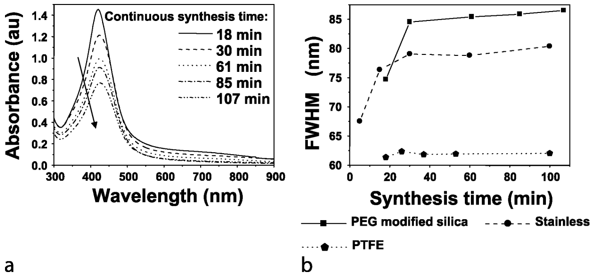
Nanoparticle Synthesis in Microreactors, Figure 7 Effect of coating time on quantum yield and full width at half maximum of fluorescence spectra of CdSe/ZnS composite particles: (**a**) microreactor; (**b**) batch reactor



Nanoparticle Synthesis in Microreactors, Figure 8 Particle growth kinetics analysis of CdSe nanoparticles: (**a**) average particle size development; (**b**) fitting result to diffusion growth model

been launched, showing the great potential of microreactors as industrial reactors for nanoparticle synthesis.

Despite the productivity of the reactors, at least two problems are found: one is the residential time distribution and the other is depositions on the reactor wall. The effects of residential time distribution on the particle size distribution was analytically discussed for CdSe nanoparticle synthesis by Krishnadasan et al. [8] As mentioned above, the growth mode of CdSe is diffusion limited, and normally gives a narrower particle size distribution for longer particle growth time (as far as particle growth is limited by monomer diffusion). However, in experiments, higher flow rate (i. e., shorter reaction time) gave a narrow particle size distribution. Krishnadasan et al. explained that the phenomenon is caused by the enlargement of absolute reaction time distribution. They also mentioned that mixing by transverse diffusion requires a long time for nanoparticles, because their size, which is much larger than small molecules, caused a reduction of diffusion rate, and was not helpful in equalizing their residential time by transverse diffusion for a practical size (i. e., of the order of 100 μm). On the other hand, a similar reaction system with higher temperature and higher flow rate gave a narrower particle size distribution [2, 5]. In this case, the absolute time was much shorter than in the work of Krishnadasan et al., and therefore the particle growth followed the batch system, thus showing that the particle growth kinetics as well as residential time distribution determined the particle size distribution. To solve the problem, a segmentation, achieved by introducing immiscible inert gas



Nanoparticle Synthesis in Microreactors, Figure 9 (**a**) UV–visible spectra of silver nanoparticle colloids at different synthesis times when a polyethylene glycol-modified silica tube was used. (**b**) Plots of corresponding full width at half maximum of surface plasmon peak of silver nanoparticles synthesized in microreactors with different wall surfaces

or liquid into the flow system, was effective [5, 6]. This method is widely applicable for many reaction systems and temperatures.

As mentioned above, precise reaction control can be realized by the high reactor surface area to reactor volume ratio of the microchannel. On the other hand, it can also cause one of the other critical problems, that is, deposition of reactants on the reactor channel wall. Obviously, a large amount of deposition will lead to clogging or uncontrollable flow in the reactor channel. However, even a small amount of deposition, which does not affect the flow pattern, can give a larger particle size distribution as He et al. reported [9]. In our experience, this is a general phenomenon and is presumed to be caused by longer residence time by adsorption deposition, or aggregation of clusters on the surface.

Deposition has serious effects in practical applications. To solve this problem, at this point, we can only suggest to *choose proper channel wall material for the reaction system*. The material can be chosen based on affinity balance between particle–particle, particle–solvent, and solvent–wall. Beside the physical or physicochemical affinities, chemical affinities such as solidification by surface reaction between adsorbed ions and dissolved ions can also induce deposition. If the affinity between particle and wall is smaller than that between solvent and wall, particles are expected not to be deposited on the wall. Therefore, proper choice of reactor wall or surface modification can be good options (Fig. 9) [9]. Also, proper choice of surfactants is also helpful. However, as far as our knowledge is concerned, it is very difficult to obtain general solutions to the deposition problem, and a good combination of reactor material, reaction system, and operation conditions is required.

Takagi et al. [10] reported a plausible method. They applied sheath flow, where raw material was dissolved only in the inner flow, and synthesized TiO_2 nanoparticles by a sol-gel method. The outer flow can be regarded as "liquid wall" and can prevent the produced particles from attaching to the wall. In the report by Shestopalov et al. on a segmented flow reactor, they mentioned that almost no deposition was found in the reactor [6]. These reports suggest that reactor design, other than the choice of reaction system and wall surface, can also solve the problem, although intrinsic resolution for long stable operation may still require the proper reaction system.

Key Research Findings

Generally, nanocrystal synthesis consists of four processes: nucleation, growth, ripening, and aggregation. To control nanocrystal properties such as particle size and distribution, it is necessary to control these processes. Precise reaction control can be realized by utilizing a microreactor. Owing to the small size dimension, this useful tool can achieve control of temperature and mixing rate in a sufficient time scale (i. e., of the order of 100 ms) as shown by the reported results. Therefore, a microreactor can tune nanocrystal properties by ensuring precise control of reaction parameters such as temperature and reaction time. Furthermore, the high controllability can help one achieve a homogeneous structure of composite particles and at the same time tune their structure. The reproducible result for particle size control also show that the nucleation and growth processes can be well controlled for the said processes. Based on the attained high reaction controllability and reproducibility by the microreactor, it is suggested that this convenient tool can be applied to particle growth analysis. Especially for systems that can combine with online monitoring, e. g., semiconductor nanoparticles which show quantum size effects, the tool could enhance the development of the synthesis process by rapid optimization and analysis. Presently, microreactor-based methods are applied to many reaction systems including aqueous methods, organometallic route, sol–gel process, hydrothermal process, and polyol process, and to the synthesis of various materials such as metals and their oxides or chalcogenides, and organic pigments.

There are some problems encountered such as residential time distribution and deposition on the wall. The residential time distribution can induce widening of the particle size distribution. This can be solved by proper design of the reactor or designing the operation such that the reaction time is reduced or by introducing segmented flow. The deposition of reactant on the wall can cause critical problems because it can induce clogging, uncontrollable flow, particle size distribution widening, and reduction of product yields. To solve these problems, proper choice of reaction systems and wall materials is necessary. Furthermore,

sheath flow and segmented flow have been reported to be considerably effective in preventing deposition.

Future Directions for Research

As discussed, precise and reproducible reaction control can be realized by using microreactors for nanoparticle synthesis. Continuous production of nanoparticles by microreactors can be made possible by maintaining their morphology and structure which consequently determine the nanoparticle properties. Therefore, microreactors can be expected to be on-site on-demand production reactors, i. e., small but flexible in operation condition, with the capability to produce the required material properties in the required amount. It should be possible to pile up or design microreactors for small-scale industry without losing the preciseness and flexibility in control of reaction conditions. For nanoparticles of high value and with properties dependent on their morphology and structure, it would be possible to establish a flexible, on-demand production process, that is, tuning properties and providing product as required. Particularly for semiconductor nanoparticles, their properties can undergo slight fluctuations in the experimental conditions including the quality of raw materials or contaminations. Therefore, equipments that tune the properties by monitoring and optimizing the properties of the products are expected, as in the *flexible on-demand process*.

By using microreactors, it is also possible to utilize an easy set-up for condition optimization and particle growth analysis. Therefore, it would also be possible to make experimental tools capable of optimization of various kinds of new nanoparticle syntheses. The small size of the reactor will make it possible to set up a combinatorial system, which would greatly enhance the methodology development speed. Therefore, this kind of reactor can also be utilized for better understanding of particle generations, for example nucleation. This kind of basic research would be helpful for further development of nanoparticle science. Such a highly efficient analyzer which can be used to realize a process design will play a major role in nanoparticle industries. After the achievement of scale-up to the industrial level, it would be possible to convey the optimized conditions directly to industry. Furthermore, these applications and basic research will help to find effective ways for nanoparticle R&D; for example, designing and producing optimum morphology and structure of nanoparticles and composite nanoparticles to control their properties such as electronic and magnetic properties, finding a reliable condition of raw material synthesis for reproducible production, and reliable and effective surface modification of nanoparticles.

Definition

Sensors with immobilized bioreceptor probes selective for target analyte molecules are called biosensors. Next-generation biosensor platforms will require significant improvements in sensitivity, specificity, and throughput. The emergence of nanotechnology opens new horizons for biological diagnosis at single cell and molecule level. Because of the small dimension, nanoscale biosensors may overcome many drawbacks of the conventional biosensors and lead to a new future in molecular diagnostics, detecting proteins, DNA, and viruses with high sensitivity and selectivity. Nanoscale biosensors can function independently or be integrated into more complex systems, for example so-called microfluidic Lab-on-a-Chip devices, to provide point-of-care detection.

Overview

Based on the detection principle, the major nanoscale biosensors are classified into the following types: electrical nanobiosensors, optical nanobiosensors, and mechanical nanobiosensors. Comprehensive descriptions of nanoscale biosensors can be found in two recent reviews [1, 2].

Electrical Nanobiosensors

Nanomaterials, such as carbon nanotubes and semiconductor or polymer nanowires, can be functionalized with appropriate chemical or biological capture probes [3, 4]. A unique property of these materials is the very high surface-to-volume ratio. The chemical binding event on their surface causes a change of the conductance of the nanotube or nanowire and thus can be identified via electrical measurement. Electrical nanobiosensors are capable of realizing sensitive, label-free, and real-time detection of a wide range chemical and biological species.

Optical Nanobiosensors

These biosensors utilize the optical properties of lasers to monitor and quantify the interactions of biomolecules that occur on functionalized surfaces or in solutions. They are further subdivided into evanescent field-based devices [5], photonic crystal devices [6], and surface plasmon resonance devices [7].

Mechanical Nanobiosensors

These biosensors exploit mechanical effects, for example the resonant frequency of materials. Cantilever-based devices [8] and acoustic devices [9] are two types of widely used nanobiosensors. After binding of molecules to the detection surface, the amount of bound mass can be determined by observing changes in the resonant frequency of the oscillator or the piezoelectric crystal.

Definition

Optofluidics refers to the complementary hybridization of photonics and fluidics. Optofluidic characterization is the analysis of a fluidic system by photonics, and vice versa. In particular, nanoscale optofluidic characterization is related to photonic phenomena based on the nanostructures. The photonic bandgap properties, surface plasmon resonance or surface-enhanced Raman scattering sensitively change with the refractive index of the surrounding fluid or the specific binding of chemicals and biomolecules on the nanostructures.

Overview

Recent advances in chemistry, biotechnology and materials science have generated an immense amount of biological and chemical information, which calls for the development of novel devices that can efficiently process the vast amount of information. An enormous amount of research has been directed toward the development of micro-total analysis systems (μ-TAS) that carry out ultra-high fidelity sensing and analysis much faster than previous devices for processing only infinitesimal amounts of chemicals and bioactive substances. A microfluidic device for precision transport and manipulation of femtoliter-scale materials is an ideal platform to put high-throughput μ-TAS to practical use. However, the current μ-TAS built on a fluidic-device platform employs conventional electrochemical and electronic detection tools, which are especially inferior to optical detection methods in terms of sensitivity and resolution. In addition, microfluidic device technology is limited to using photolithography to fabricate and integrate fluidic circuits. Although fabrication techniques have made great advances to materialize actuation parts such as microscale pumps, microvalves and complex channel geometries, the characterization system remains primitive and the system size is much larger than fluidic chips. Consequently, Lab-on-a-Chip technology such as μ-TAS that can synthesize, analyze, and refine substances with truly high efficiency is still in its early stages.

Optical systems have been widely used for high-speed communication, data processing and high-resolution sensors. However, today's optical systems are not nearly as flexible as electronic systems, and the fabrication of robust and durable optical devices has been a demanding issue for decades. The key idea to meet the increasingly important demands is the introduction of microscopic flows of liquids, i. e., microfluidic devices in the optical structures. Micro- and nano-fluidics have been used for the precise processing of extremely small amounts of liquids. These techniques perform various functions including the reconfiguration of functionality, the adjustment of properties and the transport of functional materials. In optofluidic devices, precise tuning of optical properties such as those of photonic band-gaps can be achieved by injecting liquids with different refractive indices through microfluidic channels.

At the nano-level scale, optofluidics is closely related to the nanostructures. For the dielectric materials, the photonic bandgap property can be generated by periodic nanostructures. Analogous to the X-ray diffraction phenomena in the atomic crystals, the interference of regularly diffracted light waves creates special reflection condition that can be described by Bragg's law. Bragg's reflection condition is sensitively changed by the refractive index, the lattice spacing, and the crystal structure of the materials. Each parameter can be modulated by swelling the nanostructures or filling solvents, as well as by physical adsorption or a chemical reaction of the analytes.

For metallic materials, surface plasmon resonance (SPR) and surface-enhanced Raman scattering (SERS) are the

most significant phenomena related to the nanostructures. At the interface of the dielectric and the metal, the intensity of the electromagnetic field is strongly amplified and localized by their structural characteristics. The SPR mode varies sensitively with a small refractive index change of the binding molecules. In addition, SERS enables the qualitative analysis of infinitesimal amounts of analytes. The Raman signal provides a fingerprint of the specific chemicals that originate from the chemical bonding and the molecular vibration of the analytes.

The relationship between nanostructures and light is the basis of nanophotonic characterization. High sensitivity in a nanophotonic characterization is adequate for single molecule detection without florescence labeling. Detection of a fluorescence signal requires highly sensitive detectors and signal processing units due to the weak signal intensity. Therefore, label-free indicates not only simplicity with sample preparation but also a great advantage for integrated analysis devices.

The objective of nanoscale optofluidic characterization is to combine different nanophotonics technologies with microfluidic devices, and thereby explore and develop photonic analysis techniques based on the microscopic flows of liquids and on nanophotonic properties. The optofluidic characterization techniques will be powerful new tools for a wide range of applications in optical information processing and the miniaturization of chemical and biological processes for synthesis, analysis, and recognition [1].

The optofluidic devices can be very effective in microscopic analysis just as typical optical equipment such as UV, IR, Raman, visible light spectrometers or fluorescence spectrometers are used to analyze molecular information. Therefore, optofluidic systems are more appropriate for constructing μ-TAS and have much greater levels of high-fidelity analytic resolution and sensitivity compared to existing microfluidic devices using electrical, electrochemical and thermal detection methods. Moreover, the use of fluidics provides an order of magnitude increase in the achievable refractive index modulation of the optical components compared with the application of traditional electric, acoustic and mechanical strain fields, as manipulations of the rates of the flows and the compositions of the liquids will tune the characteristics of these photonic systems in real time. These fluidically adjustable and unique properties enable flexible fine-tuning and even dynamic reconfiguration of the optical circuits. The most important technological advantage of this new optofluidic device is that it has unique features that individual devices cannot demonstrate.

Basic Methodoloy

Photonic Band-Gap Property

A photonic crystal is the special material whose refractive index is periodically modulated on a length scale of visible light. With structural periodicity, the propagation properties of photons can be controlled by changing the design of the photonic crystals intentionally. In general, wave propagation is affected by structures when the light enters the materials. Inside of the periodic photonic crystals, the photons scatter coherently at every interface of the two different refractive index regions. Consequently, the behavior of the lightwaves depends on the propagation direction through the photonic crystal. Photons of certain frequencies and directions can be forbidden in a photonic crystal. If the photons of certain energy bands are forbidden regardless of their propagation direction, they are known as photonic band-gaps (PBGs). Recently, photonic crystals were incorporated with microfluidic chips for optofluidic characterizations of chemical and biological analytes. As the band-gap properties of photonic crystals are changed sensitively by various control variables, band-gap engineering enables an effective optofluidic characterization.

The study of photonic crystals rests on the foundation of electromagnetics and solid-state physics. Analogous to the propagation of electrons in a periodic crystal potential described by the Schrödinger equation, the propagation of light is described by the well-known Maxwell equation under the periodic boundary condition. The master equation for a harmonic mode in photonic crystal can be derived from four macroscopic Maxwell equations with assumptions for simplification [2].

$$\nabla \times \left(\frac{1}{\varepsilon(\mathrm{r})} \nabla \times H(\mathrm{r}) \right) = \left(\frac{\omega}{c} \right)^2 H(\mathrm{r}) \tag{1}$$

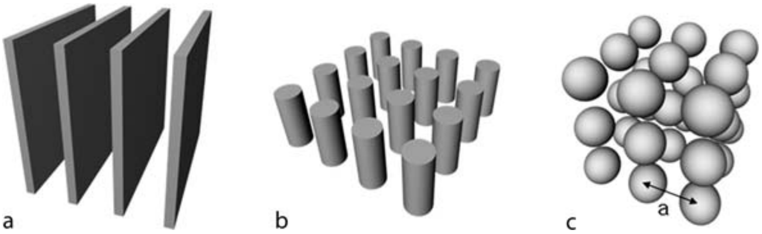
Solving the master equation is sufficient to obtain an electromagnetic field at a certain position. For a multidimensional calculation of various symmetries, a numerical method should be applied. There are three methods to calculate photonic band structures; the plane wave expansion method (PWM), Green's function expansion and the finite difference time domain (FDTD) method.

Controlling Parameters in Photonic Crystals

In order to develop an optofluidic characterization technique based on a photonic crystal, parameters for band-gap engineering must be established.

- *Dimensionality:* According to the periodicity of dielectric materials along one or more axes, the dimension of

N



Nanoscale Optofluidic Characterization Techniques, Figure 1 Multidimensional photonic crystal structures with dielectric constants that vary along the x, y and z axes. (**a**) 1D, (**b**) 2D and (**c**) 3D photonic crystal structures

photonic crystal is determined. This defines the working direction of photonic crystals to the incident lightwaves. Figure 1 shows examples of multidimensional photonic crystal structures whose refractive indices vary as a periodic function in the length scale.

- *Symmetry:* Analogous to the crystalline lattice of atomic structures, photonic nanostructures may have different symmetries. According to the structural symmetry of photonic crystals, different scattering symmetries are caused, leading to a variation of the photonic band-gap properties.
- *Lattice parameter:* The length scale of a photonic crystal is closely related to the lattice constant of scattering building blocks. The working range of the photonic crystal in the wavelength domain is proportional to the lattice parameter (a).
- *Effective refractive index:* The relative amount of one scattering material to another is known as the filling fraction. The effective refractive index (n_{eff}), which is calculated as the square root of the average dielectric constant, varies with changes in the filling fraction. The working range of the photonic crystal also depends on n_{eff}.
- *Refractive index contrast:* the scattering strength of photonic crystal structures depends on a value known as the refractive index contrast. The refractive index contrast is defined by the ratio of the materials composing the structures: the high dielectric constant to the low dielectric constant. As the refractive index contrast increases, fewer dielectric layers are needed to achieve photonic band-gap properties.

Therefore, change in these factors cause a band-gap modulation in photonic crystals, which can be characterized optically.
Surface Enhanced Raman Scattering

Raman Scattering

Raman scattering, or the *Raman effect*, was first demonstrated by Indian physicist Chandrasekhara Venkata Raman and his colleagues in 1928 [3]. It is the inelastic scattering that occurs when light is scattered from an atom or molecule. In contrast to elastic Rayleigh scattering, incident photons are inelastically scattered from a molecule and shifted in frequency by the energy of its characteristic molecular vibration and rotation. The inelastic interaction of incident light with a molecule in its vibrational or rotational ground state induces a red-shifted Stokes Raman spectrum, and a molecule in a vibrational or rotational ground state absorbs energy from the incident light. On the other hand, when the incident light interact with a molecule in its vibrational or rotational excited state, a blue-shifted anti-Stokes Raman spectrum is produced and molecules in vibrational or rotational excited state lose energy to incident light. As the absolute value of the frequency shift does not depend on the process type and because it is only dependent on the number of molecules that occupy different vibrational or rotational states, the Raman spectrum is symmetric relative to the Rayleigh scattering band. The relative intensity of Raman scatterings in the Stokes and anti-Stokes Raman spectra can be determined using a Boltzman distribution; in most cases, Stokes scattering related to lower energy levels is stronger than anti-Stokes scattering. Raman scattering interacts with the vibrational and rotational levels of the molecule, which depend on atomic species and their bond arrangements and strengths in a specific molecule. Therefore, a Raman spectrum can provide a structural *fingerprint* of the target molecule.

Surface Enhanced Raman Scattering (SERS)

However, Raman spectrum shows weak signal intensity compared with conventional Rayleigh scattering and fluorescence, which is a widely used technique for molecular detection. Raman scattering cross-sections imply that the scattering intensities are between 10^{-31} and 10^{-29} cm/molecule (for comparison, the maximum fluorescence cross-section is 10^{-16} cm^2/molecule). Resonance Raman scattering (RRS) can increase the cross-section when a molecule is excited by a laser with a resonance frequency. However, RSS still has an insufficient

cross-section compared with other optical characterization techniques; additionally, it shows strong fluorescence, which interrupts the observation of Raman scattering. In 1974, Fleischman and his colleges observed the surface-enhancing effect of Raman scattering at a roughened silver electrode, and found that the signal of Raman scattering can be dramatically enhanced by *Surface-enhanced Raman spectroscopy* (SERS) [4]. After this historical discovery, Van Duyne [5], Creighton [6] and their coworkers pointed out that the intensification of the effective Raman cross-section was far in excess of the increased surface effect. Moskovits [7] proposed that the huge increase in the Raman cross-section was a result of electromagnetic field enhancement.

The Electromagnetic Theory of SERS

Raman enhancement by SERS is mainly attributed to an electromagnetic (EM) field enhancement via localized optical fields of the metallic nanostructures that are related to plasmon resonance excitation. The increase of the cross-section with contact between the metal nanostructure and a molecule induces an additional enhancement. Without enhancement by the electrical resonance between incident light and molecules, the total Stokes–Raman signal $P^{RS}(\nu_S)$ is proportional to the number of molecules in the scattering volume N, the Raman cross-section without surface enhancement σ^R_{free}, and the excitation laser intensity $I(\nu_L)$.

$$P^{RS}(\nu_S) = N\sigma^R_{free} I(\nu_L) \tag{2}$$

For a Stokes–Raman signal enhanced by SERS, the above equation should be modified to consider the electromagnetic enhancement effects of metal nanostructures on Raman scattering.

$$P^{SERS}(\nu_S) = N'\sigma^R_{ads} \,|A(\nu_L)|^2 \,|A(\nu_S)|^2 \, I(\nu_L) \tag{3}$$

Here, N' is the number of molecules involved in the SERS process and σ^R_{ads} is the increased cross-section of the enhanced Raman process of the adsorbed molecule. For a given excitation laser and Raman scattered field, $A(\nu L)$ and $A(\nu S)$ are the enhancement factors determined by the intensity ratio of the incident field and the scattered field at a position [8].

Although the first reported signal enhancement in SERS was a factor of $10^3 - 10^5$, a further enhancement up to 10^9 becomes possible, which originates from the effect of shape and geometry together with chemical resonant mode (although why is not yet fully understood). Now, these additional factors are of practical importance because Raman signal is basically so weak as to be covered by unwanted signals and noises. Therefore, the design of SERS active substrates, the selection of suitable chemical compositions and the development of integrated SERS systems are the most important issues in today's Raman scattering research.

Key Research Findings

Bragg's Law for Simple Optofluidic Characterization of Photonic Crystals

Although the band-gap properties of photonic crystals are soluble according to Maxwell equations, classical Bragg's law provides sufficient approximations. If only one-dimensional periodicity is considered, Bragg's law provides a simplified prediction of the peak position in terms of the effective refractive index, periodicity and incident angle.

$$\lambda_{Bragg} = 2n_{eff} d \sin\phi \tag{4}$$

Here, the peak wavelength of reflected light is proportional to the effective refractive index n, structural period d and incident angle of a given light source, $\sin\phi$.

The effective refractive index of composite materials can be represented as follows:

$$n_{eff} = \sqrt{f_a n_a^2 + (1 - f_a) n_b^2} \tag{5}$$

This shows that the photonic bandgap shifts with a change in the refractive indexes of materials or the interparticle distance. Therefore, replacement of the surrounding media and swelling of the colloidal lattice is expressed by changes in the reflection color. Given that all liquid fluids have a higher refractive index compared to air, the bandgap position shifts to a longer wavelength when the fluid flows through the built-in colloidal crystal part of microfluidic chips. This means that small changes in the refractive index caused by chemicals or biomaterials can be detected by a shift in the reflection peak position. Variation of the lattice parameter under specific chemical or physical conditions can also be estimated by a simple Bragg's law.

Hydrogel is a smart material whose volume changes with the environmental condition; temperature, pH, or solvent concentration. Thus, the interparticle distance of colloidal photonic crystals combined with hydrogel can be tuned by varying these conditions. In this case, the Bragg's condition gives a simple estimation of the band-gap shift base upon a variation of the lattice constant. Asher reported the hydrogel base tuning of photonic crystals under various swelling conditions [9]. Specially synthesized hydrogel photonic crystals showed a significant change in their

reflection color with changes in the pH, temperature, heavy metals and glucose concentration. As the lattice parameter of a photonic crystal increased, the peak position of the reflectance spectra shifted toward a longer wavelength. Xia et al. showed similar results using an expansion of a PDMS/silica composite material by solvent swelling [10].

The Ozin group reported an optical chromatography method using colloidal crystal capillary columns [11]. The stop bands of colloidal crystal columns were tuned by filling the colloidal crystals with Alkanes; Octane, Nonane and Decane. Although they have similar molecular structures and weights, a reflectance peak shift was detected from small refractive index variations. This is applicable to a novel liquid-chromatography column with a higher resolution and a shorter processing time than a currently existing column. Lee et al. reported the in situ crystallization of colloidal particles in microfluidic chips under a centrifugal force field [12]. The colloidal crystallization speed was accelerated by a centrifugal force that supplied colloidal particles at a 50-fold rate. Although the processing time was dramatically reduced, the crystallinity was not seriously affected, as the colloidal arrangement time scale is still larger than crystallization scale. The sedimentation rate is proportional to the density difference that can be controlled by the selection of dispersing media. Figure 2 shows optical and scanning electron microscope images of crystallized colloidal crystal patterns inside of a centrifugal microfluidic chip. The photonic bandgap of the colloidal photonic crystals could be modulated by refractive index mismatching between the solvent and the colloidal particles. Given that all liquid fluids have a higher refractive index compared to air, the bandgap position shifted to a longer wavelength when the fluid flowed through a built-in colloidal crystal part in the microfluidic chips. However, when the refractive index of the outside materials is similar to that of the core materials, the refractive index contrast is minimized and the photonic band-gap disappears. Therefore, this cannot be used as an optofluidic characterization tool. With colloidal photonic nanostructures composed of two different refractive index materials, the undetectable ranges of one material can be eliminated by a second photonic crystal. The bandgap shift is visualized by the reflectance spectra of silica and polystyrene colloidal crystals with various solvents, as shown in Fig. 3.

As mentioned earlier, colloidal photonic crystal devices were fabricated through a self-assembly process. This process is the most economic method to produce 3D nanostructures. When the size of a colloidal building block is half the wavelength of visible light, a physical change of the photonic crystals caused by the analytes converts into a color change. However, the width of the reflectance peak is usually broad, which disturbs the high sensitive characterization.

Photonic Crystal Cavities

A defect in the photonic crystal leads to allowed states for particular frequencies and a strong localized mode in the band-gap, as shown in Fig. 4. Point defects have great importance for the control of spontaneous emission and light localization events [13]. These can be created by removing one unit structure, changing the local refractive index or by modifying the size of the structures.

In general, 2D photonic crystals are fabricated by drilling an array of holes onto high index substrates. Since Painter et al. first reported lasing from a single-defect photonic crystal cavity, many researches have attempted to create a triangular lattice, a square lattice and a quasi-periodic lattice for large quality factor in a small mode volume. In a 2D photonic crystal slab, photons are confined by the total internal reflection in the vertical direction and by the photonic band-gap effect in the in-plane direction. Consequently, compact and effective optical cavities are achieved. The characteristics of photonic crystal cavities can be modulated by introducing fluids through nanochannels [14]. As the resonance mode of a photonic crystal cavity is very narrow and sensitive to the environment, even very small changes in effective refractive of medium are clearly detectable. The specific binding of analytes onto the cavity enables sub-femtoliter scale sensitivity, which originates from variations in the effective refractive index, hole radius or surface evanescent mode. When the surrounding medium of photonic crystal cavities change from air ($n = 1$) to a liquid medium ($n > 1$), the refractive index contrast reduces and band-gap shifts to a longer wavelength. Consequently, a small change in the refractive index is represented as a shift of the lasing peak.

To fabricate 2D photonic crystal cavities, expensive e-beam lithography should be used. In addition, a bulky and complicated detection setup is required to catch the lasing signals. In spite of all the disadvantages, photonic crystal lasing units show a sub-1-nm resolution, which is required for single-molecule level detection of analytes [15].

SERS-Active Colloidal Particles

Recently, synthesis processes for colloidal dispersions have been expanded from dielectric materials to metals and semi-conductors. In addition, core-shell particles with multi-layer coatings can be synthesized via chemical processes. When metal nanostructures are located with nanoscopic gaps among them, hot spots can exist that result from strong localizations of the electromagnetic field. Core-shell particles with dielectric cores and metal shells are a representative of these nanogap structures, and such colloidal nanoshell particles exhibit strong SPR and SERS activity [16]. This originates from the interaction of electromagnetic waves and oscillating surface charges generated on the inner and outer surfaces of the metal shells. In particular, the thickness of gold and silver shells onto colloidal particles can be controlled to nanometer-scale accuracy. According to the charge distribution, plasmon resonance has differing plasmon energy states of bonding plasmons with low energy and anti-bonding plasmons with relatively higher energy. This is analogous to the molecular orbital theory of quantum mechanics.

The plasmon effect enables highly sensitive SERS detection at the single molecule level. The Halas group reported experimental and simulated results of SERS activity with various colloidal structures that included spherical particles, nanoshells, dimer clusters and nanoshell clusters. According to their results, nanoshells enhanced the signal-to-noise (S/N) ratio 548 times relative to the general particles. For dimer clusters of nanoshells, the S/N ratio was increased by 95,238 times when the polarization of the incident light was in the axial direction of the clusters.

SERS-Active Substrates

It is well known that surface-enhanced Raman scattering is observed for molecules close to surface of silver or gold nanostructures due to the existence of surface plasmon resonance. The maximum values for an electromagnetic enhancement for isolated single colloidal silver and gold nanoparticles are $\sim 10^6 - 10^7$. From theoretical studies, further enhancement can be achieved for sharp features and large curvature regions such as the junctions or edges of colloidal aggregates or nanocrystals. Moreover, closely spaced particles (inter-particle distances less than 10 nm) can produce extra Raman enhancement up to 10^{11} at the midpoint between separated particles.

SERS-active colloidal clusters show both localized surface plasmon resonance (LSPR) and extended plasmon resonance (EPR) in the extinction spectrum, unlike a single nanosphere, in which EPR can be identified from the broadened extinction peak that appears at longer wavelengths relative to LSPR. EPR induces very strong field only in a very short length scale of a few nanometers and consequently the induced field distribution is highly inhomogeneous. The highly localized surface plasmon with very strong fields termed *hot spots* plays an important role in the total electromagnetic enhancement of metal nanostructures. This can be used for single-molecule detection. The location and size of hot spots depend on the local geometry and the wavelength and polarization of the incident beam. Strongly localized hot spots provide an opportunity to detect a single selected molecule within a larger population or to probe selectively parts of large molecules such as DNA or proteins. These hot spots can

(**a**) Resonance mode of a 2D photonic crystal cavity laser calculated using the FDTD method. (**b**) Red shift of the lasing mode with varying refractive indexes of the surrounding media

produce very large electromagnetic enhancements, and the overall Raman enhancement factor is as large as 10^{14} with chemical enhancement. Therefore the cross-section enhanced by SERS is comparable with that of fluorescence and other optical characterization techniques. Transmission electron microscopy (TEM) combined with Raman spectroscopy can be used to study hot spots of immobilized nanoparticles in nanoscale by comparing their structures and Raman enhancement characteristics. In addition, a metal-coated nanoscale microscope tip such as an atomic force microscopy (AFM) tip can be combined with Raman spectroscopy for single molecule detection with extremely high resolution. This tip-based SERS characterization technique is known as tip-enhanced Raman scattering (TERS).

SERS-Based Optofluidic Detection Technique

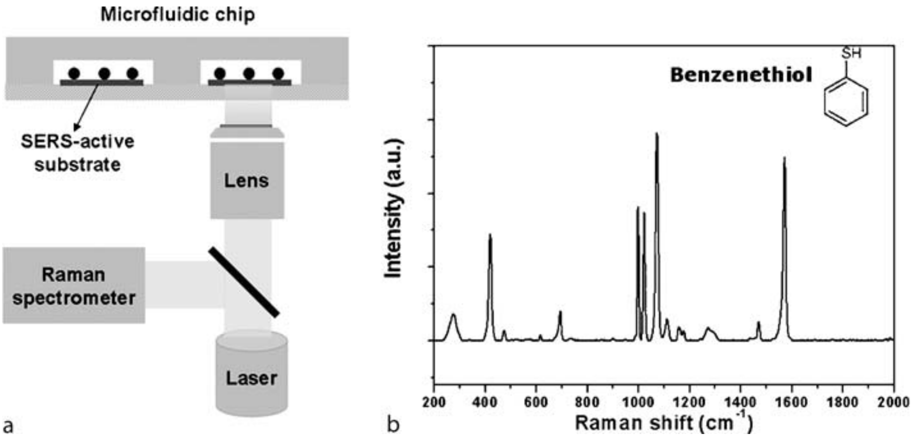
Optofluidic detection techniques based on SERS can be used as a highly sensitive biomedical and chemical sensor. Combining a microfluidic device with Raman spectroscopy provides an opportunity to analyze target molecules in real time without labeling at the single molecular level. There are several methods for combining SERS-based detection techniques with a microfluidic chip. Highly sensitive detection can be achieved by flowing biomolecules with SERS-active metal nanoparticles in a microfluidic mixer. Biomolecule-adsorbed metal nanoparticles are then analyzed by Raman spectroscopy downstream of the channel, and quantitative analysis of the Raman spectra is also possible [17]. SERS-active nanostructures with large enhancements are integrated on a microfludic chip that functions as a sample delivery device and are used for label-free biomolecular detections [18]. In addition, by using these types of optofluidic detection techniques, ultrasensitive real-time analyses down to the femto-molar level is possible. By combining a micro Raman set-up and optical tweezers with a microfluidic system, analysis of a single trapped cell can be achieved. This technique provides analysis of reaction processes in cellular systems, and has high potential for in vivo monitoring of cellular drug responses [19]. Figure 5a shows the scheme of an optofluidic SERS or SPR device and Fig. 5b is the example of Raman shift caused by benzenthiol molecules.

Integrated Optofluidic Devices

The sizes of microfluidic devices are becoming smaller and smaller for automatic, inexpensive and accurate characterizations of infinitesimal amounts of samples. However, to characterize chemical and biomedical samples, expensive and bulky instruments have been always attached to microfluidic chips. Various optical units, such as detectors, light sources, cameras, monochromators, focusing lenses, add-drop filters, amplifiers, optical fibers and microscopes should be integrated and aligned in a single chip in order to obtain a proper signal.

Optofluidic Microscope

The development of a miniaturized microscope system that can be integrated with microfluidic devices is a hot issue in the optofluidic characterization field. Lange et al. [20] succeeded in obtaining the image of *C. elegans* from a CMOS array bounded to a sample chamber. However, the resolution was poor (10 μm) compared to conventional microscopy because the resolution of the image was defined by the pitch size of the detector array. Recently, Heng et al. [18] introduced a nanofabrication technique to achieve an optofluidic microscope with high throughput



Nanoscale Optofluidic Characterization Techniques, Figure 5 Scheme of in situ optofluidic SPR and SERS devices. (**a**) Conceptual diagram of a 2D nanohole-array-based SPR or SERS sensor (**b**) Resonance peak position shift versus a refractive index change

and high resolution. When samples pass through PDMS microchannels, images are taken by a CCD array located at the bottom. To increase the spatial resolution of an image, 600 nm holes drilled by electron beam lithography are arranged in a diagonal direction with 5 μm intervals. Images are focused on the CCD array through a skewed array of apertures, which enables the production of full-size images by integrating spot images along the translation of the sample. Final images taken by the optofluidic microscope with the nanoscale hole-array showed a high resolving power equivalent to a commercial microscope. This demonstrates the potential for imaging various biological objects as well as *C. elegans* inside of microfluidic channels [21].

Future Directions for Research

Recently, most research groups have focused on the MEMS process based on microelectronics to materialize microfluidic device technology. This is one of the essential elements of optofluidics. Although microelectronics is able to manipulate fluidics at a microscopic scale, there is a serious shortcoming associated with this method. The electronic circuit to actuate fluidics on the microfluidic channels inevitably scatters or reflects light, which is a fatal weakness for an optofluidic device in which transmission of light is critical for optical functions. Novel methods including capillary, centrifugal and photothermal actuation should be applied to actuate fluidics without introducing an electronic circuit pattern to a fluidic device substrate.

From a fabrication point of view, a simple and versatile strategy for constructing nanophotonic structures is required to create fluidically tunable and robust 3D photonic band gap structures. Conventional photolithography can create a uniform pattern mostly in 2D with no defect over a large area, but it does not provide significant advantages to the proposed optofluidic device technology, as an optofluidic device requires photonic structures of very limited length scales. Furthermore, it is impossible to manipulate light in 3D space with photolithographically achievable 2D photonic crystals. Self-organization of photo-responsive complex colloids inside of microfluidic devices enables the fabrication of 3D nanophotonic structures. The efficiency of building 3D photonic structures significantly improves when photonic crystals are made by self-assembly in confined geometries of microfluidic channels with preferable crystal orientations and a lower defect density. In this case, no additional process is needed for the integration of photonic devices with microfluidic devices.

One of the most important factors is to diversify the materials constituting optofluidic devices. Physico-chemical functionalities of mobile fluids should be exploited to manipulate the optical and fluidic properties of optofluidic devices. Current optofluidic device technology has used a very limited number of materials for mobile and immobile phases of optofluidic devices; consequently, the required flexibility has not yet been achieved. As for compatibility with fluidic devices, proper affinity between liquids and substrates poses many challenges to the application of optofluidic characterization devices.

Especially for nanoscale optofluidic characterizations, the physical, chemical, biological, and electromagnetic functionalities of structures and surfaces are very important, as the optical phenomena are deeply related to these aspects in nanophotonics and fluidics.

Neural Network

Definition

A neural network is a type of computational model that can be used to analyze complicated events or phenomena. They are based on the architecture of biological brains, and consist of a collection of *neurons* (or simple processing elements) that are connected in an adaptive manner. Neural networks can be trained with existing data to generate a robust model.

Non-Centrosymmetric

Definition

A centrosymmetric material has points of inversion symmetry throughout its volume. A material that does not is said to be non-centrosymmetric. This is a key requirement for piezoelectric materials: they must be non-centrosymmetric. Not all non-centrosymmetric materials are piezoelectric, however (the exception is materials with class 432).

Definition

The fluid media are not considered continuum in a non-continuous approach. The molecular nature of fluid is recognized and explicitly considered in the development of methodologies.

Overview

An intrinsic length scale in dilute gases is the mean free path, which measure the average distance the gas molecules travel between collisions. The ratio of the molecular mean free path of gas λ to a flow characteristic length scale L is defined as the Knudsen number Kn.

$$\mathrm{Kn} = \frac{\lambda}{L} \tag{1}$$

For gas flows found in conventional macro-scale devices at atmospheric conditions, the flow characteristic length scale L in Eq. (1) can be orders of magnitude larger than the molecular mean free path, which is in the order of 10^{-8} m, and the Knudsen number approaches zero. For micro- and nano-scaled devices that operate with gases in atmospheric conditions, the scaling relation can be quite different. For example, for a micro channel that is one micron deep and one micron wide, the Knudsen number based on the cross sectional dimension is then 10^{-2}, which is four to five orders of magnitude larger than those typically found in macroscaled devices. The Knudsen numbers of micro gas flows are significantly larger than that in the macro-scaled devices. For micro flows where there are localized regions of large gradients of flow property, the device dimension can not be used as the length scale for the entire flow filed and different length scales may be required to characterize the flow in these regions. In this case, the magnitude of the Knudsen number can be even higher when a local length scale of the flow is used, instead of the global length scale. Since the mean free path varies inversely with gas density, the Knudsen number can be quite large for micro and nano fluidic devices that operate in low-pressure or low-density environment.

The kinetic theory of liquid is less well-developed compared as the gas kinetic theory. Continuous approaches in micro/nano fluidics are often used in practice with modifications to the wall boundary conditions and the surface-flow interaction mechanisms.

At zero or extremely small Knudsen number, the physical domain is large compared to the mean free path. For dilute gases, there are then a large number of molecules and, for a time period that is large compared to the mean collision time (about 10^{-10} s for air in standard atmospheric condition), a large number of collisions occur among the molecules. With sufficiently large number of molecules the statistical variation of the number of molecules in the volume can be neglected. Without external forcing, there is then no gradient in the macroscopic flow properties with both time and space due to the large number of molecular collisions. The gas is in an equilibrium state. The fraction of molecules in a velocity class remains unchanged with time, even though the velocity of the individual molecule

varies with collisions. The velocity distribution function for equilibrium gases is represented by the Maxwellian distribution function. A local equilibrium can be established when the gradient of the macroscopic properties is infinitesimal such that, with sufficiently high collision rate, the velocity distribution of the volume of gas can adjust to the local equilibrium state. The gas flows with such small Knudsen numbers can be regarded as a continuous distribution of matter where the local macroscopic properties can be determined by the sample average values of the appropriate molecular quantities, such as mass, velocity, and energy. Since the statistical fluctuations can be neglected, such averages are defined. The applications of the conservation of mass, momentum, and energy further provide a set of differential equations that regulate the changes of these quantities. By assuming linear relationship between stress and strain, and between heat transfer and temperature, the familiar Navier–Stokes equations can then be obtained. The linear constitutive relationship can also be derived from the Boltzmann equation by using, for instance, the Chapman–Enskog expansion. At large Knudsen numbers, such a constitutive relationship fails, resulting in the breakdown of continuous approaches.

For flow with high Knudsen number, the number of molecules in a significant volume of gas decreases and there could be insufficient number of molecular collisions to establish an equilibrium state. The velocity distribution function will deviate away from the Maxwellian distribution and is non-isotropic. The properties of the individual molecule then become increasingly prominent in the overall behavior of the gas as the Knudsen number increases. The implication of the larger Knudsen number is that the particulate nature of the gases needs to be included in the study. The continuum approximation used in the small Knudsen number flows becomes invalid. At the extreme end of the Knudsen number spectrum is when its value approaches infinity where the mean free path is so large or the dimension of the device is so small that intermolecular collision is not likely to occur in the device. This is called collisionless or free-molecule flows.

Non-continuous approach can be deterministic or stochastic. In deterministic approaches, such as the molecular dynamics (MD) method and the lattice Boltzmann method (LBM), the particle or molecule's trajectory, velocity and intermolecular collision are calculated or simulated in a deterministic manner. In the stochastic approaches, such as the direct simulation Monte Carlo (DSMC) method, randomness is introduced in to the solution variables.

MD was conceived in the field of theoretical physics in the 1950's. It is multidisciplinary with laws and theories stemming from mathematics, physics, and chemistry. The method simulates the movement of atoms and molecules and allows them to interact under force field or potential.

DSMC method is one form of Monte Carlo type of method that has been applied to study gas flows in microdevices (Liou and Fang [1]). Bird [2] first applied DSMC to simulate homogeneous gas relaxation problem. The fundamental idea is to track thousands or millions of randomly selected, statistically representative particles, and to use their motions and interactions to modify their positions and states appropriately in time. Each simulated particle represents a number of real molecules. Collision pairs of molecule in a small computational cell in physical space are randomly selected based on a probability distribution after each computation time step. In essence, particle motions are modeled deterministically while collisions are treated statistically. A significant advantage of DSMC is that the total computation required is proportional to the number of molecules simulated N, in contrast to N^2 for the molecular dynamics simulations.

LBM was originally proposed by McNamara and Zanetti [3] to circumvent the limitations of statistical noise that plagued Lattice Gas Automata (LGA). LBM is a simplified kinetic (mesoscopic) and discretized approximation of the continuous Boltzmann equation. LBM is mesoscopic in nature because the particles are not directly related to the number of molecules like in DSMC or MD but representative of a collection of molecules. Hence, the computational cost is less demanding compared with DSMC and MD. Typical LBM consist of the Lattice Boltzmann Equation (LBE), Lattice structure, transformation of lattice units to physical units and boundary conditions.

Basic Methodology

Molecular Dynamics

In a typical MD implementation, the trajectory $\boldsymbol{x}$ and the velocity $\boldsymbol{V}$ of N number of particles are solved using the classical laws of mechanics. The intermolecular interactions between the particles are modeled via a two body interaction potential ϕ. In obtaining the time evolution of the trajectories and velocities of the particles, initial conditions are required. The initial velocity is assigned a Boltzmann distribution at the initial temperature. After application of the initial conditions, the time evolution of the velocity $\boldsymbol{V}$ and trajectory $\boldsymbol{x}$ is solved by integration of Eqs. (2) and (3) respectively.

$$\boldsymbol{F} = -\nabla\phi = m\frac{\partial \boldsymbol{V}}{\partial t} \tag{2}$$

$$\boldsymbol{V} = \frac{\partial \boldsymbol{x}}{\partial t} \tag{3}$$

Equation (2) is the Newton's second law. There are different potentials ϕ that are use in MD. The most popular one, arguably, is the Lennard–Jones 12–6 potential as shown in Eq. (4)

$$\phi(r) = 4\varepsilon\left[\alpha\left(\frac{\sigma}{r}\right)^{12} - \beta\left(\frac{\sigma}{r}\right)^{6}\right] \quad (4)$$

where r represents the molecular separation while σ and ε the length scale and energy values, respectively. The coefficients α and β are chosen in order to simulate fluid–fluid or fluid–solid interactions. The first term in Eq. (3) represents the short range repulsive force while the other term is the long range attractive force. MD suffers from the drawback or limitation that it is computationally expensive. The computational cost scales with the square of the number of particles or molecules O(N^2) since the computation of a particle's trajectory requires consideration of other particles as possible collision partners. Due to the high computational cost and small simulation time scales, MD simulations is not usually used in many practical micro/nanofluid applications.

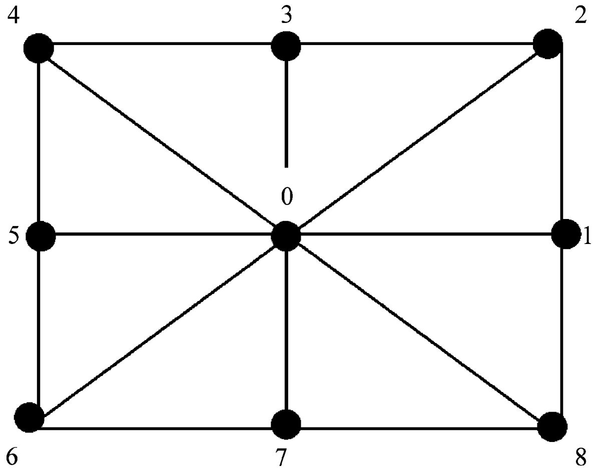
Lattice Boltzmann Method

The lattice Boltzmann equation (LBE) consists of two steps, representing the streaming and collision components. During the streaming step, the particles move to the neighboring lattice points in the direction of its velocity. During the collision step, the particles arriving at the neighboring lattice site interact with each other according to scattering rules and change their velocity directions. The Bhatnagar, Gross and Krook (BGK) LBE (LBGK) is the most widely used form of LBE and it is stated below as

$$\begin{aligned} f_i(x + e_i\Delta t,\ t + \Delta t) \ - \ f_i(x,t) \\ = -\frac{1}{\tau}\left(f_i(x,t) - f_i^{\mathrm{eq}}(x,t)\right) \end{aligned} \quad (5)$$

where f_{eq} represents the Maxwellian distribution function, f_i and e_i the distribution function and the particle speeds for particle i.

The lattice pattern in the LBM helps in the discretization of the fluid domain into nodes/particles and also in describing the microscopic motion of the particles. For a 2D model the lattice can either have a square or hexagonal lattice. The square lattice can have 4 or 5 or 8 or 9 speed models while the hexagonal lattice can have the 6 or 7 speed models.The general nomenclature used for describing the lattice structure or pattern is DxQy, the letter x and y represents the dimensions and speed model respectively. The lattice pattern shown in Fig. 1 is the D2Q9 model. The



Non-Continuous Approaches, Figure 1 D2Q9 lattice pattern

D2Q9 and D2Q7 are the most widely used 2D lattice pattern due to their symmetry (isotropy) and ability to recover the Navier–Stokes equation. For the D2Q9 lattice pattern, the lattice speed e_i can be represented as found in Fig. 1 of

$$e_i = (0,0) \quad \text{for i = 0 (rest particle)}$$

$$e_i = e\left[\frac{\cos(i-1)\pi}{4}, \frac{\sin(i-1)\pi}{4}\right]$$

$$\text{for i = 1, 3, 5 and 7} \quad (6)$$

$$e_i = \left(\sqrt{2}\right)e\left[\frac{\cos(i-1)\pi}{4}, \frac{\sin(i-1)\pi}{4}\right]$$

$$\text{for i = 2, 4, 6, 8 (for diagonal particles)}$$

Due to the kinetic nature of LBE, phenomenon or physics that involves molecular interaction can easily be applied and hence makes LBM a good tool for micro/nano fluidics simulation. Fewer sets of discrete velocities and particle density distribution function in phase space is used in LBM as opposed to a continuous velocity or distribution function in the complete functional phase space of the Boltzmann equation.

Direct Simulation Monte Carlo Method

The DSMC method often used in micro gas flow simulations was originally developed for high Knudsen number rarefied gas flow. The procedures involved in applying DSMC to steady or unsteady flow problems can be found Fig. 1 of the entry ►Monte Carlo method. Execution of the method requires the physical domain to be divided into a distribution of computational cells. The cells

N

provide geometric boundaries and volumes used to sample macroscopic properties. Also, only molecules located within the same cell, at a given time, are allowed for collision. The DSMC simulation proceeds from a set of prescribed initial condition. The molecules randomly populate the computational domain. These simulated molecules are assigned random velocities, usually based on the equilibrium distribution. The simulated representative particles move for a certain time step. This molecule motion is modeled deterministically. This process enforces the boundary conditions. With the simulated particles being appropriately indexed, the molecular collision process can be performed. The collision process is modeled statistically, which is different from deterministic simulation methods such as the molecular dynamics methods. In general, only particles within the same computational cell are considered to be possible collision partners. Within each cell, collision pairs are selected randomly and a representative set of collisions is performed. The post-collision velocities are determined. There are several collision-sampling methods that have been used successfully. The currently preferred model is the *no-time-counter* (NTC) technique used in conjunction with the sub-cell method (Bird [4]). Figure 2 of the entry ▶Monte Carlo method shows the velocity phase plane in a cell for a typical microflow simulation. The sample size is 17,370.

Key Research Findings

LBM is well suited for microflow and it has been applied to both gas and liquid flows. Pioneering applications of LBM were geared towards developing suitable boundary conditions and Kn number relations to the mesoscopic variables particularly for gas microflows using classical flows, such as Couette and Poiseuille flows. LBM has gradually matured and it has being applied to capture physics occurring in microflows such as the Knudsen layer in the transition regime. LBM has been successfully applied to capture multiphysics and multiscale phenomenon, such as reactive flows, electroosmotic flows in the presence of the Electric Double Layer (EDL), chaotic mixing using magnetohydrodynamics, surface related physics (like hydrophobicity and hydrophilicity) and thermal related flows. For microflow simulations, the statistical scatter associated with DSMC limits its applications to microflow with extremely low velocity. The information preservation (IP) method was developed to address this issue. The method [5, 6] introduces preserved information velocities collected based on inelastic collision model. Application has been applied to low-speed Couette, Poiseuille, and Rayleigh flows in the slip, transition and free-molecular flow regimes, and low-speed microflows. The computation time of an IP scheme can be several orders of magnitude lower compared with a regular DSMC simulation for convergence. Figure 3 in the entry ▶Monte Carlo method show the IP velocity phase plane results for the same microflow shown in the previous figure obtained by DSMC. The reduction of the scattering is significant.

MD in micro/nano scale fluids has generally been used as a means to validate other simulation approaches (DSMC or LBM) and it is also used for liquid microflows. The lack of wide usage of MD in practical applications is due to its high computational cost.

Future Directions for Research

The fundamental advantages of LBM such as the ease of parallelization, coding, its ability to incorporate molecular interaction, and cheaper computational cost compared to other non continuous approaches will make LBM a promising approach to the modeling of multiphysics and multiscale phenomenon with an interdisciplinary flair. The extents and limitations of LBM particularly with regards to liquid microflows need further investigation. Monte Carlo methods are inherently parallel and can be readily parallelized. With the advent of low-cost PC-based cluster computing, the parallel nature of Monte Carlo method should be further explored. Simulations of fluid behavior and properties at micro and nanoscales may be facilitated with hybrid types of method employing both Monte Carlo and molecular dynamics techniques. This combination allows the simultaneous exploration of, for instance, thermal properties and local phase space.

Non-covalent bonding; Non-covalent forces

Definition

Noncovalent interactions refer to a variety of interactions that are not covalent in nature between molecules or parts of molecules that provide force to hold the molecules or parts of molecules together, usually in a specific orientation or conformation. These noncovalent interactions include: ionic bonds, hydrophobic interactions, hydrogen bonds, Van der Waals forces (aka London dispersion forces), and Dipole-dipole bonds.

AC electro-osmosis (ACEO); Nonlinear electrophoretic mobility

Definition

Nonlinear electrokinetic phenomena are electrically driven fluid flows or particle motions, which depend nonlinearly on the applied voltage. The term is also used more specifically to refer to induced-charge electro-osmotic flow, driven by an electric field acting on diffuse charge induced near a polarizable surface.

Chemical and Physical Principles

Linear Electrokinetic Phenomena

A fundamental electrokinetic phenomenon is the ►electro-osmotic flow of a liquid electrolyte (solution of positive and negative ions) past a charged surface in response to a tangential electric field. ►Electrophoresis is the related phenomenon of motion of a colloidal particle or molecule in a background electric field, propelled by electro-osmotic flow in the opposite direction. The basic physics is as follows:

Electric fields cause positive and negative ions to migrate in opposite directions. Since each ion drags some of the surrounding fluid with it, any significant local charge imbalance yields an electrostatic stress on the fluid. Ions also exert forces on each other, which tend to neutralize the bulk solution, so electrostatic stresses are greatest in the ►electrical double layers, where diffuse charge exists to screens surface charge. The width of the diffuse part of the double layer (or "diffuse layer") is the Debye screening length ($\lambda \sim 1 - 100\,\text{nm}$ in water), which is much smaller than typical length scales in microfluidics and colloids. Such a "thin double layer" resembles a capacitor skin on the surface.

Electro-osmosis produces an effective slip of the liquid outside the double layer past to the solid surface. In the classical continuum model of the diffuse layer, the

slip velocity is given by the Helmholtz–Smoluchowski formula,

$$u_s = -\frac{\varepsilon\zeta}{\eta}\boldsymbol{E}_\mathrm{t} \tag{1}$$

where $\boldsymbol{E}_\mathrm{t}$ is the tangential electric field just outside the double layer, ε and η are the permittivity and viscosity of the liquid (both assumed constant), and ζ is the zeta potential, a measure the electro-osmotic mobility with units of voltage. In Smoluchowski's theory, the zeta potential corresponds to the potential difference ψ between the slip plane and the neutral bulk solution, just outside the double layer, but this need not be the case (see below).

Classical electrokinetic phenomena are *linear* ($u \propto \boldsymbol{E}$) since the zeta potential is assumed to be a material constant, reflecting chemical equilibrium at the liquid–solid interface:

$$u = -\frac{\varepsilon\zeta}{\eta}\boldsymbol{E} = -b\boldsymbol{E} \quad \text{(non-polarizable surface)} \tag{2}$$

The electro-osmotic mobility b is the coefficient of linear response. This ubiquitous approximation, which can be justified in the limits of thin double layers and/or weak fields, greatly limits possible flows and particle motions. With constant zeta and thin double layers, for example, electro-osmosis in a capillary is irrotational (free of vortices), and particles of different shapes and sizes have the same electrophoretic mobility $b = U/\boldsymbol{E}$ and thus cannot be separated.

Induced-Charge Electrokinetic Phenomena

The possibility of *nonlinear* electro-osmotic flow, varying as $u \propto \boldsymbol{E}^2$, seems to have been first described by Murtsovkin [1, 16], who showed that an alternating electric field can drive steady quadrupolar flow around a polarizable particle (Fig. 1a). This effect has recently been unified with other nonlinear electrokinetic phenomena in microfluidics [2], such as ►AC electro-osmotic flow (ACEO) at microelectrodes [4, 11, 12] (Fig. 1b), DC electrokinetic jets at dielectric corners [5] (Fig. 1c), and nonlinear flows around metal posts [3] (Fig. 1d–e). These are all cases of ►induced-charge electro-osmosis (ICEO) – the nonlinear electro-osmotic flow resulting from the action of an electric field on its own induced diffuse charge near a polarizable surface.

The simplest example of ICEO involves a metal sphere (1) or cylinder (2) in a suddenly applied field, sketched in Fig. 2. Conceptually, there two steps: electrochemical relaxation in response to the field, and electro-osmotic flow driven the induced charge.

1. *Charge relaxation.* When the field is turned on, electrons on the metal surface immediately drift toward one pole to induce a dipole moment making the surface equipotential (Fig. 2a). This is an unsteady configuration in an electrolyte, however, since the field drives ionic current, any normal component transports charge in or out of the diffuse layer. Ignoring surface conduction through the double layer (for thin double layers) and Faradaic reactions passing current through the particle (at low voltage), the normal current locally charges double layer, like a capacitor, until all the field lines are expelled in steady state (Fig. 2b). The time scale for this process is the "RC time" for the equivalent circuit of the bulk resistance coupled to the double layer capacitance [2–4, 12]

$$\tau = \frac{L}{\sigma}\frac{C_D}{(1+\delta)} = \frac{\lambda L}{D(1+\delta)} \tag{3}$$

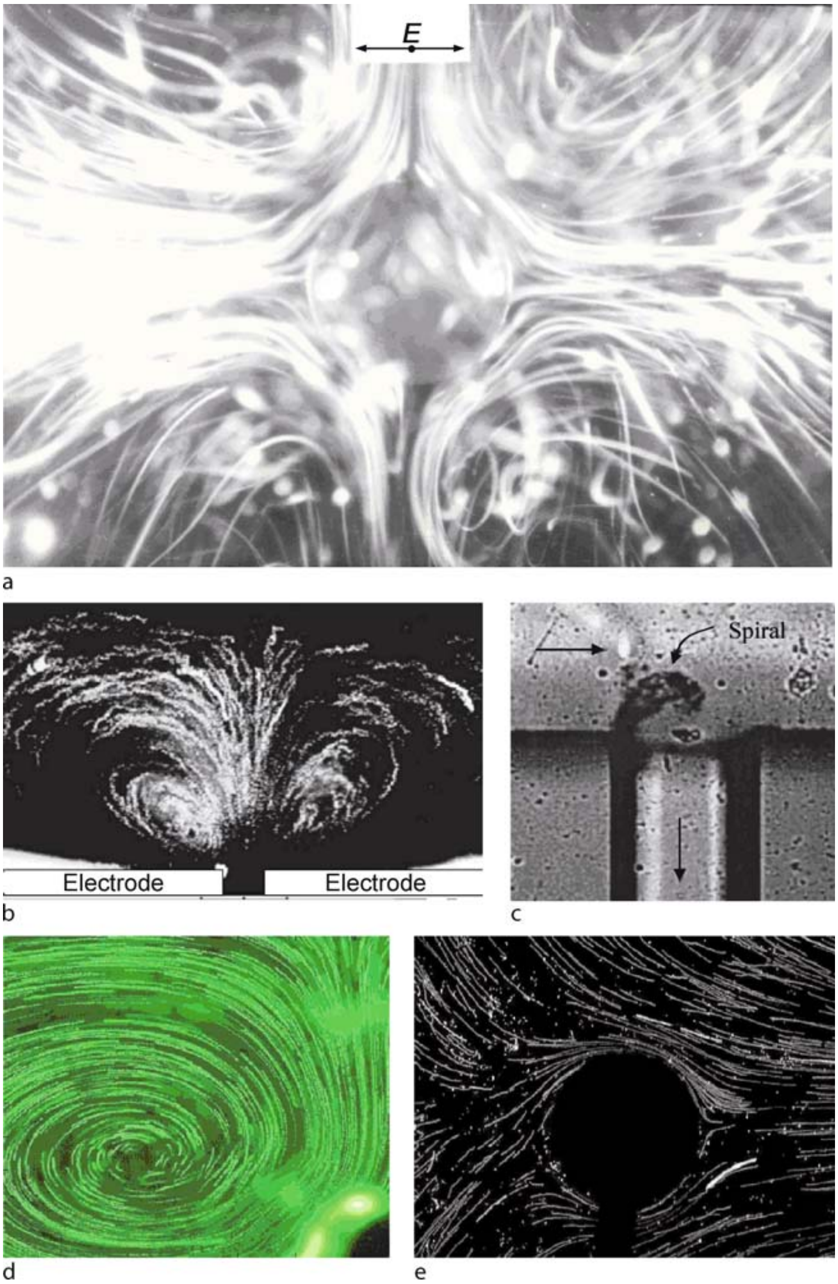
where $\delta = C_D/C_S$ is the ratio of the diffuse-layer capacitance to that of the compact layer (e. g. a Stern monolayer or dielectric coating), σ and D are the bulk conductivity and diffusivity, and L is the length (radius) of the object. In microfluidic devices, the double layer charging time (Eq. (3)) (ms) is much larger than the Debye relaxation time $\varepsilon/\sigma = \lambda^2/D$ for bulk ionic screening (µs) and much smaller than the diffusion time L^2/D for the relaxation of bulk concentration gradients (s). In nano-channels, however, all of these time scales can be comparable (µs).

2. *Fluid flow.* The tangential field acts on the non-uniform induced-charge (or ζ) distribution to produce quadrupolar ICEO flow, sucking fluid at the poles and ejecting it at the equator (Fig. 2c). The scaling of the flow can be easily understood as follows. Capacitive charging transmits a non-uniform voltage to the double layer of order EL, a fraction $(1+\delta)^{-1}$ of which is dropped across the diffuse part and contributes to the induced zeta potential. If Eq. (2) holds, then ICEO flow scales as

$$u \propto \frac{\varepsilon L E^2}{\eta(1+\delta)} \quad \text{(ideally polarizable surface)} \tag{4}$$

The flow builds up over the time scale τ in Eq. (3); if an AC field of frequency ω is aplied, then the flow decays above the RC frequency as $\left[1+(\omega\tau)^2\right]^{-1}$, assuming constant double-layer capacitance [3].

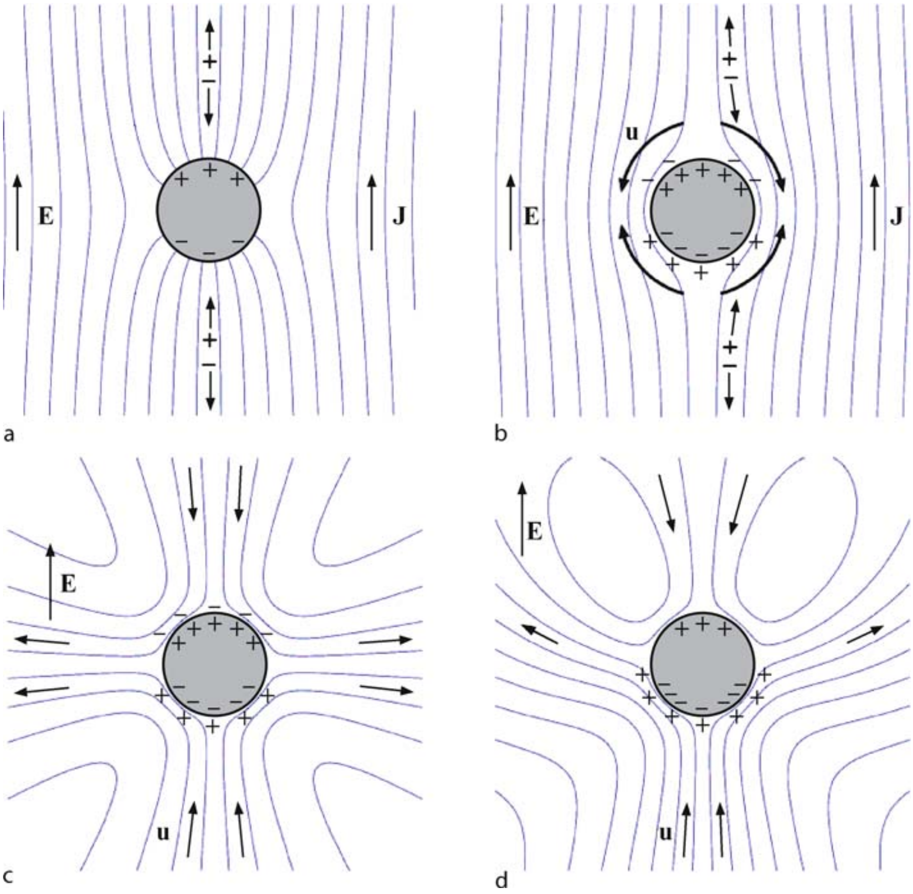
In this canonical example, broken symmetries generally lead to fluid flow past the object, if it is held fixed, or motion by ►induced-charge electrophoresis (ICEP), if it is freely suspended [2, 17]. For example, if the object



Nonlinear Electrokinetic Phenomena, Figure 1 Experimental photographs of induced-charge electro-osmosis, imaged by streaks of tracer particles. (**a**) Nonlinear flow around a 500 μm spherical ionite particle driven by a weak 10 V/cm 80 Hz background AC electric field [2]; (**b**) AC electro-osmosis at a pair of titanium electrodes applying a 2 V 100 Hz AC voltage (from [4]); (**c**) DC electrokinetic jet at a dielectric microchannel corner [5]; (**d**) one roll of quadrupolar ICEO flow around a 100 μm cylindrical gold post in a 100 V/cm 300 Hz electric field and (**e**) fixed potential ICEO flow around a gold post connected to one electrode supplying the background AC field [8] (d,e image credit: Jeremy Levitan)

has a nonzero total charge, then the ICEO flow is superimposed on the familiar streaming flow of linear electrophoresis (Fig. 2d). Whenever Eq. (2) holds, the two effects are additive, since the total charge corresponds to a constant ζ offset, relative to the background potential.

In fixed-potential ICEO (Fig. 3b), the potential of a conductor controlled so as to induce total charge in phase with a (steady or oscillating) background field [3]. The effective L in Eq. (4) is then set by the distances between the object and the electrodes supplying the background



Nonlinear Electrokinetic Phenomena, Figure 2 Physical mechanism for induced-charge electro-osmosis around an ideally polarizable metal cylinder in a suddenly applied electric field (from [2]). (**a**) When the field is turned on, electronic charges relax to make the surface an equipotential, but the normal current drives double-layer charging. (**b**) After charging, the field lines are expelled by a nonuniform distribution of induced double-layer charge. (**c**) The tangential field acts on the induced charge to drive quadrupolar ICEO flow around a neutral cylinder. (**d**) If the cylinder has a nonzero total charge, then the dipolar flow of linear electrophoresis is superimposed on the quadrupole

field, so fixed-potential ICEO flow can be much faster than the quadrupolar ICEO flow and has a different frequency response.

Other broken symmetries include irregular shapes (e. g. rods, polyhedra, etc.), non-uniform surface properties (e. g. partial dielectric or metallic coatings), and non-uniform background electric fields [17]. In each case, net pumping of the fluid by ICEO results if the object is held fixed, which requires a certain force and torque. Conversely, if the object is a colloidal particle, then broken symmetries cause it to translate and rotate ICEP, as described in companion articles on the ►electrokinetic motion of polarizable particles and heterogeneous particles.

Nonlinear Electrokinetic Phenomena Involving Dielectrics

The example above assumes an "ideally polarizable" metal surface, where the double layer charges capacitively to sustain the entire voltage applied to the object, but the phenomenon of ICEO is much more general and occurs at any polarizable surface, to varying degrees [1–3]. For example, if the metal object described above has a thin dielectric coating of width h and permittivity ε_d, then the quadrupolar ICEO flow scales as Eqs. (3)–(4) with $\delta = (\varepsilon/\varepsilon_d)(h/\lambda)$. This shows that dielectric coatings, which are thicker than the Debye length, can substantially reduce ICEO flows at metal surfaces. In the opposite limit of a purely dielectric object of length $L \gg \lambda$, the flow scales as

$$u \propto \frac{\varepsilon_d \lambda \boldsymbol{E}^2}{\eta} \quad \text{(dielectric surface)} \tag{5}$$

which is smaller than for an ideally polarizable object Eq. (4) by a factor $(\varepsilon_d/\varepsilon)(\lambda/L)$.

Although often small, ICEO flows at dielectric surfaces need not be negligible in microfluidic devices, due to

large local fields. For example, an electric field passing around a sharp corner in a dielectric microchannel can drive a strong "nonlinear electrokinetic jet" of ICEO flow due to the corner field singularity [5], as shown in Fig. 1b. In very simple terms, this phenomenon can be understood as half of the quadrupolar flow around a polarizable particle, where the jet corresponds to the outward flow at the equator in Fig. 2c.

Dielectric objects can also experience electrostatic forces. The uniform component of a background electric field induces a dipole on the object, which then feels a torque to align it with the field. A field gradient can also apply a force to the induced dipole. Higher-order multipoles in the background field can likewise cause forces and torques by acting on higher-order induced multipole moments on the object. In the case of colloidal dielectric particles, these forces and torques (balanced by hydrodynamic drag) produce translation $u \propto \varepsilon a^2 \nabla \boldsymbol{E}^2/\eta$ and rotation $\Omega \propto \varepsilon \boldsymbol{E}^2/\eta$, respectively. This general effect, known as ▶*dielectrophoresis* (DEP), is perhaps the best-known nonlinear electrokinetic phenomenon. The theory of DEP has mostly been developed for dielectric liquids, but in electrolytes, however, ICEO flows also occur, with the same scalings. The net ▶electrokinetic motion of polarizable particles results from a competition between DEP and ICEP.

Nonlinear Electrophoretic Mobility

Prior to the discovery of ICEO flow in the 1980s, the possibility of field-dependent electrophoretic mobility for charged, polarizable particles was demonstrated by several groups in the 1970s [14, 15]. A theory predicting an $\boldsymbol{E}^2$ correction to the mobility of a highly charged particle was first proposed by Simonova and Dukhin in 1976:

$$b(\boldsymbol{E}) = \frac{U(\boldsymbol{E})}{\boldsymbol{E}} \sim \frac{\varepsilon}{\eta}\left(\zeta + \alpha(\boldsymbol{E}a)^2 + \ldots\right) \tag{6}$$

It has recently been proposed to refer to this nonlinear correction as the ▶Stotz–Wien effect [14]. It can be understood as a phenomenon of induced-charge electrophoresis due to the nonlinear differential capacitance $C(\psi)$ of the diffuse layer, as a function of its voltage drop ψ, given by $\psi = (\phi - \phi_{\text{surface}})/(1+\delta)$ for a constant compact-layer capacitance. In that case, for example, the coefficient of the leading nonlinear term in a weak electric field ($\boldsymbol{E}a \ll kT/e$) is given by $\alpha = -9/8(\mathrm{d}/\mathrm{d}\psi \log C)_{\psi=\zeta}$ for an ideally polarizable sphere with a thin dielectric coating (which could model a biological cell) [15]. The basic idea is that the redistribution of diffuse charge around a polarizable particle, which is induced in response to an applied field, leads to a shift of its potential $\phi_{\text{surface}} \propto \boldsymbol{E}^2$, and thus its electrophoretic mobility, in order to maintain the same total charge with a non-constant $C(\psi)$.

In principle, the Stotz–Wien effect can be used to separate colloidal particles using an unbalanced AC field, which has zero time average $\langle \boldsymbol{E} \rangle = 0$, but nonzero time-averaged higher moments, such as $\langle \boldsymbol{E}^3 \rangle \neq 0$. An unbalanced AC field leads to a size-dependent nonlinear electrophoretic velocity for a highly charged polarizable particle

$$\langle U \rangle = \alpha \frac{\varepsilon a^2}{\eta} \left\langle \boldsymbol{E}^3 \right\rangle \quad \text{(highly charged, polarizable particle)} \tag{7}$$

This method of particle separation was first proposed by Chimenti in a US patent (5,106,648, filed in 1985) and independently in Ukraine by Dukhin's group, who called the technique "▶aperiodic electrophoresis", around the same time [14].

Electrokinetic Phenomena of the Second Kind

All of the examples above involve "blocking" surfaces, which do not pass any electrical current. If current can enter the surface, e. g. due to Faradaic reactions at a metal electrode or ionic conduction through a perm-selective porous material, then ICEO flows can be substantially modified. Electrical conduction through the surface tends to "short-circuit" the capacitive charging mechanism, so time-dependent ACEO flows tend to be reduced by Faradaic reactions. If a steady DC voltage is applied, then current into a surface can deplete the bulk salt concentration, leading to concentration polarization (breakdown of Ohm's law) and ▶diffusio-osmosis (slip driven by bulk concentration gradients). If the current is large enough to nearly deplete the bulk concentration, at the diffusion-limited current, then the diffuse-charge in the electrical double layer loses thermal equilibrium and expands into the bulk. A ▶super-limiting current causes the formation of extended ▶space charge, which can alter the nature of ICEO flow.

The possibility of nonlinear electro-osmotic flow driven by non-equilibrium space charge at large currents was predicted by S.S. Dukhin in the 1980s [6, 13]. He coined the term ▶electroosmosis of the second kind, to distinguish it from electrokinetic phenomena of the first kind (whether linear or nonlinear), which involve quasi-equilibrium double layers and non-zero bulk concentrations. In spite of appealing to very different physical mechanisms, the maximum velocity of second-kind electro-osmosis is argued to be the same as that described above for ICEO flow (Eq. (4)):

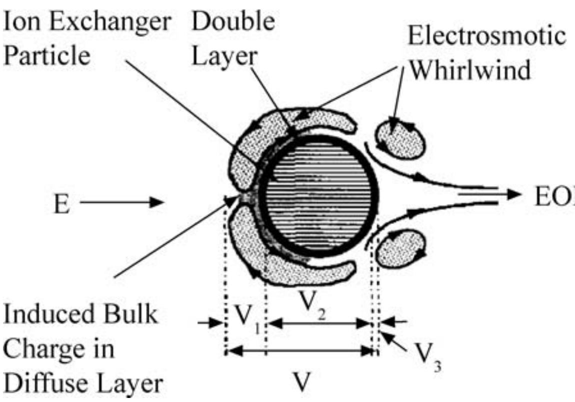
$$u \propto \frac{\varepsilon L \boldsymbol{E}^2}{\eta} \quad \text{(surface at limiting current)} \tag{8}$$

N

The reason is that in both cases the applied voltage is transferred to a charged layer near the surface as an induced zeta potential, $\zeta_{\text{induced}} \approx \boldsymbol{E}L$, either by space charge formation at large currents or by capacitive charging of the diffuse layer, respectively.

In spite of similar scaling, electro-osmosis of the second kind is fundamentally different from ICEO flow below a limiting current. Second-kind electro-osmosis requires near-total depletion of the bulk salt concentration by a large current, so it arises at the slow time scale of bulk diffusion, L^2/D, which is much greater than the capacitive double-layer charging time (Eq. (3)). It is essentially a DC effect. The passage of current through the surface also breaks symmetry in a different way in the ► electrokinetic motion of polarizable particles by ► electrophoresis of the second kind. For example, if the particle in Fig. 2c could pass a large current of counterions, then only its lower portion (facing the field) would form space charge and drive second-kind flow propelling the particle toward the field (roughly half of the quadrupolar flow field of ICEO). This picture is oversimplified, however, since experimentally observed second-kind flows can be more complicated, as sketched in Fig. 3 [6].

Space charge formation and second-kind electro-osmosis can also be observed in microfluidic devices and porous materials at interfaces between nanochannels and microchannels, as sketched in Fig. 4 [7]. Nano-scale pores with overlapping double layers act as filters, allowing the passage of only counterions. The applied electric field drives a current, which can be strong enough to deplete the nearby bulk salt concentration, resulting in a nonequilibrium space-charge layer of counterions. Tangential electric fields near the nanopore opening can then drive (often chaotic) second-kind flows in the surrounding micro-pore.



Nonlinear Electrokinetic Phenomena, Figure 3 A sketch of electro-osmotic flow of the second kind around an ion-permselective particle from experiments (from [6])

Other Nonlinear Electrokinetic Phenomena

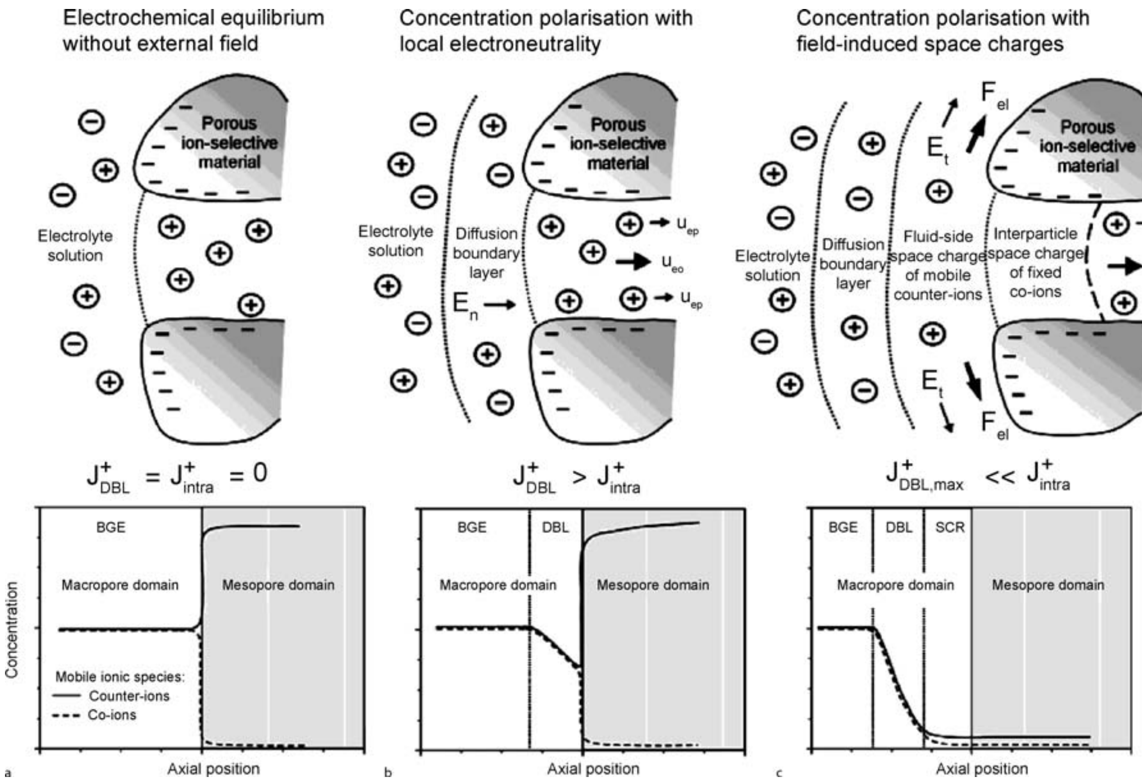
Induced-charge and second-kind electrokinetic phenomena arise due to electrohydrodynamic effects in the electric double layer, but the term *nonlinear electrokinetic phenomena* is also sometimes used more broadly to include any fluid or particle motion, which depends nonlinearly on an applied electric field. In the classical effect of ► dielectrophoresis mentioned above, electrostatic stresses on a polarized dielectric particle in a dielectric liquid cause ► dielectrophoretic motion of particles and cells along the gradient of the field intensity ($\propto \nabla \boldsymbol{E}^2$). In ► electrothermal effects, an electric field induces bulk temperature gradients by Joule heating, which in turn cause gradients in the permittivity and conductivity that couple to the field to drive nonlinear flows, e. g. via Maxwell stresses $\propto \boldsymbol{E}^2 \nabla \varepsilon$. In cases of flexible solids and emulsions, there can also be nonlinear electro-mechanical effects coupling the motions of different fluid and/or solid phases, driven by electric fields. Electric fields applied to diffuse interfaces between liquid phases, e. g. at different salt concentrations, can also produce ► electrokinetic flow instability, which depends nonlinearly on the field amplitude through the electric Rayleigh number ($\propto \boldsymbol{E}^2 \nabla \sigma$). All of these nonlinear electrokinetic phenomena can further be modified by the simultaneous application of a magnetic field, which drives fluid flow and particle motion due to the Lorentz force ($J \times B$) acting on ionic currents in solution.

Key Research Findings

Induced-Charge Electrokinetic Phenomena

The first experiments demonstrating field-dependent electrophoretic mobility of colloids (Stotz–Wien effect) were reported by several groups in the 1970s [14], and the possibility of using this effect for particle separation using unbalanced AC fields has begun to be explored [14]. This work focused on nonlinear corrections to the classical phenomenon of electrophoresis, where a particle moves in the direction of the applied electric field, $U = b(\boldsymbol{E})\boldsymbol{E}$, rather than on the associated ICEO flows and more complicated ICEP motion.

In a series of pioneering experiments on polarizable colloids, Murtsovkin and collaborators studied ICEO flows around tin, quartz, and ionite particles and liquid mercury drops in alternating electric fields and compared with the theory [1]. The scalings of the fundamental quadrupolar flow with the electric field squared and the particle size [4] were roughly verified (e. g. Fig. 5a), although in some cases the flow was observed in the opposite direction from the theory, at large induced voltages. The ► electrokinetic motion of polarizable particles and ► heterogeneous parti-



Nonlinear Electrokinetic Phenomena, Figure 4 Sketch of space charge formation and second-kind flow at the junction between a nanopore and a micropore in a microfluidic device or porous material (from [7]). (**a**) In equilibrium, the micropore contains neutral electrolyte, while the nanopore has overlapping double layers containing mostly counterions. (**b**) When an electric field is applied, the nanopore conducts a current of counterions, which depletes the nearby salt concentration in the micropore, forming a bulk diffusion layer. (**c**) If the field is strong enough, the bulk concentration goes to zero, leading to space charge formation and second-kind electro-osmotic flow in the micropore

cles by ICEP has also begun to be observed and analyzed in experiments, including unusual motion perpendicular to a uniform AC field, but much remains to be done.

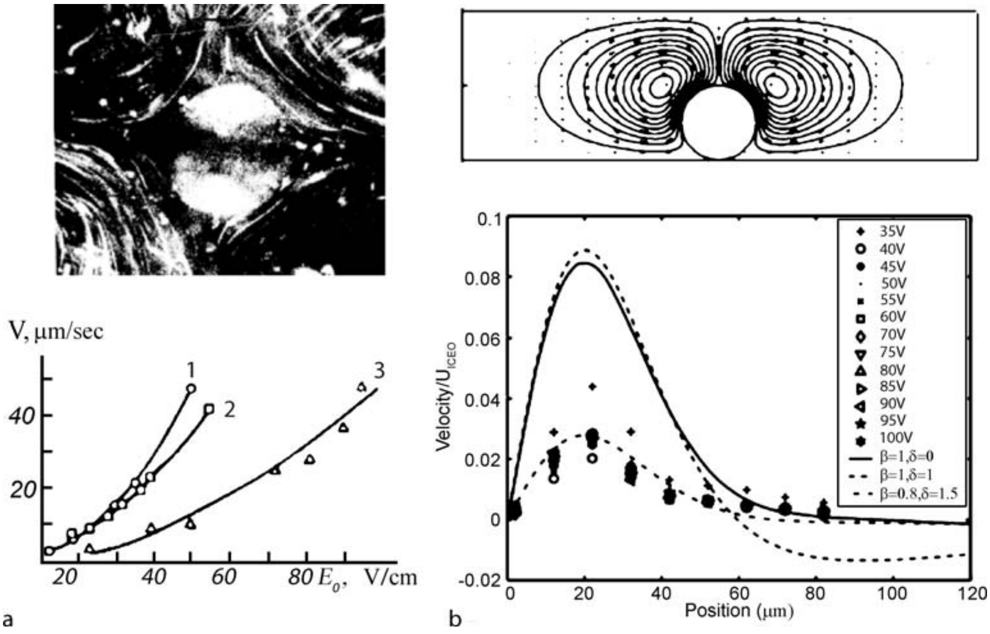
Detailed three-dimensional measurements of ICEO flows are now possible in microfluidic devices. Using particle-image velocimetry applied to thin optical slices, the ICEO flow field around a platinum cylinder has recently been reconstructed experimentally (Fig. 5b) and found to agree well with the theory, up to a scaling factor which could perhaps be attributable to compact-layer effects [8]. There has also been extensive experimental work on ▶ AC electro-osmotic flows in microfluidic devices, discussed in a separate article.

Experiments lend some support to the simplest theory of ICEO, used in nearly all calculations, which describes the bulk as an Ohmic resistor coupled to thin double layer capacitors. The mathematical model consists of Laplace's equation for the bulk electrostatic potential, $\nabla^2\phi = 0$, with an "RC" boundary condition equating the change in diffuse-layer charge density with the current entering from the bulk solution,

$$C(\psi)\frac{d\psi}{dt} = n \cdot (\sigma \nabla \phi) \tag{9}$$

Once the electrochemical problem is solved, the ICEO flow is obtained by solving Stokes' equations, $\nabla p = \eta \nabla^2 \boldsymbol{u}$ and $\nabla \cdot \boldsymbol{u} = 0$, with electro-osmotic slip given by Eq. (1) with the induced zeta potential, $\zeta = \psi$. Although this set of approximations can only be justified at low voltages in a dilute solution [3], it has had many successes in predicting induced-charge electrokinetic phenomena in experiments outside this regime.

There is, however, a need to extend the theory of ICEO to "large voltages", $\psi \gg kT/e$, where the induced diffuse-layer potential greatly exceeds the thermal voltage (25 mV at room temperature). Experiments on ▶ AC electro-osmotic flows involve micro-elecrode arrays applying several volts ($\approx 100kT/e$), and indeed many features of the data cannot be explained by the low-voltage theory, such



Nonlinear Electrokinetic Phenomena, Figure 5 Some experimental data on induced-charge electrokinetic phenomena. (4) (from [1] and references therein). (**b**) The velocity profile at different voltages, measured by micro-particle-image velocimetry, in an optical slice above a platinum cylinder in a transverse AC field, plotted with the scaling (Eq. (4)) to demonstrate data collapse. The simulated streamlines are shown above. (from [8])

as flow reversal at high frequency and flow suppression with increasing salt concentration as $u \sim \log(c_{\max}/c)$ extrapolating to zero around 10 mM. Similarly, experiments on the ►electrokinetic motion of polarizable particles and ►heterogeneous particles at somewhat lower voltages also exhibit flow reversal and the same, seemingly universal concentration dependence.

The primary consequence of a large applied voltage is the crowding of counterions near a highly polarized surface, which violates the assumptions of the classical dilute solution theory. By considering steric constraints and increased viscosity due to counterion crowding, a modified electro-osmotic slip formula has recently been derived for large induced diffuse-layer voltages in a symmetric z:z electrolyte, where

$$\bar{\zeta} = \psi - \operatorname{sgn}(\psi)\frac{kT}{ze}\log\left[1 + 4\frac{c_{\max}}{c}\sinh^2\left(\frac{ze\psi}{2kT}\right)\right] \quad (10)$$

is the apparent zeta potential in Eq. (1) and $c_{\max} = a^{-3}$ is a counterion concentration (charge density) where the viscosity is postulated to diverge [9]. The critical separation a is at least the solvated ion radius, but could be effectively larger due to under-estimation of steric effects in this lattice-gas-based model and (poorly understood) correlation effects on the viscosity. This theory reduces to Smoluchowski's at low voltages $\left(\bar{\zeta} \sim \psi \text{ for } |\psi| \ll \psi_c\right)$, but the electro-osmotic mobility saturates $\bar{\zeta} \sim \operatorname{sgn}(\psi)\psi_c$ at a concentration-dependent value,

$$\psi_c = \frac{kT}{ze}\log\left(\frac{c_{\max}}{c}\right) \quad (11)$$

at large voltages $|\psi| \gg \psi_c$. This model seems to qualitatively capture the basic features of ICEO flows in experiments, but a complete quantitative theory is still lacking. It may be necessary to go beyond the mean-field approximation (i. e. Poisson's equation for the electrostatic potential in the diffuse layer). Atomistic simulations and nanoscale experiments should be crucial to guide the further development of a modified theory of ICEO at large applied voltages.

Electrokinetic Phenomena of the Second Kind

There is growing body of experimental literature on nonlinear electro-osmotic flows around highly conductive, permselective ionite particles and porous structures in microfluidics [6, 7]. The basic velocity scaling (Eq. (8)) has been verified, and the time scale for the onset of the flow has been shown to be diffusive (L^2/D = minutes), not capacitive (Eq. (3)) (milliseconds). Imaging of second-kind flow around ionite particles with submicron tracers has shown that the largest electro-osmotic slip is near

the surfaces sustaining the largest incoming current density, resulting in a flow profile around a spherical particle, which resembles a shifted dipole or the structure in Fig. 3. Space–charge formation and concentration gradients have also been directly imaged in porous structures using charged and neutral tracers.

The mathematical theory of electro-osmosis of the second kind is still in its infancy. Scaling arguments modifying Eq. (8) have been made to quantify various effects in second-kind electrophoresis, such as advection-diffusion (large Péclet number), but precise flow fields and particle motions have not yet been calculated (or even approximated) starting from the underlying nonlinear partial differential equations of electrochemical hydrodynamics. Mathematical modeling of space charge formation has also mostly been restricted to one-dimensional conduction (as in Fig. 4).

An exception is the case of ▶electrokinetic/hydrodynamic flow instability at electro-dialysis membranes, where mathematical modeling has recently implicated second-kind electro-osmosis as a likely mechanism for super-limiting current. Starting from the classical Poisson–Nernst–Planck and Navier–Stokes equations, Rubinstein and Zaltzman have shown that one-dimensional conduction is stable until the bulk concentration approaches zero at the classical Nernst limiting current, due to fast Faradaic reactions limited by bulk diffusion [10]. In particular, hydrodynamic instability due to classical “first-kind” electro-osmotic and diffusio-osmotic flow does not occur. At the limiting current, the double layer expands, while remaining “thin” compared to the typical geometrical length scale, and assumes a non-equilibrium structure altered by the passage of normal current. In this thin space-charge layer, hydrodynamic instability occurs via second-kind electro-osmotic flows, and the resulting electro-convection brings concentrated fluid to the surface to enhance the reaction rate and exceed the diffusion-limited current.

A novel aspect of this theory is the derivation of a modified slip formula for second-kind electro-osmosis,

$$u_s = -\frac{\varepsilon V^2}{8\eta} \nabla_s \ln\left(\hat{n} \cdot \nabla c\right) \quad \text{(surface at limiting current)} \tag{12}$$

where V is the applied voltage on the surface [10]. The slip is thus given by the surface gradient of the normal diffusive flux entering the space charge layer. A unified theory of electro-osmotic slip at all applied voltages has also been derived and applied to the problem of hydrodynamic instability at electro-dialysis membranes. However, it has not yet been applied to second-kind electro-osmotic flows in other experimental situations of electrophoresis and microfluidic devices.

In spite of the complications resulting from concentration gradients and normal current, the classical transport equations used in this analysis are likely to remain valid for second-kind electro-osmosis. The reason is that the normal current prevents the overcharging of the diffuse layer, and instead most of the voltage drop occurs in the extended space charge layer, where the counterion concentration is small (and the co-ion concentration is negligible). Complicated effects of ion crowding, which are crucial in induced-charge electrokinetics at large voltages (e. g. Eqs. (9)–(11), are thus not important. This further underscores the difference between first-kind and second-kind induced-charge electrokinetic phemomena.

Examples of Applications

There are many applications of nonlinear electrokinetic phenomena in microfluidics. For example, the ▶dielectrophoretic motion of particles and cells is used for separating and concentrating biological samples. ▶Electrokinetic flow instability and ▶electrothermal effects can be used for microfluidic mixing.

Induced-charge electrokinetic phenomena are finding many new applications as well. ▶AC electro-osmotic flow is a promising means of microfluidic pumping and mixing in portable or implantable devices, since it requires low voltage and low power. ACEO has also been used in conjunction with DEP to trap, concentrate, and release particles and cells. ▶Induced-charge electro-osmosis can also be used for mixing, due to easy electrical control of complex flow patterns in space and time. ▶Induced-charge electrophoresis leads to complicated new behavior of polarizable colloids, e. g. perpendicular to an AC field, which can be exploited in new kinds of separations. In all of these cases, the use of relatively weak AC voltages, enabled by nonlinearity, is a major advantage over the large DC voltages required for linear electrokinetics, since it can greatly reduce unwanted Faradaic reactions, gas bubbles, electrode dissolution, and sample contamination.

Electrokinetic phenomena of the second kind have received mostly academic interest, but there may be important and unexpected applications. Already, second-kind electro-osmosis has been implicated as a mechanism for superlimiting current in electrodialysis. Space-charge formation at nanochannel/microchannel junctions has also been exploited to trap biomolecules, although in that case the flow is undesirable since it interferes with trapping. The speed of second-kind electrophoresis may be useful in separation or mixing, but the need to apply a large DC voltage may limit its applicability.

Non-Metallic Inorganic Materials

Synonyms

Glass; Ceramics; Oxides; Nitrides

Definition

In microfluidic systems, non-metallic inorganic material can be found as a bulk material (e. g., a glass chip or a quartz chip) or a coating (e. g., a dielectric transition metal oxide or nitride coating, or a natural silicon oxide layer on a silicon chip which is chemically similar to glass). Because of their ionic or heteropolar (dipoles) bonding character, non-metallic inorganic materials are usually hydrophilic, i. e. they are wetted rather well by water because the water molecules have also strong dipole character.

Rheological fluid flow in microchannels

Definition

Non-Newtonian fluids are characterized by the fact that the shear stresses in the fluids are not linearly proportional to the rate of deformation. It is well known that the mechanics of non-Newtonian fluids differs from the classical Newtonian fluid mechanics in many respects. One of the contrasting features of the non-Newtonian constitutive behavior is a rather non-generic nature of the pertinent governing equations, whereas for Newtonian fluids the Navier–Stokes equations are accepted without question as the appropriate conservation equations.

Chemical and Physical Principles

Biomedical micro-assay systems are continuously being developed to perform rapid clinical chemistry using minimal sample volumes. These systems are expected to improve the medical diagnostics and the patient monitoring system considerably, by eliminating the conventional protocols that are often slow and cumbersome. Other Lab-on-a-Chip based micro total analysis systems (which achieve fluid delivery, mixing, concentration and separation in a single chip, as fundamental fluidic operations) are also offering great promises in improving the sensitivity, specificity and the processing rates in several biochemical and biotechnological applications. For most of the bio-fluids that are routinely employed in these kinds of applications, Newtonian behavior appears to be an exception rather than the rule.

It is well known that the mechanics of non-Newtonian fluids differs from the classical Newtonian fluid mechanics in many respects. One of the contrasting features of the non-Newtonian constitutive behavior is a rather non-generic nature of the pertinent governing equations, whereas for Newtonian fluids the Navier–Stokes equations are accepted without question as the appropriate conservation equations.

Fundamentally, it is possible to characterize a class of fluids known as simple fluids [1], by postulating a functional relationship between the stress tensor at time t and the strain history of the material point with respect to its current configuration. For such fluids, the Cauchy stress tensor, $\boldsymbol{\tau}_{ij}$, can be expressed as [2]

$$\boldsymbol{\tau}_{ij} = -p\delta_{ij} + \mathbf{T}_{ij}\left(C_{\mathrm{mn}}^{-1}(t-s), 0 \leqslant s \leqslant \infty\right) \tag{1}$$

where $\mathbf{T}_{ij}$ is a tensor functional of the deformation history. The term in the bracket denotes the components of the Finger strain tensor of the fluid configuration at time $(t-s)$ with respect to the configuration at time t. A constitutive equation of this form implies the existence of a natural relaxation time scale λ, which can be compared with the corresponding time scale of flow, L/V. The ratio of these two quantities, known as the Weissenberg number ($\mathrm{W} = \lambda V/L$), turns out to be a key parameter in devising the mathematical forms of the non-Newtonian constitutive equations in certain cases, to be discussed later. Although somewhat generic in nature, a rather abstract form of the constitutive relationship depicted by Eq. (1) may not be sufficient to provide tractable equations for practical computations, even for the simplest of the flow problems. Physically, it may be more convenient to describe the mathematical models of constitutive behavior of non-Newtonian fluids by classifying them in terms of certain

distinctive flow features and addressing each class of fluid in a somewhat separate manner. A simple classification of non-Newtonian flows, in that perspective, is obtained as follows [2].

Flows Dominated by Shear Viscosity

For such flows, the range of flow rates is such that the variations in normal stresses are inconsequential relative to the shear stresses. Even when the fluid is highly elastic, the flow geometry and confinement may be such that the fluid elasticity has only a minor influence on the streamline orientations. On the other hand, shear-thinning effects upon the flow characteristics and the pressure distribution may appear to be quite important, even for low values of the shear rate. Such flow problems can be solved by considering constitutive equations that are of analogous (although, not necessarily the same) forms as those adopted for Newtonian flows, as follows:

$$\boldsymbol{\tau}_{ij} = -p\boldsymbol{\delta}_{ij} + 2\eta_a(I_2)D_{ij} \tag{2}$$

where $\mathbf{D}_{ij}$ is the rate of deformation tensor, η_a is the apparent viscosity and I_2 is a suitable form of the second invariant of $\mathbf{D}_{ij}$. The exact functional expressions of $\eta_a(I_2)$ are often fitted on the basis of experimental grounds; the well-known power-law fluids being just special cases of this functional behavior.

Slow Flows (Slightly Elastic Liquids)

In case the viscoelastic liquid is only slightly elastic, the general constitutive behavior depicted by Eq. (1) can be substantially simplified, by obtaining an asymptotic series of approximation in W, which can be taken as small under these conditions. As a consequence, one may arrive at the following second order constitutive model, for example [2]:

$$\boldsymbol{\tau}_{ij} = 2\eta\mathbf{D}_{ij} - \nu_1 \overset{\nabla}{\underset{ij}{D}} + 4\nu_2\mathbf{D}_{ik}\mathbf{D}_{kj} \tag{3}$$

where η, ν_1 and ν_2 are material constants and the overhead ∇ denotes the contravariant derivative, defined as

$$\overset{\nabla}{\underset{ij}{D}} = \frac{\partial \mathbf{D}_{ij}}{\partial t} + u_m \frac{\partial \mathbf{D}_{ij}}{\partial x_m} - \frac{\partial u_i}{\partial x_m}\mathbf{D}_{mj} - \frac{\partial u_j}{\partial x_m}\mathbf{D}_{im} \tag{4}$$

Substitution of Eq. (3) in the Navier's equation of motion and a subsequent expansion of the terms based on the small parameter, W, leads to a series of partial differential equations having the same structure as the Navier–Stokes equation (although, substantially more complicated in the details). However, this approach is only limited to the situations in which W can be taken as small.

Nearly Viscometric Flows

Such flows can be regarded as perturbations about basic viscometric flows, such as the Poiseuille flows or the Couette flows. Commonly, a suitable perturbation parameter is evident in nearly-viscometric flows and the problems classically solved by a perturbation expansion in that small parameter, the zero-order solution being the solution appropriate to viscometric flows. A general constitutive equation for all types of viscometric flows, however, cannot be trivially established.

Complex flows Involving Highly Elastic Fluids

These types of flows deal with fluids having a finite memory (i. e., the relaxation time, λ, is small) and the flow geometry and rates are such as to rule out the hierarchy of equations and the related constitutive expansions.
From a unified viewpoint, regardless of the class of flow, a general strategy for the solution of non-Newtonian flow problems may be to resort to the constitutive equations that are special cases of the general statement of Eq. (1) and at the same time are tractable enough to allow for numerical computations. A common approach towards achieving this goal is either to use a differential model or an integral model, relating the stress with the rate of deformation tensors. A commonly used differential model is the so-called *upper convected Maxwell model*, which has its constitutive equation in the form

$$\boldsymbol{\tau}_{ij} + \lambda \overset{\nabla}{\underset{ij}{\tau}} = 2\eta\mathbf{D}_{ij} \tag{5}$$

which is an implicit equation in the stress tensor, so that the stress components also need to be considered as dependent variables (along with the velocity components and pressure). The same model can also be expressed in an integral form, which is explicit in the stress tensor, for example

$$\boldsymbol{\tau}_{ij}(\boldsymbol{x}, t) = \frac{\eta}{\lambda^2}\int_{-\infty}^{t} \exp\left[-(t-t')/\lambda\right]\left[\mathbf{C}_{ij}^{-1}(t') - \boldsymbol{\delta}_{ij}\right] \mathrm{d}t' \tag{6}$$

where $\mathbf{C}_{ij}^{-1}$ is the Finger tensor, defined as

$$\mathbf{C}_{ij}^{-1} = \frac{\partial x_i}{\partial x_{m'}}\frac{\partial x_j}{\partial x_{m'}} \tag{7}$$

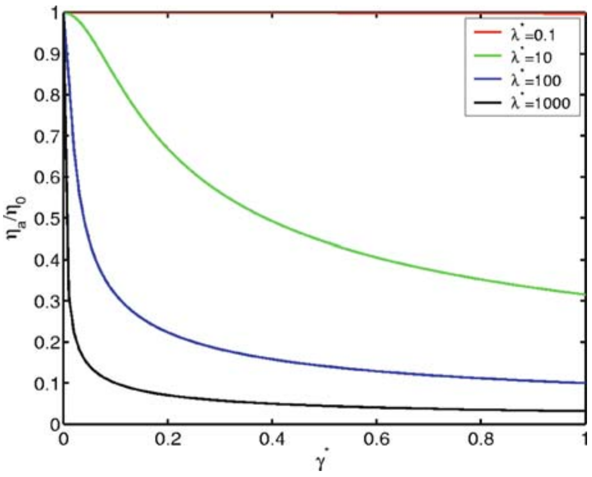
and x_i' is the position at time $t^/$ of the element that is instantaneously at the point x_i at time t'. This special form

is applicable to 'rubber-like' elastic beads, for which one needs to solve additional equations for obtaining the displacement functions (x_i'). These displacement functions can be obtained by setting $Dx_i'/Dt = 0$, for $i = 1$ to 3. The unknowns in the integral model, therefore, are the pressure, velocity and the displacement components.

Out of the various classes of non-Newtonian flows discussed as above, shear-viscosity dominated fluid flows are possibly the most common ones for typical bio-microfluidic applications. The Carreau viscosity model is one of the standard constitutive models used for many such applications. The apparent viscosity, as per this model, is given by [3]

$$\eta_a = \eta_\infty + (\eta_0 - \eta_\infty)\left[1 + (\lambda\dot{\gamma})^2\right]^{\frac{1}{2}} \tag{8}$$

The four parameters of this model, namely, $\eta_0, \eta_\infty, \lambda$ and n are the apparent viscosity at zero shear rate, apparent viscosity at infinite shear rate, time shear relaxation constant and the exponential index, respectively. The parameter λ has a unit of time and can assume any value in the range $(0, \infty)$. The index n is dimensionless, with $0 < n < 1$. Equation (8) is graphically represented in Fig. 1, for illustration. Various parameters assumed for obtaining the plots appearing in Fig. 1 are as follows: $\eta_0 = 900, \eta_\infty = 0.1$, and the non-dimensional time shear relaxation constant is defined as $\lambda^* = \lambda V/L$. From Fig. 1, it is apparent that for low values of λ^*, the constitutive behavior is practically Newtonian. For high values of λ^*, on the other hand, only marginal values of shear strain rates induce a significant non-Newtonian character. Some representative values of the Carreau parameters for different fluids are reported in the book of Tanner [3]. Based on typical values of these parameters, Zimmerman et al. [4] designed a two-dimensional finite elements model for non-Newtonian electrokinetic flows in microchannel T-junctions. Their studies revealed that the fluid experiences a range of shear rates as it turns around the corner, and the flow field was found to be extremely sensitive to the Carreau model parameters. These authors also obtained a one-to-one mapping between the model parameters and the end wall pressure, by employing a statistical analysis of the pressure profile for a wide range of operating and physical parameters. Such a mapping potentially allows one to determine the Carreau parameters of an unknown fluid if the end wall pressure profile is known, thereby establishing the working principle of a highly efficient viscometric device for microfluidics. However, the effects of viscous heating, Joule heating, net charges on the species and varying electrical properties were not considered in their study. Some of the common practical examples of non-Newtonian flows in microchannels involve the transport and manipulation of blood and blood-components in biomedical microdevices. While it has long been well-established that blood is essentially a *shear-thinning fluid'*(i.e., apparent viscosity decreases with increase in shear rate), the validity of existing constitutive models for different flow geometries at the microscale remains yet to be rigorously tested and justified. Terebotich et al. [5] investigated the use of a simple power law model for blood flow between 2.5 and 100 ml/min in microchannels with 200 μm × 60μm cross sections and having characteristic bends/sudden contractions. Including this model, in the literature, in general, there are four common models to describe the blood reheology, as follows:



Non-Newtonian Fluids in Microchannel, Figure 1 Apparent viscosity as a function of the rate of shear strain, for the Carreau viscosity model

- Casson model: $\tau = \eta_c\dot{\gamma}^{\frac{1}{2}} + \tau_Y^{\frac{1}{2}}$, for $|\tau| \geqslant \tau_Y$ and $\dot{\gamma} = 0$, otherwise; where τ, $\dot{\gamma}$, η_c and τ_Y denote shear stress, shear rate, Casson viscosity and yield stress, respectively.
- Power law model: $\tau = k|\dot{\gamma}|^{n-1}\dot{\gamma}$, where k is the consistency parameter and n is the power-law index.
- Bingham plastic model: $\tau_{ij} = 2\left(\eta_B + \tau_y/\sqrt{2P}\right)D_{ij}$ if $1/2\tau_{ij}\tau_{ji} \geqslant \tau_y^2$, and $D_{ij} = 0$, otherwise. Here η_B is the plastic viscosity, and $P = D_{ij}D_{ji}$.
- Bi-viscosity model [6]: $\tau_{ij} = 2\left(\eta_B + \tau_y/\sqrt{2|P|}\right)D_{ij}$ if $|P| \geqslant P_c$, and $\tau_{ij} = 2\left(\eta_B + \tau_y/\sqrt{2|P_c|}\right)D_{ij}$, otherwise. The parameter P_c is based on the fact that $\beta = \eta_B\sqrt{2P_c}/\tau_Y$ controls the effective viscosity in the plug region. If β is small enough, the viscosity in the plug region is so large that the predictions from the bi-viscosity model and the Bingham plastic model are virtually identical. However, if β is too small then the viscosity changes drastically at the boundary of the plug region.

N

Various criticisms have been put forward in the literature in the favor or against some of the above-mentioned models. For example, in the power law model, the apparent viscosity diverges when $\dot{\gamma} = 0$, for pseudoplastic fluids ($n < 1$). On the other hand, in the Bingham plastic model, the apparent viscosity coefficient diverges if the shear rate becomes zero. Further, the constitutive forms of the Casson model and the Bingham plastic model are greatly modified by the shear stress distributions in the fluid and in fact, explicit equations for shear stress cannot be written for very low shear rates. The bi-viscosity model, on the other hand, gives a finite apparent viscosity even in the low shear rate regimes, and therefore has been preferred by some researchers. Typical bio-fluids, in reality, are somewhat complex in constitutive behavior, and possibly any single constitutive model might not be adequate enough to represent the corresponding rheological characteristics. For example, the case of blood, which is one of the most common bio-fluids can be cited. It is well known that blood is a nonhomogeneous, anisotropic, composite fluid, composed of a suspension of many asymmetric, relatively large viscoelastic particles carried in a liquid medium, which contains high molecular weight, asymmetric, polarized, long-chain polymers that behave in a complicated way under shear loading. Thus, blood typically shows nonlinear, time-dependant (viscoelastic) flow characteristics. Some researchers prefer to describe blood as a Bingham plastic, a power law fluid, or a Casson fluid. Nevertheless, in more simple terms, blood can be described as a pseudo-plastic fluid, with non-Newtonian behavioral index (n) lying between 0 and 1. Human blood, however, can show only a very slight Bingham plasticity, attributable mainly to the presence of the protein fibrinogen [7], but only appearing in blood samples having relatively higher hematocrit percentages. Therefore, in general, for all practical purposes the Bingham plastic characteristics of human blood can be neglected, and blood can approximately be modeled either as a power law fluid or a Casson fluid.

In the power-law models of blood rheology, the indices k and n are primarily dependent on the hematocrit fraction, which is a measure of the number and size distribution of red blood cells in the sample. The above functional dependence may take the following form under time-independent circumstances [7]:

$$k = C_1 \exp(C_2 h) \tag{9}$$

and

$$n = 1 - C_3 h \tag{10}$$

where h is the hematocrit fraction in the blood cells and C_1, C_2, C_3 are species specific coefficients that can be experimentally determined [8]. These coefficients, however, are not universal constants, but are rather dependant on several biological factors. For example, C_1 depends on the plasma globulin concentration and on the hematocrit. The parameter C_2 also depends on the plasma protein. Moreover, both C_1 and C_2 show more sensitivity to viscosity of blood plasma than to any other factors related to blood cells. On the other hand, C_3 is virtually independent of plasma chemistry and is remarkably constant for a given animal species. However, C_3 correlates directly with the cellular haemoglobin concentration. Haemoglobin content being the major determinant of intracellular erythrocyte viscosity, one can assume that C_3 is somewhat related to the latter.The dependence of C_1 on plasma composition and on hematocrit can be summarized by the equation [7]:

$$C_1 = C_1^* \exp[C_4(\mathrm{TPMA})/h^2] \tag{11}$$

where TPMA is total protein minus the albumin fraction of blood, $C_1^* = 0.00797 dPa(s)^n$ and $C_4 = 145.85 d\,\mathrm{lg}^{-1}$. Typically, total protein content of human blood is around 8% and albumin constitutes 60% of the blood protein. This means that standard value of TPMA fraction in blood is 0.032. Again, the average value hematocrit in human male is 45% [8]. From this information, one may directly estimate the value of C_1. For estimation of the other rheological parameters, one may appeal to suitable experimental correlations, for example, the one variable power law of Walburn and Schneck [8], which yields the following values: $n = 0.785$ and $k = 0.0134\,Pas^n$, at 37 °C.

Key Research Findings

In a very recent study, Chakraborty [7] demonstrated the influence of non-Newtonian rheological characteristics on the dynamics of flow of blood in a microfluidic channel. In his work, special attention was devoted to estimate the effects of variable hydraulic resistance over different flow regimes, influence of suspended RBC particulates on the non-Newtonian flow characteristics and implications of a dynamically-evolving contact angle. An expression of modified viscosity was employed in the above-mentioned study, based on the consideration that blood contains a suspension of particles, length scale of which can be characterized by characteristic dimension of a typical RBC (δ, say). Accordingly flow through a microchannel of hydraulic radius r_h can be thought of as flow through r_h/δ number of concentric layers of annular laminae, each having a finite layer thickness of δ. This gives rise to

a modified apparent viscosity, given by

$$\eta_a = \frac{\eta}{\left(1 + \frac{\delta}{r_h}\right)^2} \tag{12}$$

It can easily be observed here that for δ/r_h 1, the above effect is clearly inconsequential. However, in typical microscale circulations, order of δ may approach that of r_h, which would reduce the apparent viscosity by about half of its macroscale value, and would enhance the volumetric flow rate by about 4 times, in an order of magnitude sense. Such effects can be of significant consequence in case the bio-fluid sample contains a few number of relatively large suspension particles, even though the characteristic channel dimensions might otherwise preclude microcirculation. It can be noted here that the relatively large-sized suspended particles in a bio-fluid can have other interesting implications as well. To appreciate the pertinent implications, one first needs to appreciate that the streamlines that are closer to the centerline of the microchannel represent fluid velocities that are faster than the ones associated with fluid streamlines close to the wall. This gradient in velocity across any suspended particulates (say, RBC) starts the cell spinning in such a way that the side of the cell facing the channel centerline moves in direction of the flow, whereas the side of the cell facing wall of the vascular channel moves in a direction against the flow. This leads to a drift in the particulates away from the wall, resulting in existence of a region primarily constituted of the bulk fluid within a so-called skimming layer. This implies that near the walls (where viscous effects are most predominant), the effective viscosity becomes less, and the axial pressure gradients do not have to work as hard as it would have otherwise required (if particulates were densely populated near the walls) to drive the flow, and hence, the whole bio-fluid appears to be less viscous. This can effectively be modeled by dividing the entire flow cross section into two distinct zones, which are (i) a cell-rich central zone of thickness $(r_h - \delta)$, with an averaged mixture viscosity of μ_{av} and a cell free skimming zone of thickness δ near the wall, with a liquid viscosity of μ_l. The net effect is a modified apparent viscosity, which can be computed analogous to (12) as [7]

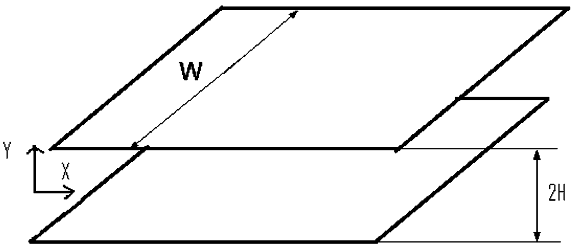
$$\eta_a = \frac{\eta_l}{1 - \left[1 - \left(\frac{\delta}{r_h}\right)\right]^4 \left[1 - \frac{\eta_l}{\eta_{av}}\right]} . \tag{13}$$

A third consequence of presence of suspension particulates can also be realized, by referring to the blood flow morphology, as an example. After the RBCs drift toward the channel centerline (due to reasons as explained earlier), the cells eventually equilibrate at some characteristic radial location. As they do so, they align with the flow streamlines in such a way that they offer least profile drag in the direction of flow. Thus, with progressive shearing, the apparent viscosity of blood tends to decrease.

Based on the above considerations, Chakraborty [7] developed a capillary-filling model for the transport of blood through microchannels. From his study, following major conclusions were drawn, regarding the implications of the non-Newtonian characteristics on the microchannel transport:

- Blunting of velocity profiles due to an axial accumulation of RBCs, as well as a streamline-RBC alignment strongly influences motion of blood into the channel.
- Axial accumulation of RBCs leaves behind a lower viscosity plasma skimming layer near the microchannel wall, which is, otherwise, a region of higher rates of strain. Consequently, the apparent viscosity of the whole blood sample decreases, and effects of this reduction become significantly prominent as size of the RBCs approaches hydraulic radius of the microchannel, leading to enhanced rates of fluidic transport.

In a more recent study, Das and Chakraborty [9] presented analytical solutions for velocity, temperature and concentration distribution in electroosmotic flows of non-Newtonian fluids in microchannels. A brief description of their transport model is summarized here, for the sake of completeness. A schematic diagram of the parallel plate microchannel configuration, as considered by the above authors, is depicted in Fig. 2. The bottom plate is denoted as $y = -H$ and top plate as $y = +H$. A potential gradient is applied along the axis of the channel, which provides the necessary driving force for electroosmotic flow. The governing equations appropriate to the physical problem are the equations for conservation of mass and linear momentum, potential distribution equation within the Electric Double Layer (EDL), energy conservation equation, and the species conservation equation for the transported solute. These equations can be described as follows:



Non-Newtonian Fluids in Microchannel, Figure 2 Schematic diagram depicting a parallel plate microchannel

Continuity Equation

$$\frac{\partial\rho}{\partial t} + \nabla\cdot(\rho \boldsymbol{V}) = 0 \quad (14)$$

where ρ is the density of the fluid and $\boldsymbol{V}$ is the flow velocity.

Linear momentum equation

$$\frac{D}{Dt}(\rho \boldsymbol{V}) = \nabla\cdot(\tau) + \boldsymbol{b} \quad (15)$$

where τ is the stress tensor and $\boldsymbol{b}$ is the body force per unit volume, given as

$$\boldsymbol{b} = \rho_e \boldsymbol{E} \quad (16)$$

In Eq. (16), ρ_e is the net electric charge density and $\vec{E}$ is the applied external electric field.

Poisson–Boltzmann equation for potential distribution within EDL

$$\nabla\cdot(\nabla\psi) = -\frac{\rho_e}{\varepsilon} \quad (17)$$

where ψ denotes the EDL potential and ε is permittivity of the fluid. The net electric charge density, ρ_e, can be described as:

$$\rho_e = -2n_0 ez \sinh\left(\frac{ez\psi}{k_B T}\right) \quad (18)$$

where, n_0 is the ion density (in molar units), e is the electronic charge, z is the valence, k_B is the Boltzmann constant, and T is the absolute temperature. To depict the relationship between the net electric charge density and Debye length, n_0 can be expressed as a function of the Debye length, λ, as follows:

$$n_0 = \frac{\varepsilon k_B T}{8\pi e^2 z^2 \lambda^2} \quad (19)$$

Energy conservation equation

$$\frac{D}{Dt}(\rho C_P T) = \nabla\cdot(k_{Th}\nabla T) + \boldsymbol{\tau}\cdot\mathbf{D} + \dot{q} \quad (20)$$

where $\mathbf{D}$ is the strain rate tensor, k_{Th} is the thermal conductivity of the fluid, and $\dot{q}$ is the heat generation per unit volume due to Joule heating (which is a consequence of application of an electric field across a conductive liquid), given by:

$$\dot{q} = \frac{(\rho_e \boldsymbol{V} + \sigma\boldsymbol{E})\cdot(\rho_e \boldsymbol{V} + \sigma\boldsymbol{E})}{\sigma} \quad (21)$$

Here, σ is the electrical conductivity of the fluid.

Species conservation equation for the transported solute

$$\frac{D}{Dt}(\rho C) = \nabla\cdot(\rho D\nabla C) \quad (22)$$

where C denotes the instantaneous concentration of the solute being transported and D is the diffusion coefficient of the solute in the fluid.

The above equations were analytically solved under the following simplifying assumptions:

- The flow is incompressible and the fluid properties are independent of temperature.
- The velocity field is steady and fully developed, i.e., $u = u(y)$ and $v = 0$.
- There is no externally imposed pressure gradient, i.e., $-\partial p/\partial x = 0$.
- The temperature field is steady and fully developed, i.e., $\partial/\partial x(\frac{T-T_W}{T_m-T_W}) = 0$, subjected a constant surface heat flux, q_s'', where $T_W(x)$ is the wall temperature and $T_m(x)$ is the bulk mean flow temperature.
- The fluid obeys a power-law constitutive model, with n as the index.
- The flow is subjected to a constant axial concentration gradient, i.e., $\partial C/\partial x = \text{cons}\tan t = M(\text{say})$.
- The charge density field is calculated on the basis of an averaged temperature (T_{av}), for the sake of analytical treatment.
- The electric double layers formed at the microchannel walls do not overlap, and the Debye–Hückel linearization principle remains as valid.

Under the above assumptions, the final forms of the governing differential equations become:

$$kn\left(\frac{du}{dy}\right)^{n-1}\frac{d^2u}{dy^2} = -\rho_e E_x \quad (23)$$

$$\frac{d^2\psi}{dy^2} = -\frac{\rho_e}{\varepsilon} \quad (24)$$

$$uM_T = k\left(\frac{du}{dy}\right)^{n+1} + k_{Th}\frac{\partial^2 T}{\partial y^2} + \dot{q} \quad (25)$$

where $\partial T/\partial x = dT_m/dx = dT_W/dx = M_T$, which is a constant for a thermally fully developed flow with constant wall heat flux boundary condition. An explicit expression for M_T is discussed later. The simplified form of the species conservation equation is as follows:

$$\frac{\partial C}{\partial t} + u\frac{\partial C}{\partial x} = D\frac{\partial^2 C}{\partial y^2} \quad (26)$$

The boundary conditions consistent with the above mentioned governing equations, with one symmetric half of the

microchannel taken as the problem domain, are as follows:

$$u = 0 \quad \text{at} \quad y = -H \quad \text{and} \quad \frac{\mathrm{d}u}{\mathrm{d}y} = 0 \quad \text{at} \quad y = 0$$

$$\psi = \psi_0 \quad \text{(zeta potential) at} \quad y = -H \quad \text{and}$$

$$\frac{\mathrm{d}\psi}{\mathrm{d}y} = 0 \quad \text{at} \quad y = 0 \tag{27}$$

$$q_s'' = -k_{\mathrm{Th}} \frac{\partial T}{\partial y} \quad \text{at} \quad y = -H \quad \text{and}$$

$$\frac{\partial T}{\partial y} = 0 \quad \text{at} \quad y = 0$$

$$D \frac{\partial C}{\partial y} = \mu(t) \quad \text{at} \quad y = -H \quad \text{and}$$

$$\frac{\partial C}{\partial y} = 0 \quad \text{at} \quad y = 0 \tag{28}$$

where $\mu(t)$ typically describes the reactions taking place at the channel surface and can be expressed as:

$$\mu(t) = -E_1 C_{\mathrm{WALL}} \tag{29a}$$

where C_{WALL} is the instantaneous wall concentration of the solute at the given axial location and E_1 is a constant. Again time dependence of C_{WALL} can be expressed as:

$$C_{\mathrm{WALL}} = E_2 \exp(-Ft) \tag{29b}$$

where E_2 and F are time-independent constants. Equations (31a, b) can be combined to yield an equation of the following form:

$$\mu(t) = E \exp(-Ft) \tag{29c}$$

where E and F are some time-independent constants. It can be noted here that for non-reactive channel walls, $\mu(t) = 0$.

The initial condition for the unsteady concentration field is taken as follows:

$$C = 0 \quad \text{at} \quad t = 0 \tag{30}$$

Analytical solutions for the velocity, temperature and concentration field, consistent with the above-mentioned physical considerations, can be obtained as a parametric function of the Debye–Hückel parameter, $\omega = \sqrt{2n_0 e^2 z^2 / \varepsilon k_{\mathrm{B}} T_{\mathrm{av}}}$, as follows:

$$u = u(y) = \left(\frac{\varepsilon \omega E_x \psi_0}{2k \cosh(\omega H)} \right)^{\frac{1}{n}} \times \begin{bmatrix} \frac{n}{\omega}\{\exp(\frac{\omega y}{n}) - \exp(-\frac{\omega H}{n})\} \\ -\frac{1}{\omega - 2\omega n}\Big\{ \exp\left(\frac{\omega y}{n} - 2\omega y\right) \\ - \exp(-\frac{\omega H}{n} + 2\omega H)\Big\} \end{bmatrix}, \tag{31a}$$

for $-H \leqslant y \leqslant 0,\ n \neq \frac{1}{2}$

$$= \left(\frac{\varepsilon \omega E_x \psi_0}{2k \cosh(\omega H)} \right)^2 \times \begin{bmatrix} \frac{1}{2\omega}\{\exp(2\omega y) - \exp(-2\omega H)\} \\ -2(y + H) \end{bmatrix}, \tag{31b}$$

for $-H \leqslant y \leqslant 0,\ n = \frac{1}{2}$.

To obtain the temperature field, it is assumed that in comparison to the electric field, the velocity field does not contribute significantly towards Joule heating. This implies

$$\dot{q} = \sigma E_x^2 \tag{32}$$

Further, the constant M_{T} can be evaluated by performing an overall energy balance for an elemental control volume, to obtain

$$\dot{m} C_P \frac{\mathrm{d}T_m}{\mathrm{d}x} = 2(q_s'' + \sigma E_x^2 H) \tag{33}$$

which yields,

$$\frac{\mathrm{d}T_m}{\mathrm{d}x} = \frac{2(q_s'' + \sigma E_x^2 H)}{\dot{m} C_P} = M_{\mathrm{T}} \tag{35a}$$

where $\dot{m}$ is the mass flow rate (per unit width of the plates), which can be evaluated as

$$\dot{m} = 2\rho \int_{-H}^{0} u \mathrm{d}y = 2\rho \left(\frac{\varepsilon \omega E_x \psi_0}{2k \cosh(\omega H)} \right)^{\frac{1}{n}} \begin{bmatrix} \frac{n}{\omega^2}\left\{ n - (n + H\omega)\exp\left(-\frac{H\omega}{n}\right) \right\} - \\ \frac{1}{(\omega - 2\omega n)^2} \left(\begin{array}{c} n - \exp\left[-\frac{H\omega}{n} + \frac{H\omega(2n-1)}{n} \right] \\ \left\{ n \exp\left(\frac{H\omega}{n}\right) + H\omega \exp\left[2H\omega - \frac{H\omega(2n-1)}{n} \right] \right. \\ \left. -2Hn\omega \exp\left[2H\omega - \frac{H\omega(2n-1)}{n} \right] \right\} \end{array} \right) \end{bmatrix} \tag{34a}$$

for $n \neq \frac{1}{2}$,

$$= 2\rho\left(\frac{\varepsilon\omega E_x\psi_0}{2k\cosh(\omega H)}\right)^2 \cdot\left[\frac{1}{4\omega^2} - \frac{1}{4\omega^2}\exp(-2\omega H) - \frac{H}{2\omega}\exp(-2\omega H) - H^2\right] \tag{34b}$$

for $n = \frac{1}{2}$.

A variation in T_w (or equivalently, T_m) can now be obtained by noting that $\mathrm{d}T_m/\mathrm{d}x = \mathrm{d}T_w/\mathrm{d}x = M_\mathrm{T}$, in conjunction with the inlet condition given as: $T_\mathrm{W} = T_\infty$ at $x = 0$, to yield:

$$T_\mathrm{W}(x) = M_\mathrm{T}x + T_\infty \tag{36}$$

Equation (25) can be subsequently solved, with the aid of following conditions:

$$T = T_\mathrm{W}(x) \quad \text{at} \quad y = -H \quad \text{and} \quad \frac{\partial T}{\partial y} = 0 \quad \text{at} \quad y = 0 \tag{37a}$$

to obtain a temperature distribution in the following form:

$$T = T(x,y) = -\frac{k}{k_\mathrm{Th}}\left(\frac{\varepsilon\omega E_x\psi_0}{2k\cosh(\omega H)}\right)^{\frac{n+1}{n}} \cdot\left[\begin{array}{c} \frac{n^2}{(n+1)^2\omega^2}\left\{\exp\left(\frac{n+1}{n}\omega y\right) - \exp\left(-\frac{n+1}{n}\omega H\right)\right\} \\ -\frac{(n-1)^2}{4\omega^2 n(n+1)}\left\{\exp\left(\frac{n+1}{n}\omega y - 2\omega y\right) - \right. \\ \left.\exp\left(-\frac{n+1}{n}\omega H + 2\omega H\right)\right\} - \frac{n^2+1}{2\omega n(n+1)}(y+H) \end{array}\right]$$

$$+ \frac{M_\mathrm{T}}{k_\mathrm{Th}}\left(\frac{\varepsilon\omega E_x\psi_0}{2k\cosh(\omega H)}\right)^{\frac{1}{n}} \left[\begin{array}{c} \frac{n^3}{\omega^3}\left\{\exp\left(\frac{\omega y}{n}\right) - \exp\left(-\frac{\omega H}{n}\right)\right\} - \frac{n}{2\omega}\exp\left(-\frac{\omega H}{n}\right) \\ (y^2 - H^2) \\ -\frac{n^2}{(\omega-2\omega n)^3}\left\{\exp\left(\frac{\omega y}{n} - 2\omega y\right) - \exp\left(-\frac{\omega H}{n} + 2\omega H\right)\right\} \\ \frac{1}{2\omega(1-2n)}\exp\left(\frac{\omega H}{n} - 2\omega H\right)(y^2 - H^2) \\ -\left\{\frac{n^2}{\omega^2} - \frac{n}{(\omega-2\omega n)^2}\right\}(y+H) \end{array}\right]$$

$$+ M_\mathrm{T}x + T_\alpha - \frac{\sigma E_x^2}{2k_\mathrm{Th}}(y^2 - H^2) \tag{36a}$$

for $-H \leqslant y \leqslant 0,\ n \neq \frac{1}{2}$,

$$= -\frac{k}{3\omega k_\mathrm{Th}}\left(\frac{\varepsilon\omega E_x\psi_0}{2k\cosh(\omega H)}\right)^3 \times\left[\frac{1}{3\omega}\{\exp(3\omega y) - \exp(-3\omega H)\} - (y+H)\right]$$

$$+ \frac{3k}{2\omega^2 k_\mathrm{Th}}\left(\frac{\varepsilon\omega E_x\psi_0}{2k\cosh(\omega H)}\right)^3 \times\left[\frac{1}{\omega}\{\exp(\omega y) - \exp(-\omega H)\} - (y+H)\right]$$

$$+ \frac{M_\mathrm{T}}{k_\mathrm{Th}}\left(\frac{\varepsilon\omega E_x\psi_0}{2k\cosh(\omega H)}\right)^2 \times\left[\begin{array}{c} \frac{1}{8\omega^3}\{\exp(2\omega y) - \exp(-2\omega H)\} - \frac{y+H}{4\omega^2} - \\ \frac{\exp(-2\omega H)}{4\omega}\left(y^2 - H^2\right) - \frac{1}{3}\left(y^3 + H^3\right) - H\left(y^2 - H^2\right) \end{array}\right]$$

$$+ M_\mathrm{T}x + T_\alpha - \frac{\sigma E_x^2}{2k_\mathrm{Th}}\left(y^2 - H^2\right) \tag{36b}$$

for $-H \leqslant y \leqslant 0,\ n = \frac{1}{2}$.

Analogously, the solutal concentration field can be obtained as

$$C = C(y,t) = \sum_{r=1}^{\infty}\left[\frac{w_0}{\exp(M_1 t)} + \frac{B_2}{M_1}\{1 - \exp(-M_1 t)\} + \frac{2EH\cos(r\pi)F}{D(r\pi)^2(M_1 - F)}\{\exp(-Ft) - \exp(-M_1 t)\}\right] \times\cos\left(\frac{r\pi y}{H}\right) - \frac{E\exp(-Ft)}{2HD}y^2 \tag{37a}$$

for $-H \leqslant y \leqslant 0,\ n \neq \frac{1}{2}$,

$$= \sum_{r=1}^{\infty}\left[\frac{w_0}{\exp(M_1 t)} + \frac{B_2'}{M_1}\{1 - \exp(-M_1 t)\} + \frac{2EH\cos(r\pi)F}{D(r\pi)^2(M_1 - F)}\{\exp(-Ft) - \exp(-M_1 t)\}\right] \times\cos\left(\frac{r\pi y}{H}\right) - \frac{E\exp(-Ft)}{2HD}y^2 \tag{37b}$$

for $-H \leqslant y \leqslant 0,\ n = \frac{1}{2}$.

The other terms appearing in the above equation are defined as follows:

$$M_1 = \left(\frac{r\pi}{H}\right)^2 \quad (37c)$$

$$w_0 = -\frac{2E}{HDM_1}\cos(r\pi) \quad (37d)$$

$$B_2 = M\left(\frac{\varepsilon\omega E_x\psi_0}{2k\cosh(\omega H)}\right)^{\frac{1}{n}} S_6 \quad (37e)$$

$$B_2' = M\left(\frac{\varepsilon\omega E_x\psi_0}{2k\cosh(\omega H)}\right)^{2} S_6' \quad (37f)$$

where $M = \frac{\partial C}{\partial x} = \cos\tan t$,

$$S_6 = \frac{2H^2n^2\left\{1-\exp\left(-\frac{H\omega}{n}\right)\cos(r\pi)\right\}}{H^2\omega^2+n^2r^2\pi} + 2\frac{\left(\begin{array}{l}\exp\left(-\frac{H\omega}{n}\right)\left\{-Hn\exp\left(-\frac{H\omega}{n}\right)\right. \\ \left.+2Hn^2\exp\left(\frac{H\omega}{n}\right)\right\} \\ +\exp\left(-\frac{H\omega}{n}+2H\omega\right)\left\{-Hn\cos(r\pi)\right. \\ \left.+2Hn^2\cos(r\pi)\right\}\end{array}\right)}{(1-2n)\left\{(2Hn\omega-H\omega)^2+(rn\pi)^2\right\}} \quad (37g)$$

$$S_6' = \frac{1}{4\omega H}\left[\frac{2\omega}{4\omega^2+M_1^2}(1-\exp(-2\omega H)\cos(M_1H))\right] - \frac{1}{HM_1^2}[1-\cos(M_1H)] \quad (37h)$$

For the cases in which the solute does not undergo any chemical reaction at the channel walls, Eq. (39) reduces to the following simplified form:

$$C = C(y,t) = \sum_{r=1}^{\infty}\left[\frac{B_2}{M_1}\{1-\exp(-M_1t)\}\right]\cos\left(\frac{r\pi y}{H}\right)$$

$$\text{for } -H \leqslant y \leqslant 0,\ n \neq \frac{1}{2} \quad (38a)$$

$$C = C(y,t) = \sum_{r=1}^{\infty}\left[\frac{B_2'}{M_1}\{1-\exp(-M_1t)\}\right]\cos\left(\frac{r\pi y}{H}\right)$$

$$\text{for } -H \leqslant y \leqslant 0,\ n = \frac{1}{2} \quad (38b)$$

Examples of Application

The applications related to non-Newtonian fluid flow through microchannels are mostly associated with the transport of biofluids, with blood as the most common example. Utilizing the mathematical model outlined as above, recent efforts have been directed to understand the implications of various rheological characteristics of blood on electrokinetically driven microfluidic transport [9]. The simulation studies based on the above-mentioned mathematical model clearly revealed that although changes in hematocrit fraction have relatively insignificant impacts on temperature distribution, their effects on concentration distribution are rather profound. As such, due to stronger dispersive effects in the velocity profile, the maximum concentration was observed to decrease with an increase in hematocrit fraction. Although the above simulation studies were executed on the basis of a fairly general framework, outlines were given on the possibilities of extending the simulation results to analyze more complicated bio-fluidic transport mechanisms. Other than understanding these basic rheological mechanisms behind microscale-transport processes of blood samples, results from the above study might also be utilized to design optimal micro-devices for blood diagnostics, by characterizing the segregation and aggregation effects of the transported solute, which can greatly influence the operating efficiency of micro-devices. For instance, the significance of leukocyte interactions with platelets, RBCs, and endothelial cells can be well characterized, by coupling the appropriate macromolecular interaction characteristics with the present generic model. The processes of leukocyte activation, adhesion and sequestration play major roles in exacerbating malperfusion associated with tissue injury and in the early stages of development of cardiovascular diseases, and this model can be extended to a basic fluid-dynamic characterization of the same. With a basic understanding of the relation between leukocyte rolling and adherence under different flow conditions, one might probe into the kinetics of interstitial accumulation of leukocytes during ischemia and after reperfusion. In fact, the increased adherence of leukocytes seen during low-flow conditions might be an important mechanism in the overall pathophysiology of inflammatory states that are accompanied by reduced blood flow. In essence, one might obtain deeper understandings regarding the effects of non-Newtonian properties of blood, nonuniform hematocrit distribution and leukocyte adhesion on flow in small vessels, by extending the general formulation to more specific cases. In particular, to trace the evolution of the core region as the blood passes by the leukocytes, an immiscibility condition between the plasma phase and RBC core phase may be imposed by introducing a solute conservation equation, of the same form as the species conservation equation employed in this study. This can also be employed to obtain a hematocrit distribution, as the same is convected along the streamlines. The species conser-

vation model can also be utilized for theoretical evaluation of concentration distribution of fluorescent particles, which are often employed for the measurement of plasma velocity in blood samples. The above-mentioned generic model can also be aimed to analyze macromolecular (such as DNA, RNA) transport characteristics within electroosmotically driven non-Newtonian microflows, with a special emphasis towards understanding the consequences of interaction between the applied electric field with the EDL potential, and the resultant temperature rises owing to Joule heating effects, which can be of utmost practical significance. Such studies, therefore, can be of particular consequence towards understanding the role of erythrocyte density on the rate of macromolecular transport through microchannels under electroosmotic effects, for designing of biomicrofluidic systems as solutal carriers.

The examples of non-Newtonian microchannel flows cited in the present article so far inherently assume that the continuum hypothesis is not disobeyed, so far as the description of the basic governing equations is concerned. This, however, ceases to be a valid consideration in certain fluidic devices, in which the characteristic system length scales are of the same order as that of the size of the macromolecules being transported. Fan et al. [10], in a related study, used the concept of finitely extended nonlinear elastic (FENE) chains to model the DNA molecules and employed the dissipative particle dynamics (DPD) approach to simulate the underlying flow behaviour in some such representative cases. From their results, it was revealed that simple DPD fluids essentially behave as Newtonian fluids in Poiseuille flows. However, the velocity profiles of FENE suspensions could be fitted with typical power-law curves, especially for dilute suspensions. More detailed investigations, indeed, need to be executed to establish and generalize this proposition for many complex fluids, possibly by drawing analogies from other theoretical viewpoints as well (the micropolar fluid theory, for instance). These system level predictions can also be substantiated by executing comprehensive molecular dynamics simulations for nano-scale flow geometries.

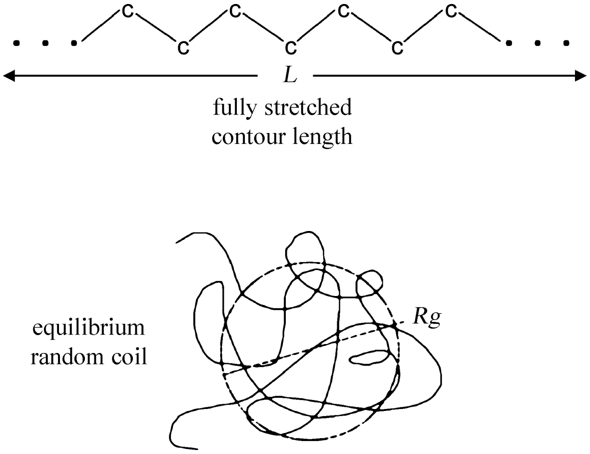
Definition

Non-Newtonian fluids exhibit complex flow behavior, typically because they contain additives such as polymers or particles that alter the response of the fluid. Unlike Newtonian fluids, which have constant viscosity (resistance to flow), the viscosity of a non-Newtonian fluid is not constant. The viscosity depends on the shear rate and the amount of strain accumulated, as well as the nature of the additives, including the concentration of additives, the

polymer molecular weight, and the particle size. In addition, flexible polymers stretch in a flow, leading to an elastic response. Development of microfluidic devices has centered on miniaturizing assays to analyze the biological, physical, and chemical properties of DNA, proteins, and biopolymers in solution, as well as suspensions of cells and bioparticles. Since the analysis is typically performed in the liquid state, non-Newtonian flow behavior must be considered. This entry discusses how biomolecules alter the flow behavior of a liquid, and how microfluidics can be used to characterize the molecular properties and the flow or *rheological* behavior.



Non-Newtonian Fluids in Microfluidics, Figure 1 Schematic illustration of the molecular conformation of a polymer, including a fully stretched chain with contour length L and an equilibrium random coil with radius of gyration R_g

Overview

The viscosity of a liquid is a parameter that measures the resistance of that liquid to flow. For example, water has a very low viscosity, while honey has a much larger, or 'thicker' viscosity. Newtonian fluids have constant values of viscosity, which means that the stress in a flowing liquid is proportional to the rate of strain of the flow. Non-Newtonian liquids do not have constant viscosity, but rather have viscosities that can be functions of the rate of strain, the total amount of strain, and other flow characteristics. Fluids are usually non-Newtonian as a result of microscopic additives such as polymers or particles. These additives alter the viscosity of a liquid and impart nonlinear flow behavior, such as viscoelasticity. The non-Newtonian behavior of many complex liquids is described thoroughly in several texts, for example [1]. In this entry we focus on behavior and applications of polymer solutions in microfluidic devices. For example, DNA is a biopolymer that is common in microfluidics applications such as gene sequencing and amplification.

A *polymer* is a long, chain-like molecule consisting of many *monomers*, or building blocks, connected together via covalent bonds. Among biologically interesting polymers used in microfluidics, DNA contains building blocks consisting of nucleotide base pairs, and proteins are built from amino acids. The *contour length* L of a polymer chain is the maximum length of the chain when fully stretched. This length is proportional to the molecular weight M. However, the fully stretched conformation is not energetically favored at equilibrium. Rotational freedom about each bond leads to flexibility and a large number of possible configurations. When the persistence length λ_p, a measure of the polymer stiffness, is much shorter than the contour length, $\lambda_p \ll L$, the polymer is said to be flexible, and its equilibrium shape is modeled as a sphere with *radius of gyration*, R_g, depicted schematically in Fig. 1. The radius of gyration depends on the molecular weight and the polymer interaction with the surrounding solvent, or the *solvent quality*. At *theta conditions*, which are conditions in which the segments of the polymer chain have equal preference to be near other polymer chain segments or solvent molecules, the polymer adopts a *random coil* conformation, in which R_g is given by

$$R^2_{g,\theta} = C_\infty n\ell^2 \tag{1}$$

where C_∞ is the characteristic ratio, which is a constant coefficient whose values are tabulated for various polymers. The characteristic ratio allows for short-range interactions due to the chemistry of the polymer chain. Also, $n = M/M_0$ is the number of bonds in the backbone, λ is the length of a bond, and M_0 is the monomer molecular weight. In a good solvent, the polymer chain has a greater affinity for the solvent molecules and the coil is expanded relative to the theta chain. The coil size is related to solvent quality through an excluded volume exponent, ν, where $R_g \sim M^\nu$. For a theta solvent, $\nu = \frac{1}{2}$, consistent with Eq. (1). For good solvents, $0.5 < \nu < 0.6$. For example, double-stranded DNA has a persistence length of about $\lambda_p = 50 - 70$ nm, and forms a random coil when the length is $50 - 1000$ kbp. T4 DNA containing 169 kbp has a contour length $L = 70$ μm, and a radius of gyration $R_g \approx 1.5$ μm [8].

Polymers increase the solution viscosity, and the *intrinsic viscosity*, $[\eta]$, is a measure of the contribution of a single polymer molecule to the overall viscosity. The intrinsic viscosity is defined by writing a Taylor expansion for the solution viscosity η as a function of concentration c,

$$\eta = \eta_s \left(1 + [\eta]\, c + k_H\, [\eta]^2\, c^2 + \dots\right) . \tag{2}$$

The intrinsic viscosity is determined by extrapolating the viscosity to infinite dilution, $c \to 0$. In Eq. (2), η_s is the solvent viscosity and k_H is a constant [2]. Thus, the solution viscosity can be written as the sum of the solvent viscosity η_s and the polymer contribution to the viscosity, $\eta = \eta_s + \eta_p$. For an equilibrium coil R_g is related to the intrinsic viscosity by the Flory–Fox equation, $[\eta] = \Phi_0 R_g^3/M$, where $\Phi_0 = 3.67 \times 10^{24}\,\text{mol}^{-1}$ is a universal constant.

When a polymer chain is placed in a flow field, the coil stretches out of its equilibrium state and rotates in the flow field. These conformation changes dramatically impact the global flow response of a polymer solution, beyond simply enhancing the viscosity of the solution. *Shear thinning* and *viscoelasticity* are two key behaviors observed in polymer solution flows. Rotation of the polymer chain in a shear flow leads to shear thinning, in which the viscosity decreases with increasing shear rate. The power law model is a simple model used to describe this behavior, where the viscosity is given by

$$\eta = m\dot{\gamma}^{n-1} \tag{3}$$

where $\dot{\gamma}$ is the shear rate and m and n are constants [3]. In reality, the viscosity of a polymer solution varies from a zero-shear-rate plateau value, η_0, to a high shear rate plateau value, $\eta_\infty \approx \eta_s$.

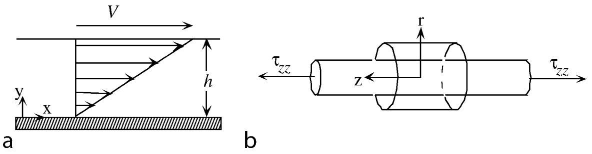
When a polymer chain stretches, entropy tends to return the coil to its equilibrium configuration, leading to an elastic restoring force. Thus, elastic stresses are generated as the polymer chain stretches and relaxes in response to flow. A liquid exhibiting both elastic and viscous stresses is *viscoelastic*. We note that the ratio of a viscosity η to an elastic modulus G yields a characteristic *relaxation time* $\lambda \sim \eta/G$ characterizing the 'memory' of a fluid of its past deformation history, or the timescale for a stretched polymer chain to relax toward equilibrium.

The relaxation time λ and the polymer contribution to the viscosity η_p depend strongly on the polymer molecular weight, concentration, and equilibrium conformation. Kinetic theory can be used to obtain scaling behavior for these quantities. At dilute concentrations, for example, the Zimm bead-spring model predicts the relaxation time as a function of the drag on polymer chain segments,

$$\lambda \sim \frac{6\pi\eta_s}{k_B T} R_g^3 \sim M^{3\nu}, \tag{4}$$

where k_B is the Boltzmann constant and T is the solution temperature [1]. Similarly,

$$\eta_p \sim \frac{c N_A k_B T \lambda}{M} \sim M^{3\nu-1} \tag{5}$$



Non-Newtonian Fluids in Microfluidics, Figure 2 Schematic diagram of two simple flow types. (**a**) Simple shear flow between parallel rigid surfaces with gap *h*. (**b**) Uniaxial elongational flow in a cylindrical fluid filament stretching along its axis *z*

where N_A is Avogadro's number. For example, T4 DNA containing 169 kbp dissolved in buffer with $\eta_s = 1$ cP has a relaxation time of $\lambda = 1.7$ s [8].

It is useful to describe non-Newtonian flows in terms of the *Deborah number*, a dimensionless group describing the ratio of the viscoelastic relaxation time, λ, and a characteristic timescale for the flow, t_{flow},

$$\text{De} = \frac{\lambda}{t_{flow}} \tag{6}$$

The flow timescale can be defined in terms of an inverse shear rate or a residence time, for example. When De is small, polymer chains have ample time to relax toward equilibrium, and the fluid behavior is viscous. When De is large, the polymer chains elongate in the flow and do not have time to relax. In this limit, the fluid behavior is predominantly elastic. The *coil-stretch transition* occurs at $\text{De} = \frac{1}{2}$, above which a majority of polymer chains elongate with the flow. Below this limit, a majority of polymer chains do not deform significantly away from the equilibrium coil size.

In addition to the flow 'strength', characterized by the Deborah number, non-Newtonian flows can also be characterized by the *flow type*. Any flow can be described in terms of contributions from three basic deformations: pure rotation, pure shearing (or sliding) motions, and pure stretching (or elongational) motions. For example, the simple shear flow depicted in Fig. 2a is described by a rate-of-strain tensor containing only off-diagonal components, while the uniaxial elongational flow depicted in Fig. 2b is described by a rate-of-strain tensor containing only diagonal components. Many useful flows contain a mixture of rotation, shearing, and stretching, which can be quantified in terms of a *flow type parameter* ξ,

$$\xi = \frac{|\mathbf{E}| - |\mathbf{\Omega}|}{|\mathbf{E}| + |\mathbf{\Omega}|} \tag{7}$$

where $|\mathbf{E}|$ and $|\mathbf{\Omega}|$ are the magnitudes of the deformation and vorticity tensors [5]. This parameter varies from $-1 < \xi < +1$, encompassing the full spectrum of flow types, where $\xi = -1$ corresponds to pure rotation, $\xi = 0$

corresponds to pure shearing, and $\xi = +1$ corresponds to pure straining. Intermediate values denote *mixed flows*.

Polymer solutions respond in dramatically different ways to pure shearing and pure straining deformations. For example, the elongational viscosity of a polymer solution can be up to 1000 times larger than the shear viscosity. Although the flow in a straight microchannel segment is a pure shearing flow, microfluidic devices often contain complex geometric elements such as contractions, expansions, and cross-flows. Flows in these geometries contain significant elongational components, and thus, characterizing the flow type in a given geometry is essential to predicting and controlling the polymer solution behavior in that device. In summary, non-Newtonian flows can be characterized by at least two key parameters: the dimensionless strain rate De, and the flow type parameter ξ. In the following sections we will describe applications of non-Newtonian flows in microfluidics that utilize the full spectrum of these parameters.

Basic Methodology

Non-Newtonian liquids are used in numerous microfluidics applications, including microscale viscosity and rheology measurements, amplification and sequencing of DNA, fundamental investigations of elastic flows, and development of fluidic memory and control devices. Although these applications span a wide range of flow conditions and non-Newtonian fluid properties, similar experimental methods are used. In this section we summarize some of the experimental considerations for driving non-Newtonian flows, controlling the nature of these flows through the device geometry, and characterizing the non-Newtonian flow behavior.

Methods available to control non-Newtonian flows are the same as for Newtonian flows, including pressure-driven flows via syringe pumps, capillary driven flows, and electrokinetic flows. These methods and others are covered in more detail in other entries. In many cases the behavior of polymer solutions subject to a driving force is similar to that of the corresponding Newtonian solvent as long as the characteristic strain rate remains below the coil-stretch transition, or $\mathrm{De} < \frac{1}{2}$. Above this critical value, shear thinning and elasticity are important.

Pressure-driven flow is one of the most common methods of driving non-Newtonian flows. Below the coil-stretch transition, a polymer solution in a straight microchannel behaves as a Newtonian liquid, exhibiting a parabolic velocity profile $u(x, y)$ and a pressure gradient $\Delta \mathrm{p}$ along the channel axis that is linearly proportional to the volumetric flow rate Q and the total viscosity of the solution $\eta = \eta_\mathrm{s} + \eta_\mathrm{p}$, given by Eq. (2). In a channel with rectangular cross-section, this pressure drop–flow rate relationship is given by

$$\frac{\Delta \mathrm{p}}{L} \cong \frac{12\eta Q}{wh^3}\left[1 - 6\left(\frac{2}{\pi}\right)^5 \frac{h}{w}\right]^{-1} \tag{8}$$

where L is the length of the channel segment, w is the width of the channel, and h is the depth of the microchannel [3]. The approximate expression given here is valid when $h/w < 0.7$. In a pressure-driven flow, the shear rate varies across the channel, with the maximum shear rate occurring at the channel walls. Thus, the dimensionless shear rate is approximately

$$\mathrm{De} = \lambda \dot{\gamma}_\mathrm{w} = \lambda \left.\frac{\partial u}{\partial y}\right|_\mathrm{wall} \approx \frac{6\lambda Q}{wh^2} \tag{9}$$

where y is the dimension across the channel depth (the smallest dimension).

When $\mathrm{De} > \frac{1}{2}$, shear thinning and elasticity influence the velocity and pressure distributions. For example, in a shear thinning liquid described by Eq. (3), the wall shear rate is modified by the exponent n such that

$$\dot{\gamma}_\mathrm{w} = \frac{6Q}{wh^2}\left(\frac{2}{3} + \frac{1}{3n}\right) \tag{10}$$

and the pressure drop for a given volumetric flow rate is modified by the viscosity index m,

$$\frac{\Delta \mathrm{p}}{L} = \frac{2m}{h}\left[\frac{6Q}{wh^2}\left(\frac{2}{3} + \frac{1}{3n}\right)\right]^n \tag{11}$$

In general, an appropriate stress-strain constitutive relationship is needed in order to predict the velocity profile, stress distribution, and pressure drop for a given non-Newtonian liquid [1].

Geometric features such as contractions and expansions can lead to pronounced non-Newtonian flow responses. For example, in a planar contraction with a ratio $\beta = w/w_\mathrm{c}$ of the upstream and downstream channel widths w and w_c, the fluid along the centerline accelerates into the contraction, leading to a significant elongational flow component. The strain rate within the contraction can be estimated by $\dot{\varepsilon}_\mathrm{c} \approx 2Q/w_\mathrm{c}^2 h$. In reality, the local strain rate reaches values several times larger than the characteristic value $\dot{\varepsilon}_\mathrm{c}$ within the contraction [10]. Elastic stresses generated by the predominantly elongational flow through the contraction lead to a pressure drop exceeding the Newtonian value.

In addition to De, which characterizes the role of elasticity in the non-Newtonian flow response, the Reynolds number Re describing the relative magnitudes of inertia and

viscous stresses remains an important parameter in contraction flows,

$$\mathrm{Re} = \frac{\rho \bar{V}_c D_h}{\eta} = \frac{2\rho Q}{\eta\,(w_c + h)} \tag{12}$$

where $\bar{V}_c$ is the average velocity in the contraction, ρ is the density of the liquid, and D_h is the hydraulic diameter of the contraction, $D_h = 2w_c h/(w_c + h)$. Since both Re and De are linearly dependent on the flow rate Q, these two parameters do not vary independently in experiments. Thus, as elastic effects become more important with increasing De, inertial effects also become more important since Re is also increasing. The ratio of the two dimensionless parameters is the Elasticity number, El,

$$\mathrm{El} = \frac{\mathrm{De}}{\mathrm{Re}} = \frac{\lambda\eta\,(w_c + h)}{\rho w_c^2 h} \tag{13}$$

Note that El depends only on fluid properties and device geometry, and its magnitude describes the rate at which Re changes with De [10].

Electric fields can also be used to drive flows of aqueous polymer solutions, and since most water-soluble polymers carry some charge, it is possible to drive both electrophoretic and electro-osmotic motions. At low field strengths, electrophoretic motions of DNA molecules in electric field gradients can be analyzed exactly analogously to hydrodynamic motions [8]. In addition, some disadvantages of microscale pressure-driven flows can be avoided by using electric fields, including the large shearing components that inevitably accompany such flows, and device failure due to large applied pressures. By placing electrodes at strategic locations within the microfluidic device, one can achieve purely elongational stretching of DNA molecules in the absence of shearing, with an equivalent stretching rate $\dot{\varepsilon}_{EL}$ and $\mathrm{De}_{EL} = \lambda\dot{\varepsilon}_{EL}$.

In all of these approaches to driving non-Newtonian flows in microfluidic devices, the geometry of the device itself plays a key role in determining the nature of the resulting flow. In pressure-driven flow, a straight channel results in pure shearing flow, while a contraction generates a significant elongational component in addition to strong shearing. Stretching flows are accomplished in several other microfluidic geometries including opposing flows in a cross-slot geometry [6], and a hyperbolic converging channel used in conjunction with electric fields [8]. More complex geometries have been designed specifically to create a range of flow types (Eq. (7)) [4, 5]. Microfluidic lithographic fabrication methods offer a significant advantage in these efforts since it is possible to design arbitrarily complex patterns. On the other hand, lithographic fabrication methods are limited to planar patterns, and a given device typically has a uniform depth throughout. In this sense, microfluidic geometries are sometimes more complicated than desired, since the cross-section of the device is rectangular and the aspect ratio of the cross-section varies throughout the device. The complex geometries in most microfluidic devices render interpretation of experiments using simple theories difficult, especially when nonlinear behavior such as non-Newtonian rheology is involved. Many recent studies have employed complementary numerical computations, experiments, and theoretical arguments to aid in the design and analysis of devices.

Finally, measurement and visualization methods are needed in order to analyze and utilize non-Newtonian microfluidic flows. Transparent materials such as glass and PDMS enable a host of optical techniques to be used. Many of these have been used to analyze non-Newtonian flows in microfluidic devices, most notably micro-PIV and related particle imaging techniques, and flow visualization using fluorescent dyes. Pressure taps have also been integrated to measure the non-Newtonian flow response simultaneous to flow visualization [9, 10].

An important visualization technique in non-Newtonian microfluidic flows is single molecule imaging of DNA via fluorescent labeling. The dynamics of bacteriophage DNA have been examined in numerous flow studies, in which DNA chains ranging in length from 2 – 140 μm have been stained with a fluorescent dye. DNA types that have been imaged include T2, T4, T7, λ-phage, and *E. Coli* DNA, and fluorescent dyes that have been used typically come from the YOYO family [7]. The large size of these molecules permits visualization using a fluorescence microscope with a high NA objective; an intensified CCD camera is needed in order to image individual molecules. At high salt concentrations in aqueous buffer solution, DNA molecules have a persistence length of $l_p \approx 50$ nm, and are therefore flexible at these lengths. Using these techniques, the dynamics of DNA molecules have been visualized in a wide range of conditions including microscale hydrodynamic flows [6, 7] and electric field gradients [8].

Key Research Findings

Non-Newtonian effects are important in numerous microfluidics applications. In some cases, microfluidic devices have been designed specifically to characterize the molecular properties and the response of a non-Newtonian liquid in a flow. Other applications involve the use of polymer molecules for specific functions, such as gene amplification and sequencing, in which the non-Newtonian behavior may also play an important role. Still others have

used non-Newtonian effects to design functional microfluidic elements. We highlight a few examples here.

Numerous microscale devices and techniques have been developed to characterize the flow behavior of polymer solutions. The principal motivation for this broad class of techniques is to enable characterization of tiny liquid volumes for which samples are costly or difficult to obtain in large quantities. These microfluidic "rheometers" fall into three categories, organized in order of increasing De: devices to measure intrinsic viscosity, shear-rate dependent viscosity, and non-Newtonian behavior for a range of flow types.

At low shear rates De $< \frac{1}{2}$, polymer chains do not stretch in a flow, but they modify the viscosity according to Eq. (2). Thus, by controlling either the pressure gradient or the volumetric flow rate in a straight microchannel, it is possible to deduce the absolute viscosity of the liquid flowing in that channel using Eq. (8). Furthermore, Eq. (2) shows that the total viscosity of a polymer solution increases relative to the solvent viscosity and the solute concentration. By successively decreasing the concentration of a solute and measuring incremental changes in the viscosity relative to η_s, one can extrapolate the value of intrinsic viscosity $[\eta]$ as the limit of the ratio $\eta_p/c\eta_s$ at infinite dilution $c \to 0$. Lee and Tripathi recently reported on a microfluidic network that successively dilutes a sample by mixing two streams, one containing a polymer solution and the other containing a dyed stream of the base solvent [2]. By applying a known pressure at the inlet of each stream and analyzing the flow rate distribution within the network using an electric circuit analogy, the authors show that the ratio of flow rates entering the mixed stream is related to the concentration of polymer in that stream, allowing the authors to measure the fluorescence intensity of the dye and infer the concentration. The device yields intrinsic viscosity measurements for polymer solutions with volumes as small as 3 μL, opening the possibility to characterize high value molecules of biological and pharmaceutical interest, and eliminating the need for manual dilutions that are typical of standard $[\eta]$ measurements.

The flow of a liquid in a microcapillary can also be used to characterize the shear-rate dependent viscosity for larger De values. Srivastava and Burns have reported on a device that draws a liquid droplet into a microchannel via capillary filling [3]. Due to the changing radius of the entering droplet, the pressure gradient within the channel changes with time, and therefore the filling rate and the length of the filled region of the capillary also vary with time and with the viscosity of the liquid. The authors monitored the filling length with time, and used Eqs. (10) and (11) to deduce the viscosity of the liquid as a function of the changing shear rate during the experiment. A reference channel allows the device to self-calibrate, and the results agree well with measurements from a conventional rheometer. The approach taken in this example is also useful because the method of sample loading circumvents the usual "world-to-chip" interface problem faced in many microfluidic devices.

Pressure-driven flows in straight microchannels with uniform cross-section are purely shearing flows ($\xi = 0$ in Eq. (7)). Thus, although the micro-viscometers described in the previous two examples will provide useful information about molecular conformation (through $[\eta]$) and shear flow behavior, they cannot yield information about a liquid's response to any flow that contains elongational components, encompassing many complex microfluidic geometries. Two recent microfluidic devices have been designed to address this need; both devices mimic a conventional, bulk-scale device called a *four roll mill* in which it is possible to generate a wide range of flow types $-1 \le \xi \le +1$. In one microfluidic analog, six channels meet in a cross configuration at a junction [4]. Two pairs of channels are positioned opposite each other with asymmetric baffles in between to offset the opposing flows. The remaining two channels are exit channels oriented perpendicular to the inlet pairs. By adjusting the ratio of the volumetric flow rates entering through the inlet channel pairs, one can vary the flow type parameter from a maximum of $\xi = +1$ to a minimum near $\xi \approx -1$. In this device it is not possible to achieve purely rotational flow. An alternate design reported by Lee et al. offers a similar concept, with opposing flows meeting at a central stagnation region, but in this case both incoming and outgoing channels contain *symmetric* baffles [5]. In this case, varying the flow rate ratio spans the complete range of flow types, including pure rotational flow $\xi = -1$. The performance of both devices is sensitive to the aspect ratio of the channels, requiring validation of the concept using flow visualization experiments and numerical computations. The first device has been used to investigate complex flows of wormlike micelle solutions, but in general neither device has been extensively validated against data from conventional devices.

The previous examples show that various microfluidic geometries can be used to successfully measure the viscoelastic properties of polymer solutions. Together with some of the advantages highlighted above, microfluidic devices offer the benefit that the devices are closed systems with no free surfaces, placing few limitations on the range of fluid viscosities that can be used, beyond pressure limitations on the device materials. On the other hand, there are also potential disadvantages. Most notably, the large surface areas lead to unavoidable shearing effects, which are difficult to de-couple when interpreting the response to

elongational or mixed flows. In this vein, shearing within the inlet regions of a device will lead to 'pre-conditioning' of the polymer chain conformations prior to entering the region of interest. Memory of past deformation history can dramatically alter a fluid's response to a flow, which can be either advantageous or detrimental depending on the application.

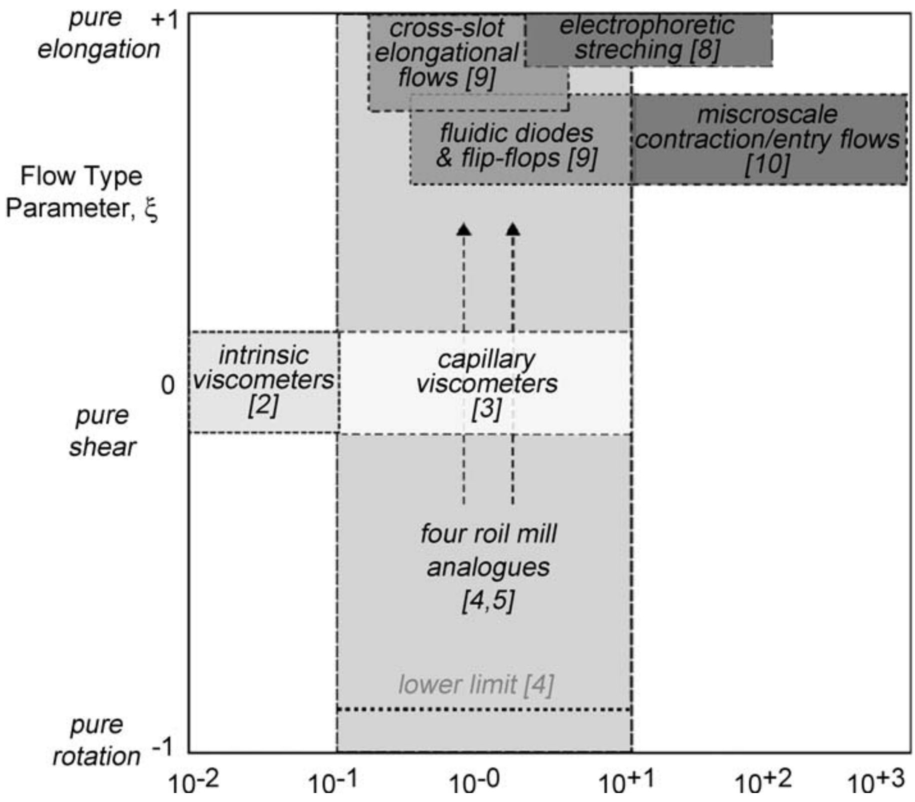
The ability to fluorescently tag individual DNA molecules and visualize their dynamics in these flows can considerably enhance the information we obtain from these flows. Numerous single molecule visualization experiments have already led to significant advancements in our understanding of polymer chain dynamics in viscous flows. In addition, these experiments have recently been combined with Brownian dynamics simulations, which simulate the motion of bead-rod chains in viscous flows and can quantitatively predict the chain conformation for given flow conditions. This powerful combination has allowed for the validation of detailed molecular scale physics, as well as the development of new physical insights. These conclusions are described in a recent review [7]; we summarize a few of the salient conclusions here.

Arguably the most important new concept to result from single molecule visualization experiments is that of "molecular individualism". In a set of groundbreaking experiments, Perkins, Smith, and Chu placed DNA molecules in a variety of flow conditions and tracked the dynamics of the polymer chains individually. Their observations confirmed several assumptions that had formed the basis for polymer dynamics theories in the absence of the ability to directly measure the chain conformation (although many other measurements supported these hypotheses). Among these, one study observed the dynamics of DNA molecules in dilute solution as they passed through the predominantly elongational flow in a microfluidic cross-slot geometry [6]. The authors collected measurements of the elongation of many individual DNA molecules, and noted several distinct conformation types including folded, kinked, and dumbbell-like configurations. An important observation from these measurements is that the configuration realized by an individual chain is highly sensitive to its initial configuration. This sensitivity to the initial configuration, dubbed 'molecular individualism', leads to highly heterogeneous conformation 'trajectories' as the chains stretch in a flow. Molecular individualism also leads to the idea that 'pre-conditioning' the polymer chains prior to stretching can result in a different flow response. For example, Brownian dynamics simulations have shown that exposing the polymer solution to shearing prior to stretching leads to fewer kinked and folded conformations among the stretched chains. Other studies have shown that in mixed flows, the elongational strain determines the amount of stretching, but the rate of stretching is much slower in mixed flows than in purely elongational flows [7].

Statistics computed from individual measurements form the link between single molecule observations and bulk flow measurements. In the study of Perkins et al. described above, the statistics indicate that the distribution of chain sizes is Gaussian during the majority of stretching; however, when the chains approach full stretch, the statistical distribution becomes highly non-Gaussian. This observation is essential to the development of stress-strain constitutive relationships for polymer solutions. It also helps explain such important observations as 'stress-conformation hysteresis'. Microfluidic devices incorporating non-Newtonian flow have played a central role in developing these conclusions [7].

A novel method for gene sequencing builds upon the ideas developed from single molecule experiments. The idea is to sequence individual DNA strands by directly detecting each base pair along the backbone [8]. To implement this concept, the DNA strand must be fully elongated. While this can be accomplished by exposing the molecules to an elongational flow, the sensitivity of the stretching profile to the initial chain conformation and the degree of shearing in the flow renders hydrodynamic methods impractical. Instead, it has been noted that electric field gradients can efficiently stretch DNA molecules using the charge along the backbone, as we described earlier. Randall and Doyle have presented a method to use electrophoretic motions of DNA in electric field gradients to stretch long DNA strands [8]. In particular, electric fields can be used to achieve pure stretching in the absence of uncontrolled shear flows, such as those that occur in hydrodynamic flows due to the no-slip condition at the walls. Randall and Doyle present a two-step microfluidic process that is designed to control molecular individualism by pre-conditioning the molecular conformation using a gel matrix to pre-stretch the molecules upstream, and then using electric field gradients to further stretch the molecules inside a hyperbolic contraction downstream. The authors show that this method is an efficient alternative to hydrodynamics for achieving continuous stretching of long strands of DNA.

Many microfluidic geometries are not as simple as those described above, and the *mixed* flow type within complex geometries can lead to other interesting flow behaviors, especially at elevated De values. For example, contraction flows of highly elastic non-Newtonian fluids can be unstable due to the interaction of elastic stresses with streamline curvature in the vortices upstream of the contraction. The upstream vortices grow relative to the New-



Non-Newtonian Fluids in Microfluidics, Figure 3 Deborah number – flow type phase diagram depicting the range of flow conditions utilized in each of the examples discussed

tonian case as De increases. At high enough flow rates, the vortex structure becomes unstable and begins to fluctuate, contributing to the measured overall pressure drop. As described earlier, De and Re do not vary independently in these flows (see Eqs. (12) and (13)), and their ratio contains a geometric length scale, suggesting that microscale contractions can be useful in accessing new regions of the De–Re phase space. Recently, Rodd and McKinley utilized this control over the geometric length scale to perform fundamental studies of viscoelastic contraction flows, measuring the pressure drop and the vortex lengths as functions of De, mapping the steady flow patterns as a function of De and Re, and characterizing the onset of inertio-elastic flow transitions [10]. These nonlinearities and instabilities have also been utilized to design functional microfluidic components. For example, as elastic instabilities develop and grow at larger De values, the flow becomes chaotic and has the ability to enhance mixing (see ► chaotic mixing based on viscoelasticity). In addition, the nonlinearity inherent in viscoelastic contraction flows has led to the design of microfluidic memory and control devices, including a 'fluidic diode' in which flux is significantly easier in one direction, and a bistable 'flip-flop' which utilizes an elastic instability to modulate the direction of flow at a junction [9].

Based on the examples described, it is clear that at least two essential factors determine the nature of a microscale non-Newtonian flow: the dimensionless strain rate, or De, and the device geometry or the flow type. The utility of each device relies on the ability to operate within a particular range of De and ξ values. Fig. 3 shows a schematic diagram of the De–ξ phase space for non-Newtonian flows, indicating the region of interest for the applications described.

Future Directions for Research

Non-Newtonian flows will remain important in microfluidic applications as long as there is the need to transport and characterize long chain molecules such as DNA and proteins. In fact, increasingly longer strands of DNA are becoming common in gene sequencing and amplification. Thus the development of new ideas for manipulating and characterizing those molecules will be essential to the success of future microfluidic devices. In

addition, an understanding of the non-Newtonian behavior in microfluidic devices can be helpful in optimizing the performance of newly developed assays incorporating large macromolecules and particles. Most of the applications highlighted here are just in their beginning stages, and future research will inevitably focus on further development, validation, and uses for these techniques.

Definition

The Boltzmann equation describes the behavior of gas flows in non-equilibrium due to molecular motion. It is applicable for all mean free paths λ between the molecules, that is, for all Knudsen numbers Kn ($= \lambda/L$, where L is a characteristic dimension in the flow). Thus it can be employed to calculate the flow fields in a variety of applications ranging from hypersonic flow past a space shuttle to flow in microdevices, where all the flow regimes – continuum (Kn $\to 0$), transitional (Kn $\sim O(1)$) and rarefied (Kn $\gg 1$) – may be encountered. The classical Boltzmann equation (CBE) describes the flow of monatomic gases (such as argon and helium) in translational non-equilibrium. The behavior of polyatomic gases (such as nitrogen and oxygen) is described by the generalized Boltzmann equation (GBE) or Wang-Chang–Uhlenbeck equation (WC–UE) [1], wherein the internal (rotational and vibrational) and translational degrees of freedom are considered in the framework of quantum and classical mechanics respectively. The molecular motion in the Boltzmann equation is described by a distribution function f which describes both the motion of the molecules and their collisions. The motion of the molecules is described by a convective differential operator while the molecular collisions result in an integral in molecular velocity space. Thus the Boltzmann equation is an integrodifferential equation whose numerical solution becomes quite a difficult task. One of the most widely used methods for the numerical solution of the Boltzmann equation is due to Cheremisin and his colleagues at the Russian Academy of Science in Moscow [2]. In this method the convective operator is discretized by an explicit scheme and the collision integral is solved by the method of discrete ordinates. A two-step method for time integration is employed that sequentially includes the convective step and the collision step.

Overview

In principle, the Boltzmann equation describes the flow at all Knudsen numbers Kn. For very small values of Kn (say < 0.01), the flow approaches the continuum regime, while for very large values of Kn (say > 10), the flow can be considered free molecular. When Kn $= O(1)$, the flow is in the continuum transition regime. In the continuum regime, Navier–Stokes equations can accurately predict the flow field, while for Kn > 1, the direct simulation Monte Carlo (DSMC) method [3] can be successfully employed. However in a variety of applications ranging from hypersonic flow past a space shuttle to flow in microdevices, part of the flow field may be in the transition regime. In the transition regime, both the Navier–Stokes equations and the DSMC method have significant limitations. Navier–Stokes equations are no longer accurate because of significant departure from equilibrium and the DSMC method becomes computationally prohibitive because of the large number of particles required for accurate simulations. A number of alternative approaches have been proposed and investigated in the literature such as the Burnett equations, Grad's moment equations or Eu's equations. These equations collectively are known as the extended hydrodynamics (EHD) equations. However, the progress has been limited and furthermore the accuracy of the EHD equations remains questionable because of

the asymptotic nature of the Chapman–Enskog expansion (e. g. for the Burnett equations), the issues related to regularization and the difficulty in imposing the exact kinetic boundary conditions on the surface of the body.

Physically, gas flows in the transition regime, where Kn is $O(1)$, are characterized by the formation of narrow, highly non-equilibrium zones (Knudsen layers) of thickness of the order of the molecular mean free path λ; the flow structure is then determined by the fast kinetic processes. Moreover, in the case of unsteady flows, an initial Knudsen time interval is of the order $\tau_0 = \lambda/v$, where v is the molecular velocity. Thus, the Knudsen layer can be computed accurately only by directly solving the Boltzmann equation.

For calculating the non-equilibrium flow of polyatomic gases, the DSMC method is currently the most widely used technique. In the DSMC approach, one usually employs some empirical models [4], which very much resemble a BGK type relaxation model with a constant relaxation time. There are only a few attempts due to Koura [5] and Erofeev [6], for example, which employ the so called *trajectory calculations*, where a realistic modeling of inelastic collisions with translational–rotational (T–R) transfer of energy is made. These computations require enormous CPU time. For vibrational excitations, no trajectory calculations with the DSMC method have been attempted to date. The physical reality is such that the vibrational term becomes important at much higher temperature than the rotational term. For the N_2 molecule the quanta of vibrational temperature is 3340 K and the quanta of rotational temperature is 2.89 K; the corresponding quanta for the O_2 molecule are 2230 and 2.1 K respectively. Therefore, rotational energy levels are important at all temperatures, but the vibrational energy levels are important only at high temperatures. Thus, each vibration energy level splits into a high number of rotational energy levels. The characteristic relaxation times for T–T, T–R, and T–V transfer of energy are in the proportion of about $1:5:100$ (or several thousands). A good physical assumption is that the translational and rotational energy are in thermodynamic equilibrium during the vibrational relaxation process.

Taking into account the above observations, let us consider hypersonic flow at different Knudsen numbers. If $\mathrm{Kn} > 1$, then no internal energies need to be taken into account, except the reactions at the boundaries. If $0.1 < \mathrm{Kn} < 1$, only the rotational levels play a role. For $\mathrm{Kn} < 0.01$, in the majority of the flow field the rotational and translational energies can be considered in equilibrium, but the vibrational relaxation continues. What can therefore be expected in the case of a shock wave (SW) at high Mach number? At the beginning, the SW structure will be formed by T–T and R–T transfers and the structure should be the same as in a gas having no vibrational levels. This SW structure with a characteristic length of about 10 mean free paths will be followed by a large zone of the size of several hundreds of mean free paths formed by the vibrational excitation. Therefore, the computation of the SW structure including the vibrational excitation becomes much more difficult than that with only T–R exchange. The computations with both the rotational and vibrational energy levels will include $N_{\mathrm{total}} = N_{\mathrm{r}} \times N_{\mathrm{v}}$ levels (N_{r} = number of rotational levels and N_{v} = number of vibrational levels) which are equivalent to a gas with N_{total} components. These computations thus require significant computational resources. It is therefore important to reduce the numbers N_{r} and N_{v} for efficient calculations without sacrificing the accuracy. Further increase in the efficiency can be obtained by exploiting the big difference between the rotational and vibrational characteristic times. As mentioned before, vibrational degrees of freedom become important when the flow is in rotational–translational equilibrium. Therefore, under such conditions, $N_{\mathrm{total}} = N_{\mathrm{v}}$. Further efficiency can be achieved by using the simplified molecular potentials, for example the inverse power potential and simple R–T cross-sections.

The solution of the GBE at high Mach numbers requires both large memory and CPU time. Following Cheremisin's work on a monatomic gas [2], one can employ a large time step in velocity space (of the order of the mean thermal velocity) ahead of the SW in the GBE code. It is also possible to use fewer levels (6 to 10) in the rotational spectrum to reduce both the memory and CPU requirements as described by Agarwal et al. [7]. Another source of large CPU time in the currently used time-explicit algorithm for solution of the Boltzmann equation is the requirement of a very small time step which results from the condition that the distribution function remains positive after the relaxation stage. For example, for a monatomic gas, at Mach 20, the time step is of the order of 0.001 of the mean free path time. In order to overcome this problem, two strategies can be employed: (a) use a filter that excludes the negligibly small contributions to the collision integral and (b) modify the algorithm to a mixed explicit–implicit scheme to increase the time step by at least a factor of 10. All these improvements result in an accurate and efficient GBE solver for computing the flow field of a diatomic gas at high Mach numbers including the rotational and vibrational excitations.

Basic Methodology

It should be noted that the GBE [8] replaces the classical WC–UE for the case when energy levels are degenerate. In its mathematical form, the GBE is similar to WC–UE and differs from the latter by a factor related to the statistical

weights of the levels. Thus, the GBE gives the equilibrium spectrum different from WC–UE. The GBE has the form

$$\frac{\partial f_i}{\partial t} + \xi \frac{\partial f_i}{\partial \boldsymbol{x}} = R_i \,. \tag{1}$$

The collision operator is given by

$$R_i = \sum_{jkl} \int_{-\infty}^{\infty} \int_0^{2\pi} \int_0^{b_m} \left(f_k f_l \omega_{ij}^{kl} - f_i f_j \right) P_{ij}^{kl} g b \, \mathrm{d}b \, \mathrm{d}\varphi \, \mathrm{d}\xi_j \,. \tag{2}$$

Here f_i is the distribution function for the energy level i, P_{ij}^{kl} is the probability of the transfer from levels i, j to levels k, l, and the factor $\omega_{ij}^{kl} = (q_k q_l)/(q_i q_j)$ (q_i being the degeneracy of the energy level). For simple levels, the GBE changes to the WC–UE; therefore it can also be considered as a more general form of the latter. In [8] the GBE was obtained directly from WC–UE by grouping the q_i single levels that have the same energy and form a degenerate level.

Let us consider molecular nitrogen having the Lennard–Jones potential (6–12), given in Ferziger and Kaper [9], with the depth of the energy hole $\varepsilon = 91$ K, degeneracy of rotational level $q_i = 2i + 1$, $i = 0, 1, \ldots \infty$, and the rotational energy of the level $e_{ri} = \varepsilon_0 i(i+1)$, $\varepsilon_0 = 2.9$ K. The molecular interaction during the collision consists of two phases. In the first phase, the molecules interact in an elastic manner according to the molecular potential. This stage determines the deviation angle of the relative velocity. In the second stage, the modulus of the relative velocity changes according to the energy conservation equation. For the transition probabilities P_{ij}^{kl} we apply the formulas given in [7] that are obtained by fitting the experimental data of molecular dynamics simulations of interactions of rigid rotors that model N_2 molecules:

$$P_{ij}^{kl} = P_0 \omega_{ij}^{kl} \left[\alpha_0 \exp\left(-\Delta_1 - \Delta_2 - \Delta_3 - \Delta_4\right) + \frac{1}{\alpha_0} \exp\left(-\Delta_3 - \Delta_4\right) \right],$$

where

$$\Delta_1 = \frac{|\Delta e_1 + \Delta e_2|}{e_{tr0}}, \qquad \Delta_2 = 2\frac{|\Delta e_2 - \Delta e_1|}{e_{\mathrm{tot}}},$$

$$\Delta_3 = 4\frac{|\Delta e_1|}{(e_{tr0} + e_{ri})}, \qquad \Delta_4 = 4\frac{|\Delta e_2|}{\left(e_{tr0} + e_{rj}\right)},$$

$$\Delta e_1 = e_{ri} - e_{rk}\,, \qquad \Delta e_2 = e_{rj} - e_{rl}\,,$$

$$\alpha_0 = 0.4\frac{e_{\mathrm{tot}}}{e_{tr0}}, \qquad e_{tr0} = \frac{mg^2}{4},$$

$$e_{\mathrm{tot}} = e_{tr0} + e_{ri} + e_{rj}\,.$$

The energy conservation law in a collision selects virtual collisions with nonzero probability. From the equation

$$\frac{mg_{ij}^2}{4} + e_{ri} + e_{rj} = \frac{mg_{kl}^2}{4} + e_{rk} + e_{rl}$$

it can be shown that $P_{ij}^{kl} > 0$, if $g_{kl}^2 \geq 0$, otherwise $P_{ij}^{kl} = 0$. The elastic collision is a particular case of the collision. The probabilities obey the normalization condition $\sum_{k,l} P_{ij}^{kl} = 1$. The kinetic equation (1) is solved by the splitting scheme described by Cheremisin [2]. At a time step $\tau < \tau_0$, where τ_0 is a mean intercollision time, Eq. (1) is replaced by the sequence of equations

$$\text{(a)} \quad \frac{\partial f_i}{\partial t} + \xi \frac{\partial f_i}{\partial \boldsymbol{x}} = 0\,, \quad \text{(b)} \quad \frac{\partial f_i}{\partial t} = R_i\,.$$

The collision operator R_i is evaluated at the uniform grid S_0 in the velocity space by the conservative projection method proposed in [2].

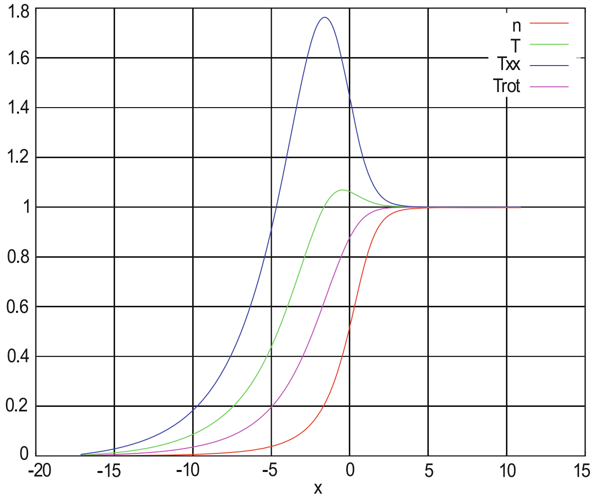
Sample Results on Computation of Shock Structure

Some sample results on the computation of shock structure in nitrogen in rotational and vibrational non-equilibrium are presented here in two parts: (a) the computations are presented for shock structure in nitrogen including the rotational degrees of freedom up to Mach 15 by solving the complete WC–UE with a number of energy levels, and (b) the computations are presented for shock structure in nitrogen with both rotational and vibrational degrees of freedom by solving the complete WC–UE for V–T relaxations and employing the two-level kinetic model for R–T relaxations. Some of the details of this two-level kinetic model for R–T relaxations are not given here but can be obtained from Morse [10]. The model reproduces the results obtained by the complete WC–UE.

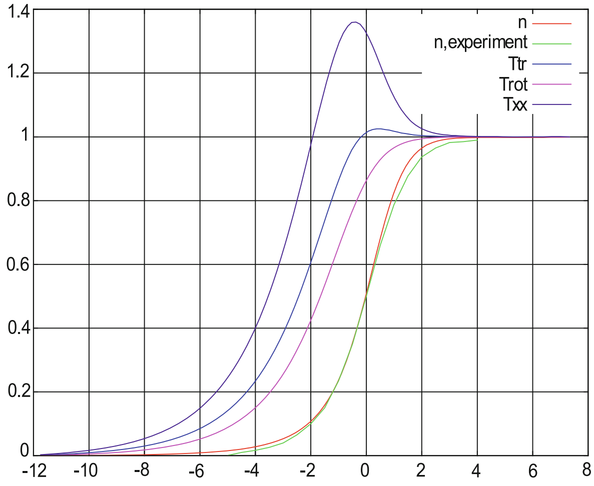
(a) The SW structure is formed as a final stage of the evolution of discontinuity in the initial distribution function. The problem is considered for the interval $-L_1 \leq x \leq L_2$ with the discontinuity at $x = 0$. The initial distribution function on both sides of the discontinuity is described by the velocities and spectral levels. It has the form

$$f_i^{1,2}(\xi, x) = n^{1,2} \left[\frac{m}{2\pi T^{1,2}} \right]^{\frac{3}{2}} \left[-\frac{m\left(\xi - u^{1,2}\right)^2}{2T^{1,2}} \right] \times \frac{2i+1}{Q_r} \exp\left(-\frac{e_{ri}}{T^{1,2}} \right)$$

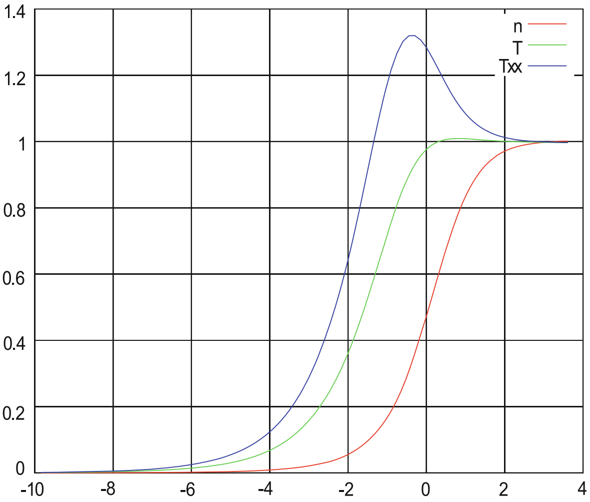
where Q_r denotes the statistical sum. Parameters $(n, T, u)^{1,2}$ are defined by the Rankine–Hugoniot relations with $\gamma = 7/5$. At the boundary the initial distribution function is kept constant.



Numerical Solution of Boltzmann Equation, Figure 1 Shock wave structure in nitrogen for $M = 15$; n = density, T = translational temperature, Txx = longitudinal translational temperature, Trot = rotational temperature (normalized)



Numerical Solution of Boltzmann Equation, Figure 2 Shock wave structure in nitrogen for $M = 10$; n = computed density, n, experiment = experimental density, T = translational temperature, Txx = longitudinal translational temperature, Trot = rotational temperature (normalized)

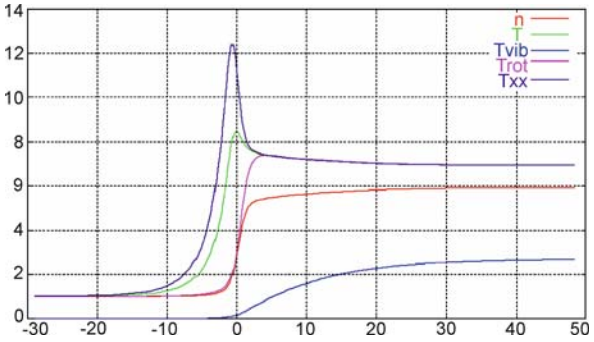


Numerical Solution of Boltzmann Equation, Figure 3 Shock wave structure in a monatomic gas for $M = 25$; n = density, T = translational temperature, Txx = longitudinal translational temperature (normalized)

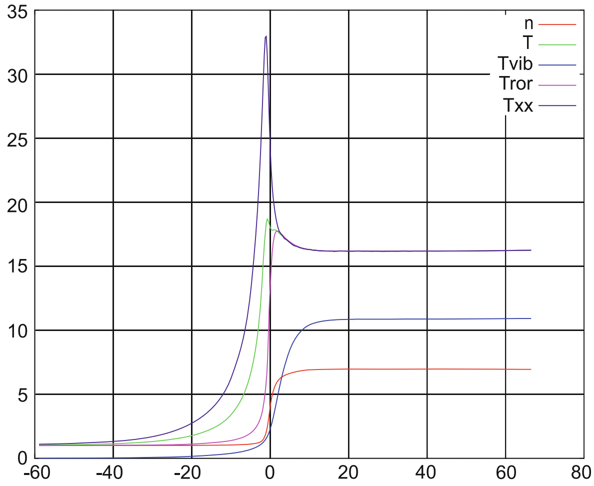
For moderate Mach numbers, the SW structure in nitrogen can be computed with real values of the spectral energy gap ε_0, but for the hypersonic case the needed number of levels becomes too high (up to 50 – 70 levels) and therefore the computations become very time consuming. To facilitate this problem it is possible to increase this energy gap and thereby reduce the number of levels. By conducting numerical experiments at Mach 4, it was determined that this increase in spectral energy gap does not influence the results of calculations in any significant way. Figure 1 shows an example of hypersonic SW structure in nitrogen at Mach 15, computed with 16 levels instead of nearly 70 "natural" levels. These types of calculations compare well with the experiments of Alsmeyer [11] for density n for reported Mach numbers up to 10. Figure 2 shows the comparison for density distribution at Mach 10 between the computation and experimental data; excellent agreement is obtained.

Figure 3 shows the hypersonic SW structure in a monatomic gas at $M = 25$. It should be noted that for this case, the temperature behind the SW increases about 200 times, which makes the computation very difficult; it required an important improvement to the algorithm.

(b) In this part we consider the gas with both rotational and vibrational degrees of freedom. The interaction potential is the Lennard–Jones potential with parameters of nitrogen taken at room temperature of 300 K. The vibrational spectrum corresponds to nitrogen with energy gap of 3340 K. For the rotational spectrum the energy quantum was increased against the actual (which is equal to 2.9 K) for reducing the number of the levels as described before in part (a). The probabilities of R–T transfers are taken from the data of mathematical simulation by Beylich [8]. The probabilities of V–T transfers are generally accepted to be much smaller than those of the R–T transfers and are in the range of 0.005 – 0.001 of the elastic collision probability. As mentioned above, V–T transfers are computed using WC–UE and the R–T transfers are computed using the two-level kinetic model to simplify the computations. Computations are performed at Mach 6 and 10.



Numerical Solution of Boltzmann Equation, Figure 4 Shock wave structure in nitrogen at $M = 6$; $n =$ density, $T =$ translational temperature, Tvib = vibrational temperature, Trot = rotational temperature, Txx = longitudinal translational temperature



Numerical Solution of Boltzmann Equation, Figure 5 Shock wave structure in nitrogen at $M = 10$; $n =$ density, $T =$ translational temperature, Tvib = vibrational temperature, Trot = rotational temperature, Txx = longitudinal translational temperature

In Figs. 4 and 5, the density, total translational, parallel translational, vibrational and rotational temperatures are shown. It is important to note that the vibrational temperature does not reach the equilibrium state with translational and rotational temperatures. This is due to the large energy quantum of the vibrational spectrum. The deviation from the equilibrium diminishes when Mach number increases. The SW structure is characterized by two phases. In the first phase, the elastic and R–T collisions are essential and the influence of V–T transfers is negligible. The translational temperature here rises above the equilibrium value. The rotational and translational temperatures reach the equilibrium at the end of this stage. At the second stage the gas energy goes to the vibrational degrees of freedom and the above indicated temperatures decrease.

At Mach 6, the vibrational spectrum consists of four levels which are sufficient to cover the entire energy range. At Mach 10, the number of needed levels is eight. In Figs. 4 and 5, a part of the x-axes is shown. The computations were made for $x = (-120, 250)$. The deviation of the final vibrational temperature from the equilibrium T–R temperatures decreases when the Mach number increases and thus the temperature behind the SW increases.

Key Research Findings

For computing the non-equilibrium flow fields of polyatomic gases in all flow regimes ranging from continuum to transitional to rarefied, the WC–UE or GBE can be successfully solved numerically to account for both the RT and VT energy transfers in very high Mach number flows. The biggest challenge is the computational efficiency for high Mach number flows using the complete GBE or WC–UE including both the RT and VT energy transfers. This issue has been addressed by reducing the number of energy levels for RT relaxations by increasing the ground state energy quantum (e. g. for Mach 15 flow, we have demonstrated that it is possible to reduce the number of levels from 70 to 16), by coarsening the grid in the velocity space without compromising the accuracy, and by treating the convective operator implicitly.

In addition, a newly developed BGK type 2-level model for R–T energy transfers (2LRT) can be employed to reproduce the calculations of the complete WC–UE; however 2LRT is 20 times faster. Thus the computations including both the R–T and V–T relaxations can be performed efficiently using the 2LRT since the number of vibrational energy levels required is usually four to six even at high Mach numbers. For example, at Mach 15, the complete solution of the WC–UE will require total number of levels $= N_r \times N_v = 70 \times 6 = 420$. With 2LRT, we require only 12.

Furthermore, it is important to note that the quantum of rotational energy for diatomic gases such as nitrogen and oxygen is much smaller than that of vibrational energy; therefore accounting for the rotational spectra is important for all Mach numbers for flows with Kn below 0.3 or so. The influence of vibrational energy should be taken into account for high Mach numbers and much smaller Kn. For Kn > 0.3, the CBE can be applied.

Future Directions for Research

The basic methodology presented here should be extended to a mixture of reactive gases. In addition, several improvements can be made for increasing the efficiency of the computations:

- implicit treatment of the convective operator,
- efficient treatment of collision integral in velocity space by employing the conservative projection method,
- increasing the ground state energy quantum of rotational energy to reduce the number of energy levels required at high Mach numbers, and
- including the adaptive meshing and parallelization in the Boltzmann solver.

Definition

Numerical techniques for free surface flows refer to methods for solving multiphase flows of liquids and gases with sharp moving and deforming interfaces. The solution of these types of flows is complex since the boundary between the two phases is not known a priori and it is part of the solution. In addition, the problem usually involves fluid flows with very large density, viscosity and velocity ratios. This makes the solution of the governing partial differential equations (PDEs) very difficult. Several numerical techniques have been developed to tackle this complex fluid flow. They can be categorized based on the type of flow modeling (Eulerian, Lagrangian or mixed), type of interface modeling (capturing or tracking), type of flow–interface coupling (integrated or segregated) and type of spatial discretization (meshless, finite difference, finite volume, finite element or others).

Overview

Free surface flows and interfaces between two or more immiscible fluids or phases are observed in many natural and industrial processes at macro- and microscales. Different numerical techniques are developed to simulate these flows. However, due to the complexity of the problem, each technique is tailored to a particular category of flows. Finite element (FE), finite volume (FV) and finite difference (FD) methods are all potentially applicable to generalized Navier–Stokes equations. However, they have to be coupled with a technique to track moving fluid boundaries and interfaces. The difficulty in tackling interfacial flows is inherently related to the complexity of interface topology and the fact that the interface location is unknown.

There are two main categories of interface solvers. The first category of methods involve mesh motion and deformation while the second group are based on fixed grids. In the moving mesh methods, the grid points move according

to the local flow characteristics. In most cases where all grid points are moved, the method is Lagrangian; otherwise, it is a mixed Lagrangian–Eulerian approach. These include methods such as FE-based Lagrangian [1], interface fitting (or boundary-fitted coordinate) [2] and boundary integral [3] approaches. In these methods, the grid points near the interface essentially play the role of marker points. Thus, these techniques are confronted with difficulties when applied to large surface deformations, surface breaking and merging.

Interface fitting methods, Fig. 1a, are efficient and accurate in the study of shaping processes of viscous materials. However, these methods rapidly become inappropriate, indeed impossible, to apply with less viscous materials that undergo large deformations. Mesh regenerations are necessary when mesh cells and elements become highly skewed, to prevent computational failures. This can make the interface fitting scheme and other moving mesh techniques become very complicated and inefficient.

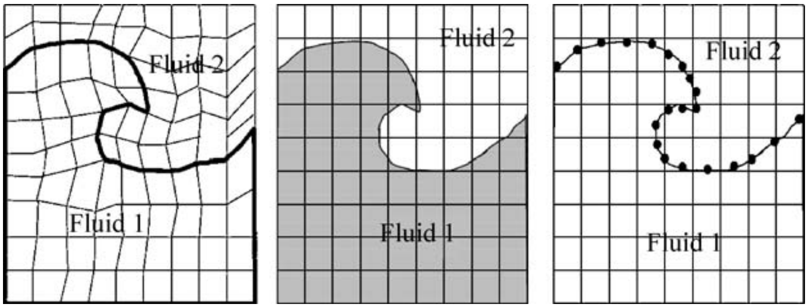
The fixed grid methods, on contrast, operate in the pure Eulerian and, sometimes, combined Lagrangian–Eulerian framework. The main distinction between moving mesh and fixed mesh lies in the fact that fixed mesh methods use an additional agent such as a Lagrangian marker or indicator function to follow the interface motion instead of grid points used by moving mesh methods. The fixed grid methods are divided into three main categories: interface capturing (Fig. 1b), interface tracking (Fig. 1c) and combined interface capturing–interface tracking techniques. Examples of interface capturing methods include marker and cell (MAC) [4], volume of fluid (VOF) [5, 6], level set (LS) [7], and diffuse interface (DI) (or phase field) [8] methods. The most widely used interface tracking method is Glimm's front tracking method [9]. The notable combined techniques which inherit from both interface capturing and interface tracking methods are Tryggvason's front tracking [10], sharp interface (SI) [11], immersed boundary (IB) [12] and immersed interface (II) [13] methods.

Techniques based on interface tracking and interface capturing avoid the grid-related problems associated with interface fitting methods by employing a grid which is fixed and by defining the location of the liquid and gas regions relative to the fixed grid. This practice requires an enlargement of the computational domain to encompass the entire container, since the free surface can potentially occupy any position within the fixed grid. In general, interface capturing methods can handle complex interfacial regions more easily, but interface tracking methods give a more accurate description of the free surface because of their Lagrangian nature. In interface tracking methods, the position of the free surface is described in a direct way; either by specifying a set of marker points located on the free surface [9] or by introducing a height function which explicitly describes the free surface position [14]. Furthermore, in interface tracking schemes, implementation of the surface tension force is straightforward given the location and curvature of the free surface. The limitation of these methods, unlike interface capturing methods, is their inability to cope naturally with folding or rupturing interfaces.

In the interface capturing techniques, the interface motion can be reproduced using different approaches. In MAC, hundreds of massless marker particles are added to the fluid. These particles are then advected in Lagrangian sense using the average of Eulerian velocities in their vicinity. In the VOF method, the use of volume fractions to mark the fluid regions is adopted because of its efficiency and simplicity and the natural way in which complex interfaces can be treated as internal moving boundaries. The volume fractions are convected through the flow domain by solving a scalar convection equation. In the level set method, a smooth distance function is used as the indicator function for the interface. A similar approach is taken in the diffuse interface method, by devising an equation which governs the continuity of mass concentration. The methods of using volume fractions, level sets or mass concentration are robust enough to handle the breakup and coalescence of fluid masses.

The advantage of LS and DI techniques over the VOF method is that their indicator functions are smooth, rather than discontinuous, and are easier to solve. Another advantage of the LS and DI methods over the MAC method is that these two techniques do not suffer from the lack of divisibility that discrete particles exhibit. There are highly accurate numerical schemes that can be applied to the level set equation. The disadvantage of level set method, however, is that the level set needs to be reset periodically which is not strictly mass conservative. The DI method models interfacial forces as continuum forces by smoothing interface discontinuities and forces over thin but numerically resolvable layers. This smoothing allows use of conventional numerical approximations, sometimes even central differencing, of interface kinematics on fixed grids with acceptable accuracy. This is because the DI method relies on the physical mechanisms on which it is based, rather than special numerical schemes to capture the interface.

Given the shortcoming of different interface solution techniques such as interface tracking and capturing methods and considering their strengths, progress has been made by combining different methods and taking advantage of the best features of each technique while removing or alleviating their drawbacks. A class of promising techniques is the combined Eulerian–Lagrangian meth-



Numerical Techniques for Free Surface Flows: Interface Capturing and Interface Tracking, Figure 1 Different interfacial flow solution methodologies: (**a**) interface fitting; (**b**) interface capturing; (**c**) interface tracking [15]

ods which have the potential to deliver both accuracy and efficiency. This class of methods combines some features of the Eulerian and Lagrangian approaches. The interface is tracked explicitly as curves (or surfaces in three dimensions). The computations are performed on fixed meshes whose topology is independent of that of the interface. One example of this type of method is the immersed boundary technique used for a range of multi-fluid problems [10, 11] and for fluid–structure interaction problems. While explicitly tracking the interface, this method transmits the information regarding the discontinuity across the interface to the grid in much the same way as purely Eulerian methods, i. e. by casting the surface forces into a body force term in the governing equations. Therefore the solution reverts to a single-fluid approach, i. e. the solver does not see a discontinuity at the location of the interface, but experiences distributed forces and material properties in the vicinity of the interface. On the other hand, the cut-cell treatment [11] proceeds to reconstruct the domain on either side of the interface with attention to the immersed boundary and its geometry overlying the grid. Phases are treated separately and no smearing of the interface takes place at the formulation level.

In the following sections, first, different formulations of interfacial flows are presented. Then, different interface solution techniques are presented with the details of each method to the extent possible.

Basic Methodology

Fluid Flow Formulations

Let us consider an arbitrary control volume Ω with boundary $\partial\Omega$ containing a portion of the two fluids. Both fluids divide the volume into two sub-volumes Ω_1 and Ω_2 by the interface Γ. The flow equations can be written in two different forms: two-fluid and single-fluid formulations.

Two-Fluid Formulation

The two-fluid formulation consists of solving the governing equations in both phases independently and then matching the interfacial boundary conditions at the interface, which usually requires an iterative algorithm. This approach keeps the interface as a discontinuity, consistent with the continuum mechanics concept. For each phase, we can write the following momentum equation along with the incompressibility constraint:

$$\frac{\mathrm{D}(\rho_i \boldsymbol{u}_i)}{\mathrm{D}t} = \nabla \cdot \boldsymbol{\Pi}_i + \rho_i \boldsymbol{g}$$
$$\nabla \cdot \boldsymbol{u}_i = 0 \quad \boldsymbol{x} \in \Omega_i\,, \quad i = 1, 2 \tag{1}$$

where $\mathrm{D}/\mathrm{D}t$ is the material derivative $\partial/\partial t + \boldsymbol{u}_i \cdot \nabla$. The subscript i denotes fluids 1 and 2 respectively. The stress tensor is defined as

$$\Pi_i = -p_i \boldsymbol{I} + \mu_i \big(\nabla \boldsymbol{u}_i + (\nabla \boldsymbol{u}_i)^T\big) \tag{2}$$

where ρ and μ are density and viscosity respectively. The last term in Eq. (1) is the body force due to gravity and buoyancy effects. The fluid interface Γ is impermeable and assuming no mass transfer between the two fluids yields a continuous velocity condition at the interface:

$$\boldsymbol{u}_1 = \boldsymbol{u}_2 \quad \text{for} \quad x \in \Gamma\,. \tag{3}$$

The jump in normal stresses along the fluid interface is balanced with the surface tension. Neglecting the variations of the surface tension coefficient, σ, gives the following Laplace–Young boundary condition for momentum conservation at the interface:

$$\boldsymbol{\Pi}_1 - \boldsymbol{\Pi}_2 = \sigma \kappa \boldsymbol{n} \quad \text{for} \quad x \in \Gamma \tag{4}$$

where σ is surface tension coefficient and $\boldsymbol{n}$ is the unit normal vector along the interface pointing outwards from

fluid 2 into fluid 1. The curvature κ of the interface is given as $-\nabla \cdot \boldsymbol{n}$.

Single-Fluid Formulation

The two-fluid formulation is in general demanding in computational operations and complex to implement. A more popular method is the single-fluid formulation of interfacial flows. In the single-fluid approach, one set of equations are solved in the whole domain making use of appropriate physical properties of each phase. The conservation of total momentum for the body of fluid in control volume Ω can be written as

$$\int_\Omega \frac{\mathrm{D}(\rho \boldsymbol{u})}{\mathrm{D}t}\,\mathrm{d}x = \int_\Omega \nabla \cdot \boldsymbol{\Pi}\,\mathrm{d}x + \int_\Gamma \sigma\kappa\boldsymbol{n}\,\mathrm{d}s + \int_\Omega \rho\boldsymbol{g}\,\mathrm{d}x\,. \tag{5}$$

It is assumed that the velocity field is continuous across the interface and the interface boundary conditions are implicitly contained within the equation of motion.

An important aspect of the surface tension is that it creates a jump in pressure across a curved interface. The pressure jump is discontinuous and located only at the interface. This singularity creates difficulties when deriving a continuum formulation of the momentum equation. The interfacial conditions should be embedded in the field equations as source terms. Once the equations are discretized in a finite-thickness interfacial zone, within which the flow properties change smoothly. It is therefore necessary to create a continuum surface force equal to the surface tension at the interface, or in a transitional region, and zero elsewhere.

Thus, the surface integral term in Eq. (5) could be rewritten into an appropriate volume integral:

$$\int_\Omega \sigma\kappa\delta(\chi)\nabla\chi\,\mathrm{d}x \tag{6}$$

where $\delta(\chi)$ is a one-dimensional Dirac delta function which is equal to 1 at the interface and 0 elsewhere. After replacing the surface integral with the obtained volume integral, the final form of unsteady Navier–Stokes equations for a system consisting of two incompressible phases is

$$\frac{\partial(\rho\boldsymbol{u})}{\partial t} + \nabla \cdot (\rho\boldsymbol{u}\boldsymbol{u}) = \nabla \cdot \boldsymbol{\Pi} + \sigma\kappa\delta(\chi)\nabla\chi + \rho\boldsymbol{g} \tag{7}$$

with the incompressibility constraint

$$\nabla \cdot \boldsymbol{u} = 0 \tag{8}$$

The single-fluid approach has been undertaken utilizing Eulerian methods such as the VOF, level set, and mixed Eulerian–Lagrangian methods [10, 11].

Interface Advection Equation for Single-Fluid Formulation

For most interface capturing schemes, which use the single-fluid formulation, an additional equation is solved to obtain the interface evolution and topology. This equation governs the advection of a variable that can be attributed to the interface. The equation of interface motion is as follows:

$$\frac{\partial\chi}{\partial t} + \boldsymbol{u} \cdot \nabla\chi = 0 \tag{9}$$

where χ is an indicator (or color) function which represents the location of interface. The scalar χ is defined differently in different interface capturing techniques. For example, χ is a volume fraction in the VOF volume tracking method, a distance function in the level set method or a Heaviside (step) function in the front tracking method.

The normal vector and curvature are computed from the indicator function using the following formulas:

$$\boldsymbol{n} = \frac{\nabla\chi}{|\nabla\chi|} \quad \kappa = -\nabla \cdot \boldsymbol{n}\,. \tag{10}$$

The physical properties, such as density and viscosity, used in the single-fluid approach are dependent on the value of χ in the cells throughout the computational domain. For example, if χ is a normalized color function such as volume fraction in the VOF method which changes between 0 and 1 throughout the domain, the following formulas determine the density and viscosity:

$$\rho = \rho_2 + (\rho_1 - \rho_2)\chi \tag{11}$$

$$\mu = \mu_2 + (\mu_1 - \mu_2)\chi \tag{12}$$

where subscripts 1 and 2 refer to the first and second fluids, respectively.

Interface Solution Methodologies

Moving and Deforming Mesh Methods

FE-Based Lagrangian Methods While FD- and FV-based techniques have been commonly used to simulate large surface deformations including the breakup and merging of liquids, the FE-based techniques have been more common in simulating less complicated surface deformations. FE performs on either fixed or deforming spatial meshes (see Fig. 2a). Deforming meshes are more

N

popular and are divided into three sub-categories. The first is based on a three-stage iterative cycle by guessing the location of the free surface, solving the governing equations and updating the free surface. Iterations are repeated until the difference between the two successively updated free surface locations becomes less than some desired convergence tolerance. The second approach eliminates the iterations by introducing the position of the nodes on the free surface as a degree of freedom. The third technique is the height flux (HF) method. In this technique, neither iterations are involved for locating the free surface nor is one degree of freedom added to the set of the unknowns. The free surface is found by using the volume of fluid inside sub-volumes which are updated at any time step using the velocity field.

As a sample simulation using the Lagrangian FE method, Fig. 3 shows the deformation of a droplet after impaction on a flat substrate simulated by Fukai et al. [1]. The deformation of the grid as the droplet spreads can be observed. For low to moderate interface deformations, this method gives accurate results and sometimes is even more efficient than interface capturing simulations with high grid resolutions since in FE-based methods, the region near interface can be adapted locally and reduce the number of cells required.

Interface Fitting (Boundary-Fitted Coordinate) Method In the interface fitting, or boundary-fitted method (Fig. 1a), the interface is tracked by attaching it to a mesh surface which is forced to move with the interface. This can be considered a Lagrangian mesh method. The motion of the free surface is accounted for by a coordinate transformation which maps the moving, body-fitted coordinate system in physical space to a uniformly spaced coordinate system in computational space. If the free surface becomes highly distorted, a new mesh may have to be generated in order to prevent both grid singularities and highly skewed grid point distributions.

For the low-deformation bubble simulations where the boundary-fitted method is most widely used, it is assumed that Reynolds number ($\mathrm{Re} = \rho U D/\mu$) is low, the gas flow inside bubbles is neglected and a constant gas pressure assumed. The following boundary conditions are applied at the interface:

- velocity continuity,
- zero tangential stress, and
- balance of normal stress (Π) contributions by pressure, viscous and capillary forces.

The interface position is tracked by introducing a curvilinear interface-fitted non-orthogonal coordinate system. By means of a coordinate transformation, the physical domain is converted to a computational domain with known boundaries that are coordinate isolines. A boundary-fitted grid is generated around the deformed interface at each iteration by a pair of Poisson equations associated with spacing control functions.

The major difficulty arising in free surface flow computation is that the interface location is unknown together with the velocity and pressure fields. Therefore, one has to obtain the physical velocity boundary conditions and the interface position from the boundary conditions.

The following iterative procedure is used in boundary fitted method:

1. Choose an initial state (bubble shape, velocity and pressure fields) with desired values of Reynolds and Weber ($\mathrm{We} = \rho U^2 D/\sigma$) numbers.
2. Compute a curvilinear coordinate interface-fitted grid by carrying out some iterations on the mapping equations.
3. Calculate the velocity boundary conditions from the velocity continuity and tangential stress.
4. Solve Navier–Stokes equations using the fractional steps method.
5. Check the normal stress condition: if not satisfied, displace each interfacial point proportionally to the current normal stress excess Π^n; a new interface position X^{n+1} is then defined at each iteration (Fig. 4).
6. Continue the iterative process from step 2 until boundary conditions and incompressibility condition are satisfied.

The interface position correction at step 5 is given by

$$k_\Pi \Pi^n \boldsymbol{n}^n \tag{13}$$

where k_Π is a constant coefficient, and Π^n and $\boldsymbol{n}^n$ are respectively the current normal stress excess and interface normal vector at iteration n. The iterative process is stopped when

$$\Pi^n \leqslant \varepsilon_\Pi \tag{14}$$

with $\varepsilon_\Pi = 10^{-2}$. The value of k_Π depends on the Weber number and varies between $k_\Pi = 10^{-1}$ (for small Weber numbers) and $k_\Pi = 10^{-3}$ (for large Weber numbers). Conservation of the bubble volume is controlled at each iteration after the interface position correction step (step 5) in order to avoid accumulation of numerical errors and to ensure the convergence of the whole procedure.

This method is best suited and gives very accurate results for relatively simple geometries especially those encountered in two-dimensional and axisymmetric problems. However, application of the boundary-fitted method to complex fully three-dimensional problems with unsteady deforming phase boundaries is very rare [17].

Boundary Integral (BI) Method The low Reynolds number approximation of the Navier–Stokes equations (also known as Stokes equations) is an acceptable model for a number of interfacial flow problems. For instance, the typical example of drop coalescence also belongs to this case. A boundary integral method [3] arises from a reformulation of the Stokes equations in terms of boundary integral expressions and the subsequent numerical solution of the integral equations.

The main advantage of the boundary integral methods, compared with other methods (e. g. FD, FE), is that for a number of multiphase flow problems its implementation involves integration on the interfaces only. Thus, discretization is required only for the interfaces, which allows for higher accuracy and performance, especially in three-dimensional simulations. An important feature of the mathematical model used in the BI method is that the velocity at a given time instant depends only on the position of the interfaces at that time instant.

For a system of two incompressible Newtonian fluids separated by an immiscible interface, and neglecting inertial forces, the two-fluid system of Eq. (1) can be simplified to

$$\nabla \cdot \boldsymbol{\Pi}_i = 0\,,$$
$$\nabla \cdot \boldsymbol{u}_i = 0 \quad x \in \Omega_i\,, \quad i = 1, 2 \tag{15}$$

where $\boldsymbol{\Pi}_i = -p_i \boldsymbol{I} + \mu_i(\nabla \boldsymbol{u}_i + (\nabla \boldsymbol{u}_i)^T)$ is the stress tensor. The boundary conditions at the interface $S = \Omega_0 \bigcap \Omega_1$ are the stress balance boundary condition and continuity of the velocity across the interface,

$$(\Pi_1(\boldsymbol{x}) - \Pi_2(\boldsymbol{x})) \cdot \boldsymbol{n}(\boldsymbol{x}) = f(\boldsymbol{x})\boldsymbol{n}(\boldsymbol{x})\,, \quad \boldsymbol{u}_1(\boldsymbol{x}) = \boldsymbol{u}_2(\boldsymbol{x}) \tag{16}$$

where $\boldsymbol{n}(\boldsymbol{x})$ is the unit vector normal to S. The present formulation is limited to interfacial forces, such as capillary effects, that are normal to the interfaces:

$$f(\boldsymbol{x}) = 2\sigma\kappa(\boldsymbol{x}) \tag{17}$$

where $k(\boldsymbol{x}) = 0.5(1/R^1 + 1/R^2)$ is the mean curvature of the interface, and R^1 and R^2 are the main radii of the curvature.

The velocity at infinity is prescribed via a boundary condition,

$$\boldsymbol{u}_\infty(\boldsymbol{x}) = \boldsymbol{L} \cdot \boldsymbol{x}, \quad ||\boldsymbol{x}|| = \infty \tag{18}$$

where $\boldsymbol{L}$ specifies the type of linear flow.

The evolution of the interface $S(\boldsymbol{x}, t)$ is given by the kinematic condition

$$\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} = \boldsymbol{u}(\boldsymbol{x}, t) + \boldsymbol{w}(\boldsymbol{x}, t), \quad \boldsymbol{x} \in S \tag{19}$$

where $\boldsymbol{w}$ can be an arbitrary velocity, tangential to S.

For a given position of the interfaces S the solution of the mathematical model (Eqs. (15)–(17)) for the velocity $\boldsymbol{u}(\boldsymbol{x}_0)$ at a given point $\boldsymbol{x}_0$ can be obtained by means of the boundary integral formulation. The equations are nondimensionalized and, for simplicity, the same notations for the dimensionless velocity, pressure, space and time variables are used as those for the corresponding dimensional variables from the previous equations.

$$\begin{aligned}\boldsymbol{u}(\boldsymbol{x}_0) = {} & \frac{2}{\lambda+1}\boldsymbol{u}_\infty(\boldsymbol{x}_0) \\ & - \frac{2}{\lambda+1}\frac{1}{8\pi}\int_S f(\boldsymbol{x})\boldsymbol{G}(\boldsymbol{x}_0, \boldsymbol{x}) \cdot \boldsymbol{n}(\boldsymbol{x})\,\mathrm{d}s(\boldsymbol{x}) \\ & - \frac{\lambda-1}{\lambda+1}\frac{1}{4\pi}\int_S \boldsymbol{u}(\boldsymbol{x}) \cdot \boldsymbol{T}(\boldsymbol{x}_0, \boldsymbol{x}) \cdot \boldsymbol{n}(\boldsymbol{x})\,\mathrm{d}s(\boldsymbol{x})\end{aligned} \tag{20}$$

where the integration is over the total interfacial area $S = \bigcup_i S^i$. Here, λ is the non-dimensional viscosity. Tensors $\mathbf{G}$ and $\mathbf{T}$ are the Stokeslet and stresslet, respectively:

$$\mathbf{G}(\boldsymbol{x}_0, \boldsymbol{x}) = \frac{\boldsymbol{I}}{r} + \frac{\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}{r^3}, \quad \mathbf{T}(\boldsymbol{x}_0, \boldsymbol{x}) = \frac{-6\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}\hat{\boldsymbol{x}}}{r^5} \tag{21}$$

where $\hat{\boldsymbol{x}} = \boldsymbol{x} - \boldsymbol{x}_0$, $r = |\hat{\boldsymbol{x}}|$.

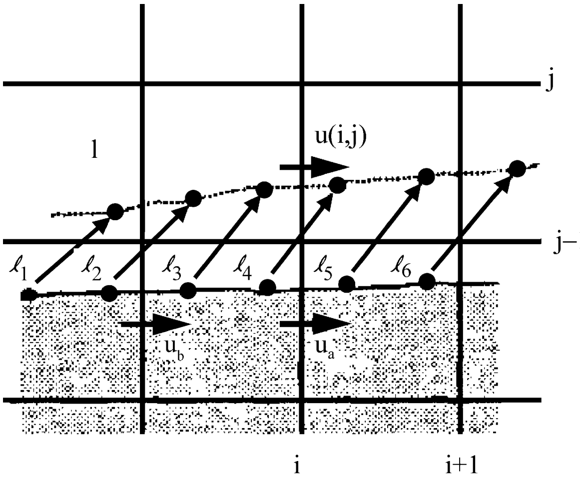
The main advantage of a boundary integral method is that it involves integration only on the interfaces. The main problem, however, regarding the numerical implementation of Eq. (20) is due to the singularities of the kernels $\mathbf{G}$ and $\mathbf{T}$ at $\boldsymbol{x} = \boldsymbol{x}_0$, which is described in detail elsewhere [3].

Among the numerical methods for interfacial flow problems the boundary integral method seems to be one of the most appropriate for problems involving interfaces in close approach. Such situations are typical for most of the practically important multiphase flows including drop deformation and drop-to-drop interaction. Well-known examples are neck formation and its thinning during breakup as well as film formation and drainage during drop coalescence. A simulation of these processes requires a good resolution and accuracy in the neck and film regions. However, the main difficulty for the implementation of a boundary integral method is due to the singularity of the free-space Green's kernels and sensitivity of the method to numerical instabilities. Another disadvantage of this method is that the topological changes do not occur naturally, rather by algorithm intervention.

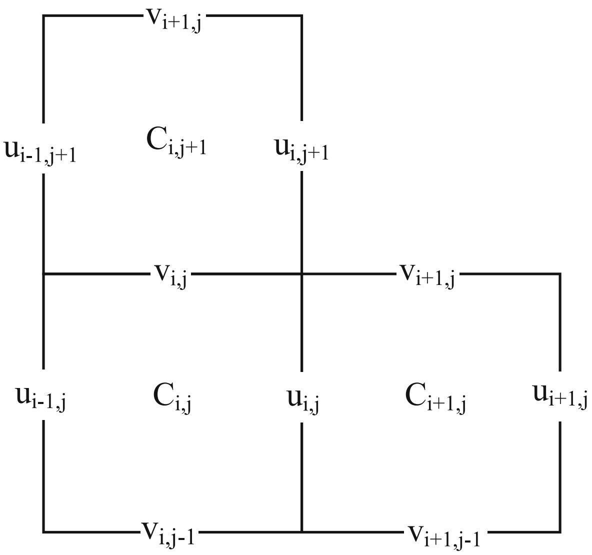
Interface Capturing

Marker and Cell (MAC) Method The first method capable of modeling gas–liquid flows, separated by a moving interface, was the MAC of Harlow and Welch [4]. In the MAC method, as shown in Fig. 2b, the massless markers are used to define the location and track the movement of free surface. This is in fact a combination of a Eulerian solution of the basic flow field, with Lagrangian tracking of marker particles. The computational cycle in the MAC method consists of the advancement of discrete field variables from an initial time t_0 to the subsequent time $t_0 + \Delta t$ by accomplishing the steps below. The computation starts with a predictor–corrector algorithm for the determination of velocity field at $t_0 + \Delta t$. In the predictor stage of the solution algorithm, the pressure is replaced by an arbitrary pseudo-pressure β (which in most cases is set equal to zero at full cells), and tentative velocities are then calculated. A pseudo-pressure boundary condition is applied in surface cells to satisfy the normal stress condition. Since pressure has been ignored in the full cells, the tentative velocity field does not satisfy the incompressible continuity equation. The deviation from incompressibility is used to calculate a pressure potential field ψ, which then is used to correct the velocity field. In the final steps, the velocity boundary conditions are calculated, the new location of free surface is determined by tracking the markers and the velocity boundary conditions associated with the new fluid cells are assigned (Fig. 5).

The MAC method, which allows arbitrary free surface flows to be simulated, is widely used and can be readily extended to three dimensions. Its drawback lies in the fact that it is computationally demanding to trace a large number of particles, especially in three-dimensional simulations. In addition, it may result in some regions void of par-



Numerical Techniques for Free Surface Flows: Interface Capturing and Interface Tracking, Figure 5 Free surface and velocity distribution in MAC family of interface tracking schemes. The circles represent surface markers, while continuous and dotted lines show the old and new free surface topology. $u(i,j)$ is a new fluid cell velocity [18]



Numerical Techniques for Free Surface Flows: Interface Capturing and Interface Tracking, Figure 6 Variable arrangement for staggered grid according to the MAC method [4]

ticles because the density of particles is finite. The impact of the MAC method is much beyond its interface capturing scheme. The staggered mesh layout (Fig. 6) and other features of MAC have become a standard model for many other Eulerian codes (even numerical techniques involving mono-phase flows).

Volume of Fluid (VOF) Technique In the VOF method [5, 6], free surface is represented on fixed grids using fractional fluid volume in a cell. Each rectangle in Fig. 2c denotes a unit cell. The fractional volume-of-fluid, C, is defined such that it is equal to unity at any point occupied by the heavier fluid and zero elsewhere. As the free surface moves, the fractional volume of fluid of each cell is updated. In a numerical sense, every cell is classified into three categories according to the value of C (see Fig. 2c). If a cell is completely filled with the first (heavier) fluid, the fractional volume of fluid of the cell is unity ($C = 1$). If a cell is filled with the second (lighter) fluid, its volume of fluid is zero ($C = 0$). A cell is considered to be on the free surface when the values of C lie between 0 and 1 ($0 < C < 1$). Discontinuity in C propagates according to the following transport equation [5, 6]:

$$\frac{\partial C}{\partial t} + \boldsymbol{u} \cdot \nabla C = 0 . \tag{22}$$

By solving Eq. (22), distribution of C is obtained and thus free surface location can be identified. In a physical sense, the equation implies mass conservation of one phase in the mixture. Numerically, this equation is characterized as a hyperbolic or pure convection equation.

The formulation of the VOF model requires that the convection and diffusion fluxes through the control volume faces be computed and balanced with source terms within the cell itself. The interface will be approximately reconstructed in each cell by a proper interpolating formulation, since interface information is lost when the interface is represented by a volume fraction field. The application of Eq. (22) to the interface cells is not trivial and requires certain knowledge of the interface shape. The problem of reconstructing an interface by using the volume fraction field data (updated or given at the start) has generated a multitude of approaches and methods. The geometric piecewise linear interface calculation (PLIC) scheme is commonly employed because of its accuracy and applicability for complex flows, compared to other methods such as the donor–acceptor, Euler explicit and implicit schemes. An interface is viewed as comprised of line segments. This is acceptable when the grid system is fine enough. Inside of each cell, this line segment determines uniquely what the volume fraction inside that cell is. However, the reverse correlation is not unique, since more than one location of the interface may determine the same volume fraction in the cell. One has to take into account a group of neighboring cells in order to reconstruct the interface accurately.

A VOF geometric reconstruction scheme is divided into two parts: a reconstruction step and a propagation step. The key part of the reconstruction step is the determination

of the orientation of the segment. This is equivalent to the determination of the unit normal vector $\boldsymbol{n}$ to the segment. Then, the normal vector $\boldsymbol{n}_{i,j}$ and the volume fraction $C_{i,j}$ uniquely determine a straight line. Once the interface has been reconstructed, its motion by the underlying flow field must be modeled by a suitable algorithm.

In the PLIC method, the interface is approximated by a straight line of appropriate inclination in each cell. A typical reconstruction of the interface with a straight line in cell (i,j), which yields an unambiguous solution, is perpendicular to an interface normal vector $\boldsymbol{n}_{i,j}$ and delimits a fluid volume matching the given $C_{i,j}$ for the cell. A unit vector $\boldsymbol{n}$ is determined from the immediate neighboring cells based on a stencil $C_{i,j}$ of nine cells in two dimensions. The normal vector $\boldsymbol{n}_{i,j}$ is thus a function of $C_{i,j}$, $\boldsymbol{n}_{i,j} = \nabla C_{i,j}$. Initially, a cell-corner value of the normal vector $\boldsymbol{n}_{i,j}$ is computed. For a uniform grid, an example at $(i+1/2,\ j+1/2)$ in two dimensions is as follows:

$$n_{x,i+\frac{1}{2},j+\frac{1}{2}} = \frac{1}{2h}(C_{i+1,j} - C_{i,j} + C_{i+1,j+1} - C_{i,j+1}) \tag{23}$$

$$n_{y,i+\frac{1}{2},j+\frac{1}{2}} = \frac{1}{2h}(C_{i,j+1} - C_{i,j} + C_{i+1,j+1} - C_{i+1,j}) \tag{24}$$

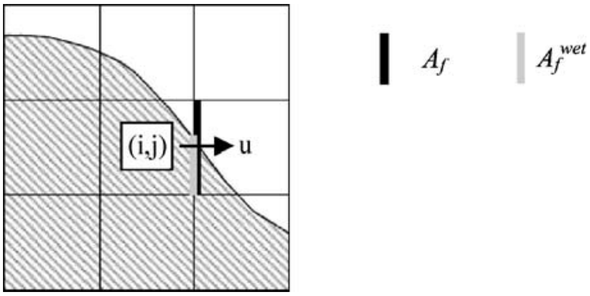
where $h = \Delta x = \Delta y$ is the computational cell size. Similar relations are used in other interface capturing schemes such as level set or diffuse interface method to calculate the interface normal vector from the proper indicator function. The required cell-centered values are given by averaging

$$\boldsymbol{n}_{i,j} = \frac{1}{4}(\boldsymbol{n}_{i+\frac{1}{2},j-\frac{1}{2}} + \boldsymbol{n}_{i-\frac{1}{2},j-\frac{1}{2}} + \boldsymbol{n}_{i+\frac{1}{2},j+\frac{1}{2}} + \boldsymbol{n}_{i-\frac{1}{2},j+\frac{1}{2}}) . \tag{25}$$

The most general equation for a straight line on a Cartesian mesh with normal $\boldsymbol{n}_{i,j}$ is

$$n_x x + n_y y = \alpha . \tag{26}$$

The normal vector $\boldsymbol{n}_{i,j}$ is defined by the vector gradient of $C_{i,j}$, which can be derived from different finite difference approximations which directly influence the accuracy of algorithms. These include Green–Gauss, volume-average, least-squares, minimization principle and Young's gradients. It is noted that a wide, symmetric stencil for $\boldsymbol{n}_{i,j}$ is necessary for a reasonable estimation of the interface orientation.



Numerical Techniques for Free Surface Flows: Interface Capturing and Interface Tracking, Figure 7 Definitions of wet-out fraction for the k-th face of cell (i,j), $C_{\Gamma k}$

Geometrical VOF Advection Algorithm In order to trace the free surface location on a fixed mesh using a volume flux-based scheme, fluid volume fluxes through every cell boundary should be calculated. To handle the time derivative in Eq. (22), explicit and implicit time integration can be adopted. Generally, implicit integration gives a solution with higher accuracy, but requires more complex and time-consuming algorithm. In the explicit integration, in contrast, values at the new time step are updated from those at the old time step using the known flow field. In most studies, explicit integration is adopted due to its simplicity in updating the free surface location. After the divergence theorem is applied and the time integration is performed, Eq. (22) is reduced to

$$C_{i,j}^{n+1} = C_{i,j}^{n} + \frac{\Delta t}{V_{i,j}}\left[-\sum_k (C_{\Gamma k}\boldsymbol{u} \cdot \boldsymbol{n})\, A_k \right] \tag{27}$$

where the subscripts (i,j) and k represent the cell and the face numbers, respectively; $C_{i,j}^{n+1}$ and $C_{i,j}^{n}$ denote the values of C in the (i,j) cell at the new and the old time steps; Δt is the size of time increment; $V_{i,j}$ is the volume of the cell and A_k is the area of its k-th face; and $\boldsymbol{u}$ and $\boldsymbol{n}$ are the velocity and the unit outward normal vectors at the k-th face, respectively. From Eq. (27), it can be stated that the change in fluid volume in a cell during a given time interval is equal to the net fluid volume flux through every cell boundary. Here, $C_{\Gamma k}$ represents the *actual fractional volume-of-fluid* at the k-th face of the cell during a given time increment. Also, it can be interpreted as the wet-out fraction at a cell boundary, which indicates to what extent the cell boundary is wetted by the fluid (see Fig 7). In two dimensions, it can be expressed as $C_{\Gamma k} = A_f^{\text{wet}}/A_{\text{f}}$.

In general, $C_{\Gamma k}$ in Eq. (27) is dependent upon the free surface orientation and the value of f in the cell as well as the size of time increment Δt. However, due to the explicit

nature of the time integration illustrated here, dependency of $C_{\Gamma k}$ on Δt becomes out of question. As a result, $C_{\Gamma k}$ is a function of the free surface orientation (or normal vector $\boldsymbol{n}$) and $C_{i,j}$ so that

$$C_{\Gamma k} = C_{\Gamma k}(\boldsymbol{n}, C_{i,j}) \tag{28}$$

The relations between $C_{\Gamma k}$ and volume fraction and normal vector components for three-dimensional interfaces can be found in Jafari et al. [19]. In the VOF-PLIC method, the fluxes are calculated using geometric approaches.

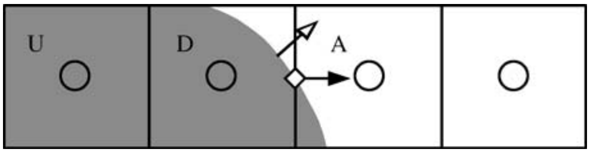
VOF Advection Based on High-resolution Difference Schemes It becomes complicated to use a geometric line reconstruction scheme on unstructured grids and more difficulty is encountered in extending it to three-dimensional calculations. To circumvent this limitation in VOF methods, a class of high resolution difference schemes is utilized, instead of geometric calculations, to capture the interface motion. Using standard convection schemes, the advection operator will lead to significant smearing of the interface (an effect of upwind scheme) or unbounded values of volume fraction (a result of using central difference schemes). A variety of compressive advection schemes have been devised to minimize the diffusion and promote boundedness. The compressiveness is often obtained by using a controlled downwinding of the fluxes. Controlled downwinding schemes have compressive characteristics which depend upon the time step, and therefore require small time steps to achieve sharp interfaces even for steady-state free surface flows.

One of the most widely used difference-based VOF schemes is the high-resolution interface-capturing scheme (HRIC) [21]. It is a normalized variable diagram (NVD) scheme based on a nonlinear blending of the bounded downwind (BD) and upwind differencing (UD) schemes, with the aim of combining the compressive property of the BD scheme with the stability of the UD scheme.

The normalized cell value of volume fraction $\tilde{C}_\mathrm{c}$ which is used to find the normalized face value $\tilde{C}_\mathrm{f}$ for face f is defined as follows:

$$\tilde{C}_\mathrm{c} = \frac{C_\mathrm{D} - C_\mathrm{U}}{C_\mathrm{A} - C_\mathrm{U}} \tag{29}$$

where U, D, and A represent upwind, donor and acceptor cells respectively. The normalized functional relationships



Numerical Techniques for Free Surface Flows: Interface Capturing and Interface Tracking, Figure 8 Interface and volume fraction distribution in neighboring cells [20]

of the BD and UD schemes are given by

$$\tilde{C}_\mathrm{f}^\mathrm{BD} = \begin{cases} 2\tilde{C}_\mathrm{c} & 0 < \tilde{C}_\mathrm{c} \leqslant 0.5 \\ 1 & 0.5 < \tilde{C}_\mathrm{c} \leqslant 1 \\ \tilde{C}_\mathrm{c} & \text{otherwise} \end{cases} \tag{30}$$

$$\tilde{C}_\mathrm{f}^\mathrm{UD} = \tilde{C}_\mathrm{c} \tag{31}$$

The functional relationship of the HRIC scheme is also function of the angle θ between the normal to the interface and the normal to the cell face (Fig. 8). For an interface aligned with the cell face ($\theta = 0$) the bounded downwind scheme is used, while for an interface perpendicular to the cell face the upwind scheme is used. For an interface with θ between these two limits, $f(\theta)$ is chosen to be $\sqrt{\cos\theta}$ and the blending formula is given by

$$\tilde{C}_\mathrm{f} = \tilde{C}_\mathrm{f}^\mathrm{BD}\sqrt{\cos\theta} + \tilde{C}_\mathrm{f}^\mathrm{UD}(1 - \sqrt{\cos\theta}) \tag{32}$$

where

$$\cos\theta = \frac{\nabla \boldsymbol{C} \cdot \boldsymbol{d}}{|\nabla \boldsymbol{C}|\,|\boldsymbol{d}|} \tag{33}$$

and $\boldsymbol{d}$ is a vector connecting cell centers adjacent to the face f. With this formulation, Eq. (32), the blending of the upwind and downwind schemes is dynamic and accounts for the spatial distribution of the C field.

The face volume fraction is now obtained from the normalized value computed above as follows:

$$C_\mathrm{f} = \tilde{C}_\mathrm{f}(C_\mathrm{A} - C_\mathrm{U}) + C_\mathrm{U}\,. \tag{34}$$

The use of high-resolution schemes in interfacial flow calculations is promising, but existing schemes are still too diffusive for the capturing of sharp interfaces. Implementation in multiple dimensions is also restricted to the technique of operator splitting. A generalization for implementation on unstructured meshes is still required.

N

Surface Tension Calculation in VOF Method Modeling interfacial tension effects is important because it is a potentially large force which is concentrated on the interface. There are two different approaches to modeling surface tension forces. The first one is continuum surface force (CSF) defined as

$$F^{\mathrm{st}} = -\sigma\kappa \boldsymbol{n}\delta_{\mathrm{s}} = \sigma\nabla\cdot\left(\frac{\nabla C}{|\nabla C|}\right)\frac{\nabla C}{[C]} \tag{35}$$

where the normal vector and curvature are calculated from Eq. (10). The delta function is approximated as $\delta_{\mathrm{s}} = |\nabla C|/[C]$ and $[C] = C_1 - C_2$ is the difference between maximum and minimum values of C.

The second approach is the continuous surface stress (CSS) model where the surface force is expressed as the divergence of a surface tension tensor:

$$\mathbf{T} = -\sigma(\boldsymbol{I} - \boldsymbol{n}\otimes\boldsymbol{n})\,|\nabla C|\,,$$

$$F^{\mathrm{st}} = -\nabla\cdot\mathbf{T} = \sigma\nabla\cdot\left(|\nabla C|\boldsymbol{I} - \frac{\nabla C\otimes\nabla C}{|\nabla C|}\right) \tag{36}$$

An advantage of the CSS model is that it does not explicitly contain the curvature term since curvatures calculated from the VOF method are less accurate than those calculated from other methods such level set. This is because curvature evaluation in effect requires the second derivative of the discontinuous volume fraction field. Therefore, care must be taken in order to avoid errors in curvature calculations.

Since the movement of free surface is accomplished by solving Eq. (22) in the VOF method, instead of deforming the mesh as in the Lagrangian method or tracing marker particles as in the MAC method, an overall solution algorithm becomes simple and efficient. Combined with advantages of fixed grids which can accommodate complex geometry, the VOF method is adaptable to any existing CFD codes regardless of the solution methods such as FD, FV or FE. For this reason, the VOF-based methods have been used extensively in the simulation of general free surface flow problems. There are several extended or modified versions of the VOF method [22]. If mass conservation is a design constraint, geometrically based algorithms tend to result rather than simpler algebraically based techniques. Geometrically based algorithms, on the other hand, tend to exhibit *numerical surface tension* when interface features are not resolved [23].

The basic idea behind the VOF method is to discretize the equations for conservation of volume in either conservative flux or equivalent form resulting in near-perfect volume conservation except for small over and under shoots. The main disadvantage of the VOF method, however, is that it suffers from the numerical errors typical of Eulerian schemes such as the level set method. The imposition of a volume preservation constraint does not eliminate these errors, but instead changes their symptoms replacing mass loss with inaccurate mass motion leading to small pieces of fluid non-physically being ejected as flotsam or jetsam, artificial surface tension forces that cause parasitic currents and an inability to calculate accurately geometric information such as normal vector and curvature. Due to this deficiency, most VOF methods are not well suited for surface tension-driven flows unless some improvements are made [19].

Level Set (LS) Method In the level set method, the interface between the two phases is represented by a continuous scalar function $\phi(\boldsymbol{x}, t)$, which is set to zero at the interface, is positive on one side and negative on the other. This way both phases are identified, and the location of the physical interface is associated with the surface $\phi = 0$. The function ϕ is called the level set function and is typically defined as the signed distance to the interface; i. e. $\phi = -d(\boldsymbol{x}, t)$ on one side of the interface and $\phi = +d(\boldsymbol{x}, t)$ on the other, where $d(\boldsymbol{x}, t)$ is the shortest distance from the point $\boldsymbol{x}$ to the interface.

When the interface is advected by the flow, the evolution of the level set function is given by

$$\frac{\partial\phi}{\partial t} + \boldsymbol{u}\cdot\nabla\phi = 0 \tag{37}$$

The level set Eq. (37) moves the interface along its normal vector field with the normal speed $v^n = \boldsymbol{u}\cdot\boldsymbol{n}$. Note that any tangential component will have no effect on the position of the front. Using the normal vector $\boldsymbol{n}$ given as $\nabla\phi/|\nabla\phi|$ we can rewrite Eq. (37) as

$$\frac{\partial\phi}{\partial t} + v^n\,|\nabla\phi| = 0 \tag{38}$$

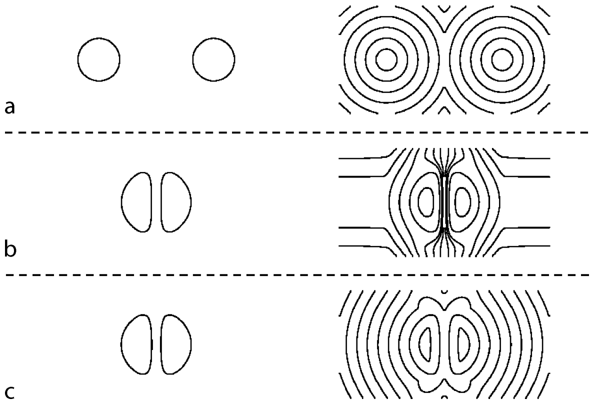
This is called the *Hamilton–Jacobi* formulation and yields the motion of the front $\Gamma(t)$ with normal velocity v^n on the zero level set, $\phi = 0$.

In the level set formulation, the density and viscosity are typically interpolated across the interface as follows:

$$\rho(\boldsymbol{x}, t) = \rho_2 + (\rho_1 - \rho_2)H_\varepsilon(\phi(\boldsymbol{x}, t)) \tag{39}$$

$$\mu(\boldsymbol{x}, t) = \mu_2 + (\mu_1 - \mu_2)H_\varepsilon(\phi(\boldsymbol{x}, t)) \tag{40}$$

where subscripts 1 and 2 denote the values corresponding, respectively, to the two different phases. Here, $H_\varepsilon(\phi)$ is



Numerical Techniques for Free Surface Flows: Interface Capturing and Interface Tracking, Figure 9 Effect of re-initialization for two merging bubbles. Left columns show the interface and right columns show contours of the level set function ϕ. (**a**) Initial configuration; (**b**) just before merging (time step $n = 100$) with no re-initialization; (**c**) just before merging ($n = 100$) with re-initialization back to a distance function [24]

a smoothed Heaviside function, which is defined as

$$H_\varepsilon(\phi) = \begin{cases} 0 & \text{if } \phi < -\varepsilon \\ \frac{(\phi+\varepsilon)}{(2\varepsilon)} + \frac{\sin(\frac{\pi\phi}{\varepsilon})}{(2\pi)} & \text{if } |\phi| \leqslant \varepsilon \\ 1 & \text{if } \phi > \varepsilon \end{cases} \quad (41)$$

where ε is a small parameter of the order of the size of a mesh cell close to the interface. By using the smoothed Heaviside function, one effectively assigns the interface a fixed finite thickness of 2ε, over which the phase properties are interpolated. Hence, the value of ε can be considered to be the half-thickness of the numerical interface.

The level set function will not necessarily remain a distance function as the front propagates. For large time computations this distortion will give a non-uniform thickness of the interface causing a randomness in the distance over which fluid properties change and surface tension forces are distributed.

There are basically two reasons for this distortion. Standard differencing schemes introduce numerical diffusion to the initial distance function. This problem can be reduced by using higher order numerical methods. The second reason is that the flow field is very rarely of that character so that the level set function ϕ would be kept as a distance function. For example, the maximum and minimum values of the level set function will remain the same throughout the computations. For two merging interfaces (e. g. two bubbles) this will cause a steep gradient and an impenetrable sheet between the two merging interfaces (see Fig. 9). It is therefore necessary to reinitiate the distance function after each time step.

Re-Initialization Procedure Maintaining ϕ as a distance function becomes important for providing a uniform thickness at the interface with a fixed width in time and to avoid steep gradients. It is also essential that the level set function is re-initialized to a distance function without changing its zero level set. An iterative procedure is used to maintain ϕ as a distance function. Their re-initialization procedure is based on solving the following partial differential equation to steady-state solution at each time step:

$$\frac{\partial d}{\partial \tau} = sign(\phi)(1 - |\nabla d|) \quad (42)$$

with initial condition

$$d(\boldsymbol{x}, 0) = \phi(\boldsymbol{x}, t)\,, \quad (43)$$

where τ is an artificial time. It has also been proposed to use a smooth sign function in order to eliminate numerical oscillations,

$$sign_\varepsilon(\phi) = \frac{\phi}{\sqrt{\phi^2 + \varepsilon^2}}\,. \quad (44)$$

The steady-state solution of Eq. (42) is a distance function and, since $sign(\phi = 0) = 0$, the zero level set of $d(\boldsymbol{x}, \tau)$ and $\phi(\boldsymbol{x}, t)$ are the same. When the steady-state solution of Eq. (42) is obtained at $\tau = \tau_S$, we simply replace $\phi(\boldsymbol{x}, t)$ by $d(\boldsymbol{x}, \tau_S)$.

Surface Tension Solution in Level Set (LS) Methods As for the discontinuous Heaviside function there will be numerical difficulties with discretization of the singular Dirac delta function. This function is therefore smoothed over the interface thickness and commonly defined as

$$\delta_\varepsilon(\phi) = \frac{\partial H_\varepsilon(\phi)}{\partial \phi} \quad (45)$$

or

$$\delta_\varepsilon(\phi) = \begin{cases} \frac{1}{(2\varepsilon)}\left[1 + \cos\left(\frac{\pi\phi}{\varepsilon}\right)\right] & \text{if } |\phi| \leqslant \varepsilon \\ 0 & \text{otherwise.} \end{cases} \quad (46)$$

Introducing the regularized delta function δ_ε into Eq. (6) smears out the surface tension force across the interface. The level set formulation of Eq. (6) takes the form

$$F^{\text{st}} = -\sigma \nabla \cdot \left(\frac{\nabla\phi}{|\nabla\phi|}\right)\delta_\varepsilon(\phi)\nabla\phi\,, \quad (47)$$

where we have expressed the curvature in terms of ϕ. This is similar to the widely used continuum surface force (CSF) model.

Diffuse Interface (Phase Field) Method The diffuse interface (DI) model, also known as partial miscibility or phase field method, is based on the idea that a fluid–fluid interface has a finite thickness over which various thermodynamic variables change continuously. The concept was first used by van der Waals in 1893 to explain why equilibrium interfaces have surface tension and, hence, the DI method is endowed with capillarity. The thickness of the interface is closely related to the finite range of molecular interactions. The finite interaction range is represented by a non-local effect in the free energy: the local free energy density not only depends on the local composition but also on the composition of the immediate environment. By using a mean-field approximation, the non-local effect in the free energy is represented by the dependence on the local composition gradients rather than on the non-local composition. This free energy determines both the interfacial thickness and the surface tension that now appears in the equations of motion as a distributed stress over the interfacial region. The position and the shape of the interface is a part of the solution that is continuous throughout the system but may have large variations in the interfacial region of the governing equations of DI. Originally designed to model the initial stages of spinodal decomposition, the DI approach has recently been used to model a wide range of hydrodynamic and interfacial phenomena.

The following Cahn–Hilliard equation governs the continuity of mass concentration:

$$\frac{\partial C}{\partial t} + \boldsymbol{u} \cdot \nabla C = \nabla \cdot (M(C) \nabla \xi) \tag{48}$$

$$\xi = F'(C) - \varepsilon^2 \Delta C \tag{49}$$

where $M(C) = C(1-C)$ is the mobility and $F(C) = 1/4C^2(1-C)^2$ denotes Helmholtz free energy, and ε is the interface thickness which is a measure of gradient energy. This equation can be solved using ordinary difference schemes and it is an advantage of the DI method.

Surface Tension Simulation in Diffuse Interface Method Similar to surface tension modeling in the VOF method, both CSF and CSS methods are applicable, with minor adjustments, to the diffuse interface method. The CSF method is as follows:

$$F^{\mathrm{st}} = -\alpha \sigma \varepsilon \nabla \cdot \left(\frac{\nabla C}{|\nabla C|} \right) |\nabla C| \; \nabla C \tag{50}$$

The CSS formulation of surface tension force is given as

$$F^{\mathrm{st}} = \alpha \sigma \varepsilon \nabla \cdot \left(|\nabla C|^2 \boldsymbol{I} - \nabla C \otimes \nabla C \right) \tag{51}$$

Here, α is constant and has the value of $6\sqrt{2}$.

The diffuse interface method is rapidly developing into a reliable technique for investigation of multiphase and interfacial flows. Its advantages are automatic handling of topological changes, the possibility of easy implementation of physical phenomena and its applicability for treating multiphase flows involving more than two phases, miscible and immiscible [25].

Interface Tracking Methods

Glimm's Front Tracking Method In Glimm's front tracking method [9], the discrete representation of the flow is based on a composite grid that consists of a spatial grid representing the flow field in the bulk fluid, together with a lower dimension grid that represents the fronts. Figure 1c shows a two-dimensional schematic of a time step snapshot of such a grid. The front is represented by a piecewise linear curve, the sections of which are called bonds. In contrast to the spatial grid, which is fixed in time (i. e. Eulerian), the fronts move according to the dynamics of the wave fronts that they represent. A single time step is divided into two processes: the propagation of the fronts and the updating of the solution on the spatial grid.

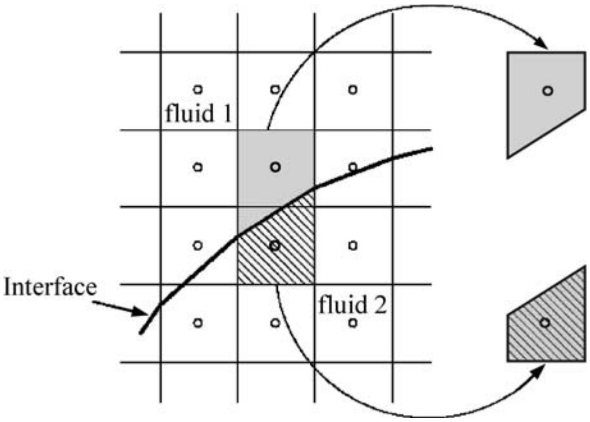
Front tracking has several features in common with the arbitrary Lagrangian Eulerian (ALE) family of methods in which the solution grid is adapted to the flow. ALE methods are based on a moving mesh formulation of the flow equations where the mesh motion is chosen to maintain desirable features of both the Lagrangian (fluid following) or Eulerian (fixed grid) formulations. Front tracking is a special case where adaptivity is used on a lower dimensional manifold corresponding to wave fronts.

Two key features are exploited by the tracking. When the orientation and position of a front is known, one can locally rotate into a coordinate system that is aligned with the wave front so that the normal and tangential directions to the front are grid lines in the local coordinate system. Such a grid substantially improves the quality of the solution near the front.

A tracked interface is a collection of geometric objects describing the location of a set of fronts at a given time. They consist of discrete representations of points, curves and surfaces. A curve is a connected oriented piecewise linear list of bonds, which are connectors between adjacent points. A surface is a connected oriented piecewise

linear collection of triangles, which are in turn connectors between three adjacent points. Both bonds and triangles are linking objects in the sense that they contain pointers to their neighbors. Each bond points to both the previous and following bonds that share its endpoints. It is assumed that a valid interface is non-intersecting in the interior of the surfaces and curves. Thus curves may only intersect along nodes or surfaces along curves. Front intersections produced during propagation correspond to wave interactions and require special treatment to resolve the interaction and untangle the interface.

This technique has been extensively developed by Glimm and collaborators. Details can be found in Glimm et al. [9]. Front tracking is accurate in locating interfaces. However, it is difficult to implement and simulation of rupturing and merging interfaces is not automatically done and needs algorithm intervention.



Numerical Techniques for Free Surface Flows: Interface Capturing and Interface Tracking, Figure 10 Illustration of the cell–interface intersection in the sharp interface method. Trapezoidal cells are formed near the interface [27]

Combined Interface Capturing–Interface Tracking Methods

Tryggvason's Hybrid Method Although this method is also called front tracking, it is a hybrid between interface capturing and interface tracking techniques. A stationary regular grid is used for the fluid flow, but the interface is tracked by a separate grid of lower dimension, similar to Glimm's method. This grid is usually called the front. However, unlike interface tracking method of Glimm [9] where each phase is treated separately, Tryggvason's method follows front capturing methods and treats all phases by a single set of governing equations throughout the whole flow field [10]. Interfacial source terms such as surface tension are computed on the front and transferred to the fixed grid. Advection of fluid properties such as density is done by following the motion of the front.

Although the front tracking method has been successfully applied to different interfacial flows, there are problems associated with these kinds of interface tracking methods. The main drawback is that the marker points will be non-uniformly distributed as the interface evolves. Also, relatively high computer storage is needed to maintain the interface continuous and smooth. The need to provide element connectivity for a moving, adaptive surface mesh significantly complicates three-dimensional interface tracking. To alleviate this problem, Shin and Juric [26] developed a method which automatically provides for element addition/deletion and topology change.

Sharp Interface Method The sharp interface (SI) method [27] employs a combined Eulerian–Lagrangian strategy. It uses the finite volume method and solves two sets of governing equations instead of using the single set of governing equations for the entire domain of all phases/materials. This enables the method to handle large property (such as density) ratios across the interface with relative ease. The interface is sharp with almost no numerical smearing. In SI method, interfacial constraints are imposed as the distinct boundary conditions, instead of being incorporated through source terms in the governing equations. The cubic B-spline curve fitting method is employed to represent the interface.

An illustration of the cell and interface intersection treated in the sharp interface method is depicted in Fig. 10. It is noted that the small fragments of cut-cells are absorbed into the neighboring cells in the same phase to form larger, trapezoid cells. The interface, represented by suitable geometric representations based on massless markers, intersects with the underlying, fixed Cartesian grid. A compact interpolation method near the interface is adopted to retain second-order accuracy and conservation property. The SI is accurate in capturing interface evolution. However, it is in general demanding in computational operations and complex to implement.

Immersed Boundary (IB) and Immersed Interface (II) Techniques The immersed boundary technique [28] is a combined Eulerian–Lagrangian method in the sense that the flow is solved using a Eulerian approach on a fixed Cartesian mesh, and the interface is represented by a discrete set of points and advected in a Lagrangian way. In this method, a single set of conservation equations valid for both phases is solved. The interface conditions are incorporated into the governing field equa-

tion as source terms using the continuum surface force (CSF) method [22]. As a result, the interface is considered to be of small nonzero thickness within which the values of the properties change smoothly. The immersed boundary method tracks the interface explicitly instead of reconstructing it as a posteriori measure. Furthermore, the fluid properties are not advected but prescribed based on the known interface position, therefore keeping the transitional zone on both parts of the interface constant and avoiding any numerical diffusion. This method is suitable for solving bubble and drop dynamics that often encounter large deformation, as has been proved in the existing literature.

In the immersed boundary method, the information between the moving interface and the field variables is exchanged through interpolation. Since the locations of the marker points in general do not coincide with the underlying grid points employed to solve the field equations, the velocity of the field equation, defined according to the Cartesian grid system, is interpolated to obtain the marker velocity. Furthermore, the interfacial force acting on the marker points is spread to the nearby grid points. The concept is illustrated in Fig. 11b. The interpolations are performed via a discrete Dirac delta function taken in this study as Eq. (46) where the interface half-thickness of $\varepsilon = 2h$ with h as grid size is used.

Interface Tracking in Immersed Boundary Method The immersed boundary or interface denoted by $C(t)$ (a curve in two dimensions or a surface in three dimensions), see Fig. 11a, is represented by K markers of coordinates $\boldsymbol{x}_k(s)$ with $k = 1, 2, \ldots, K$. The markers are uniformly distributed along $C(t)$ at some fraction of the grid spacing, $0.5h < ds < 1.5h$. The interface is parameterized as a function of the arclength s by fitting quadratic polynomials $\boldsymbol{x}_k(s) = \boldsymbol{a}_k s^2 + \boldsymbol{b}_k s + \boldsymbol{c}_k$ through three consecutive marker points of coordinates $\boldsymbol{x}_{k-1}, \boldsymbol{x}_k, \boldsymbol{x}_{k+1}$.

The II method [29] is similar to the IB technique with some differences. The IB method uses a set of discrete delta functions to spread the entire singular force exerted by the immersed boundary to the nearby fluid grid points. However, the II method instead incorporates part of this force into jump conditions for the pressure, avoiding discrete dipole terms that adversely affect the accuracy near the immersed boundary.

Hybrid Techniques

There are a number of hybrid techniques which integrate different methodologies. These include (a) coupled level set–volume of fluid (CLSVOF) which combines mass conserving properties with accurate normal and curvature calculation of level set, (b) particle level set which uses particles to enhance mass conservation, (c) mixed markers and volume of fluid with which one obtains a smooth motion of the interface, typical of the marker approach, with a good volume conservation, as in standard VOF methods and (d) hybrid immersed interface–level set which, instead of tracking the interface explicitly, captures the interface similar to level set method (purely Eulerian technique). There are a number of other hybrid techniques which have been less widely used.

Other Methods

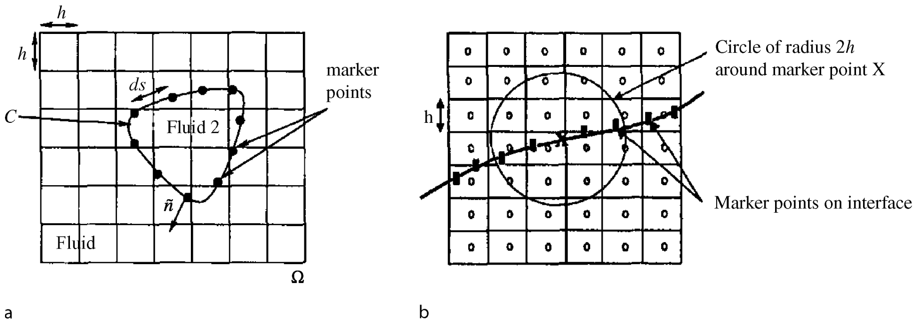
There are other methods which are used in some studies of multiphase and interfacial flows. These include particle-based methods and also techniques that do not rely on Navier–Stokes equations for flow solution.

Particle-based methods are roughly divided into two main categories: those that use particles in conjunction with a grid, namely particle-in-cell (PIC) methods; and those that are massless, such as smoothed particle hydrodynamics (SPH). The most striking feature of particle-based methods is their ease of implementation. They are essentially as easy to implement on three-dimensional unstructured meshes as on two-dimensional structured meshes. However, they are very demanding in terms of memory and processing power that has caused their limited use in interfacial flows so far.

There are methods which are not based on Navier–Stokes equations. These include molecular dynamics (MD) and lattice Boltzmann (LB) methods applied to two-phase flows. A MD study of any physical phenomenon attempts to simulate the real behavior of nature by identifying each molecule and following its motion in time through the basic laws of classical mechanics. The system behavior and temporal evolution of its thermodynamic and transport properties are, therefore, nothing more than the cumulative result of individual molecular motion. The simulation of macroscopic multiphase flow phenomena such as droplet evaporation using MD is not yet possible due to the prohibitively large computational requirements both in terms of CPU time and memory. However, a system involving a submicrometer droplet is small enough to successfully apply MD. Consolini et al. [30] studied evaporation of submicrometer droplets in a gaseous surrounding using MD.

The LB method [31] is a relatively new computational method for fluid dynamics. It is based on the foundations of kinetic theory and involves the solution of a kinetic equation, a simplified form of the Boltzmann equation.

This equation describes the evolution of the distribution of the population of particles whose collective behavior reproduces fluid behavior. The distribution of the popu-



Numerical Techniques for Free Surface Flows: Interface Capturing and Interface Tracking, Figure 11 Immersed boundary method: (**a**) computational domain composed of two immiscible fluids; (**b**) grid points considered for the interface velocity around the marker X [12]

lation of particles is modified by the movement and collisions of the particles simulated on a lattice. This lattice restricts the movement and interaction of particles to selected discrete directions such that in the continuum, i. e. longer length and time scales, the collective behavior of the particle populations corresponds to the dynamics of fluid flow described by the Navier–Stokes equations. In contrast to the conventional computational methods for fluid dynamics, which solve macroscopic equations, the LB method effectively simulates macroscopic fluid flow by solving the kinetic equations at the mesoscopic level. This modeling of physics at a smaller scale relative to the macroscopic scale enables it to naturally incorporate physical properties needed to compute complex flows. In the case of multiphase flows, phase segregation and interfacial dynamics can be simulated by incorporating appropriate intermolecular attraction forces or by employing concepts based on the free-energy approach. LB-based methods do not track interfaces, but can maintain sharp interfaces without any artificial treatments. Also, the LB method is accurate for the mass conservation of each component of the fluid. Recently, Inamuro et al. developed a LB method which is applicable to real interfacial flows with density ratios as high as 1000 [32].

Key Research Findings

Despite advances in moving and deforming mesh methods, it remains the case that these methods are useful primarily when the interface topology is straightforward. Effects such as splashing, breaking and colliding remain difficult challenges.

Eulerian methods perform well for a variety of moving boundary problems. However, in these problems, particularly when surface forces are to be included in the flow calculations, the interface is diffused and occupies a few grid cells in practical calculations. This is undesirable in many problems both from an accuracy as well as physical realizability/modeling standpoint.

In the Lagrangian methods, the grid adapts to the interface and hence grid rearrangement and motion terms have to be incorporated. When the interface begins to distort, the grid needs to be regenerated each time. The resulting grid on which the field variables are computed may be skewed and unevenly distributed, thus influencing the accuracy of the field solver. The Eulerian methods have an advantage in this regard since the computations are performed on a fixed grid, hence obviating the need for grid rearrangement. In these methods, mergers and fragmentations are taken care of automatically, merely by updating the values of the phase fraction. However, when the interface is arbitrarily shaped, improved resolution in desired regions is difficult to obtain due to smearing of information, unless complicated local refinements are adopted [33].

As also mentioned by Prosperetti and Tryggvason [17], no method can be regarded as the best technique for handling interfacial flows. This is because each method is tailored for a certain range of flows and it depends on the level of detail that is expected from the numerical simulations.

Future Directions for Research

It is predicted that in the short term, the well-known interface simulation techniques such as VOF and level set will continue to dominate interfacial flow investigations. The algorithmic improvements of these methods are still being made. However, newer techniques which combine Eulerian and Lagrangian features, such as sharp interface and particle level set methods, seem to be the more promising ones. They are conceptually based on a more rigorous flow solution paradigm. Although the new combined methods have not been extensively tested for real flow problems, they show promise in handling interface motions accurately. They still need more developments regarding effi-

ciency and feasibility to solve three-dimensional complex interface motion, breakup and merging.

Turning attention to multiphase micro- and nanoflows, the interface simulation techniques are used to simulate different phenomena encountered in micro- and nanofluidic devices. These include liquid dispensing, handling, breakup into droplets and merging, compound droplet and bubble encapsulation and, finally, formation of slug bubbly flows. In some cases where thin ligaments are formed, such as film formation on the surface or necking of microjets and microdroplets upon breakup, the adaptive grid methods become important to implement into the interface simulation technique. In cases where heat transfer or phase change is involved, the proper form of energy equation should be added to the system of flow equations and coupled accordingly.

Since in most microfluidic applications wall effects are important, development of accurate contact angle handling techniques is vital. Care should be given on implementation and coupling of flow, heat transfer and electric effects. For example in electro-wetting processes, the voltage and temperature dependence of contact angle should be taken into account in the numerical model. Since micro- and nanoscale devices may have complex shapes, development of proper numerical methods, which can handle such geometries, seems inevitable. In these devices, and also in devices with moving components such as micro-dispensing devices, the free surface may interact with the structure. In such cases, a method that can treat fluid–structure interaction with free surface flows is desirable. For simulation of three-phase interfacial microflows, such as formation of double emulsion and compound bubbles, appropriate interface solvers which account for the third phase are necessary to be developed.

Ohnesorge Number

Definition

To account for the liquid viscosity in droplet formation, the appropriate nondimensional number is the *Ohnesorge number* which represents the ratio of internal viscosity dissipation to the surface tension energy. The *Ohnesorge number* may be written in terms of the square root of the ►Weber number divided by the Reynolds number. The *Ohnesorge number* is sometimes also referred to as stability number, viscosity number, Laplace number, or Z number. It is independent on the velocity and therefore only adequate to describe droplet ejection in conjunction with the *Weber number*.
The lower the *Ohnesorge number* the weaker are the friction losses due to viscous forces. This means that most of the inserted energy converts into surface tension energy, i. e. a droplet can be formed. The higher the *Ohnesorge number* the more dominant is the internal viscous dissipation. This means that most of the inserted energy converts into internal viscous dissipation, i. e. that a droplet formation is critical or even impossible.

Cell disruption; Permeabilization of cells

Definition

Cell lysis is the process of releasing intercellular biological molecules into the extracellular milieu by disrupting the cellular membrane. On-chip cell lysis is the process of lysing a cellular sample on a biochip.

Overview

On-chip cell lysis is a crucial component of integrated micro total analysis systems (μTAS). In order to perform biochemical analysis of intercellular molecules (i. e. proteins, lipids and nucleic acids), the cells at first have to be disrupted releasing the biomolecules from inside the cell. The molecules of interest can then be separated or purified from the cell lysate using affinity purification, charge- and size-based separation, filtration, precipitation etc. The process of on-chip cell lysis followed by extraction of the desired biomolecules is collectively referred to as on-chip sample preparation.

Several approaches have proven useful in releasing biomolecules from inside a cell. The most commonly used techniques are

- chemical lysis or permeabilization of the cells,
- physical disruption of the cell wall and cell membrane.

The most commonly used chemical lysis methods include the use of detergents (such as Triton-X, sodium dodecyl sulphate (SDS) etc.), and chaotropic agents (such as guanidinium thiocyanate (GuSCN), guanidine hydrochloride (GuHCL), ethanol, etc.).

Detergent-based lysis is the easiest and mildest form of cell lysis. Detergents disrupt the lipid bilayer surrounding cells by solubilizing proteins and disrupting lipid-protein interactions. Salts, chelating agents (e. g. EDTA) and reducing agents (e. g. dithiothreitol (DTT)) can be added for more efficient lysis. Detergents are comprised of a polar hydrophilic head and a non-polar hydrophobic tail. The nature of the head group is used to categorize the detergent as either ionic (cationic or anionic), non-ionic or zwitterionic. Non-ionic detergents (such as the Triton-X series) and zwitterionic detergents (such as CHAPS) are less denaturing than ionic detergents and retain native protein functions. Ionic detergents (such as sodium dodecyl sulphate (SDS)) are strong solubilizing agents and tend to denature proteins.

Chaotropes are strong protein denaturants and induce cell permeabilization by weakening the hydrophobic interactions of the membrane. In case of bacterial cells, chaotropic agents also inhibit the assembly of cross-linked peptidoglycans in the cell wall. Another common method of disrupting bacterial cell walls is enzymatic digestion using lysozyme, which hydrolyzes the polysaccharide component of the cell wall.

For microchip-based chemical treatments, optimal lysis depends on mixing of the lysis agent with the cell sample. Due to laminar flow in microfluidic channels, mixing occurs solely due to diffusion, which limits the exposure of individual cells to the lysis agent. To enhance the cell lysis efficiency, microfluidic mixing mechanisms can be introduced on the chip. Toner et al. have successfully demonstrated a continuous flow microfluidic system where lysis is achieved by flanking the cell suspension on both sides by the chemical reagent (Sethu et al. [1]). Bhattacharyya and Klapperich demonstrated continuous lysis by mixing chaotropic buffer (GuSCN) and cell suspension in serpentine mixing channel with sharp turns that enhances diffusive mixing (Bhattacharyya and Klapperich, [2]). Lee et al. presented a novel method of chemical cell lysis on-chip using hydroxide ions that porate the cell membrane and cause cell lysis (Di Carlo et al. [3]). A combination of one or more lysis methods may produce optimal lysis in some cases. Bau et al. demonstrated a microfluidic cassette where lysis of gram-positive bacteria was achieved by incubation of the bacteria sample with a solution containing detergents and lysozme, followed by incubation in chaotropic buffer (GuHCl) and proteinase K (Wang et al. [4]).

In addition to these various chemical treatment methods, a number of physical methods of cell disruption can be used in a chip-based system. These physical methods include osmotic shock, which occurs when cells are suspended in a hypotonic solution; shearing and fracturing of cells walls and membranes using microfabricated needles or spherical particles (beads); application of an electric field that causes electroporation; ultrasonication of the cell sample; and thermal lysis.

Lee et al. implemented a mechanical lysis device in which cells were lysed using a microfluidic filter with nanostructured barbs which they refer to as *nano-knives* (Di Carlo et al. [3]). Madou et al. demonstrated disruption of mammalian, bacterial and yeast cells on a microfluidic compact disc platform using spherical beads in a lysis chamber (Kim et al. [6]). Klapperich et al. demonstrated lysis of bacteria using carbon nanotubes embedded in a porous polymer monolith within a microfluidic channel (Klapperich et al. [7]). Jensen et al. demonstrated the electrolysis of human carcinoma cells in a micro-electroporation device to release the subcellular materials. They also demonstrated using simple circuit models that electrical lysis is selective towards plasma membrane and leaves organelle membranes undamaged (Lu et al. [8]). Lysis of white blood cells and murine clonal cells by electroporation in a continuous flow microfluidic device has also been demonstrated (Ramadan et al. [9]). Ultrasonication is frequently used for cell lysis. Ultrasonication is particular advantageous for lysing bacterial or fungal spores. Northrop, et al. performed ultrasonic lysis of bacterial spores trapped in a microfilter. However, in this application the ultrasonic horn was not incorporated in the microfluidic device due to its large size (Taylor et al. [10]). Northrop et al. went on to successfully implement ultrasonication lysis of epithelial and sperm cells on a microfluidic cartridge with an integrated sonication module (Devitt et al. [11]). Grodzinski et al. demonstrated thermal lysis of trapped E. coli cells using embedded heaters (Liu et al. [12]). A single step thermal cell lysis and PCR amplification of E. coli in a microreactor has also been presented (Ke et al. [13]).

The choice of cell lysis method depends to a large extent on sample type. Mammalian cells, bacteria and yeast all have different requirements for lysis depending on the presence or absence of a cell wall. In some cases, a combination of chemical and mechanical disruption may yield best results. Another important factor in the choice of lysis

method is the sample size of cells to be disrupted. If only a very small volume of sample is available, care must be taken to reduce loss and avoid cross-contamination. Consideration should also be given to the compatibility of the chosen method with downstream applications.

Definition

Using optical fibers to perform detection *on-chip* is an excellent example of two completely different technologies merging together to produce a synergistic result. In this entry, *on-chip* refers to a Lab-on-a-Chip (LOC) or micro total analysis system (μTAS). The optical fiber or fibre is a thin, transparent strand, usually made of glass or plastic, for transmitting light. Optical fibers integrated with an LOC, may be used to detect particles, chemicals, biomaterials, or other analytes, typically in an aqueous medium. The fibers are used to deliver source light to the chip and to collect emitted light from the sample located in the detection zone of the chip.

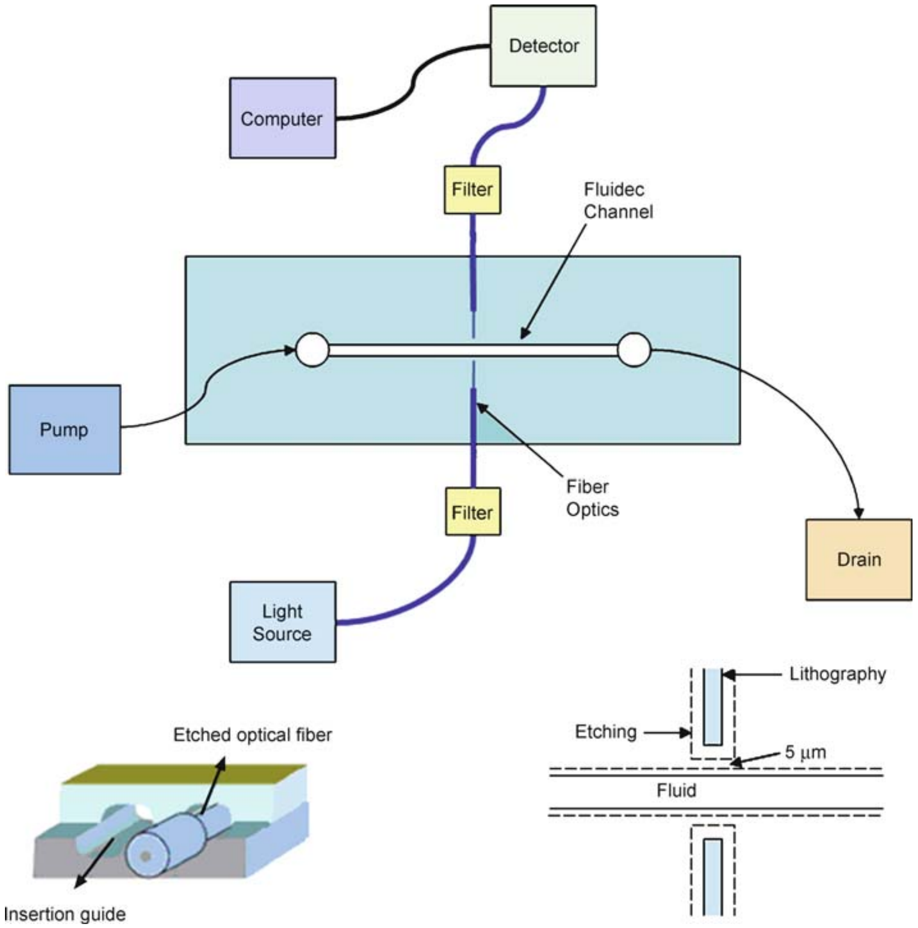
O

Overview

The phenomenon of total internal reflection confines light in one material surrounded by another material of lower refractive index. In the 1840's, physicists showed that light could be guided along jets of water for fountain displays. Later, inventors realized that bent quartz rods could carry light, and patented them as dental illuminators and lighted tongue depressors. During the 1920's, Baird and Hansell patented arrays of glass rods for transmitting television images. These early fibers were *bare*, with total internal reflection at a glass–air interface. Later, fibers were coated with *cladding* of lower refractive index to protect the surface and reduce light leakage [1].

By 1960, fibers had reached signal attenuation of about one decibel per meter, much too high for communication distances. In 1970, Corning Inc. produced fibers with attenuation below 20 dB/km and Bell Laboratories produced the first semiconductor diode laser. In the 1980's, carriers built telephone systems of single-mode fiber with 1300 nm sources. Those technologies spread to other communication platforms and remain the standard for most fiber optic systems today [2].

By the mid 1990's, the need for portable chemical and/or biological detection systems has emerged, as later rein-



On-Chip Detection Using Optical Fibers, Figure 1 Embedded fiber device with source and detection fibers adjacent to microchannel (top). Etched fiber placed into an insertion guide (bottom left). Embedded fibers located within 5μm of the fluid channel (bottom right)

forced by research supports for portable biochemical warfare agent detection systems (e. g. U.S. DARPA, Defense Advanced Research Projects Agency) [3].

Initially, fiber ends were conjugated with biomolecule sensing layers and dipped into test tubes while reactions occurred and were monitored with photomultiplier tubes (PMTs). These types of devices are called fiber optic biosensors (FOB) and are not performed *on-chip*. Many experiments and devices were developed throughout the 1990's using FOB techniques [4].

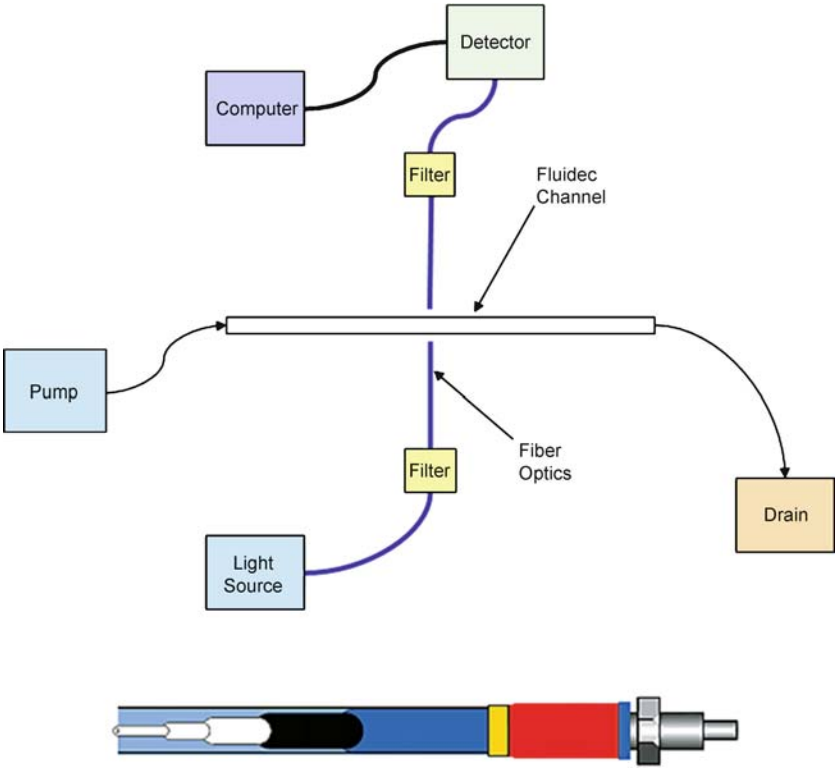
In the early 2000's, researchers began to incorporate fiber optics with the LOC for doing *on-chip* detection. The number of publications involving on-chip detection using optical fibers has been growing exponentially each year [5].

This entry reviews the basic fabrication methods for various LOCs using optical fibers. A description of fiber optics technology used with LOC applications is discussed. Light sources, detectors, filters and lenses are also discussed.

Basic Methodology

Similar to any bench-scale optical detections, there are multiple measurement modes commonly used with optical fibers, including fluorescence (excite at a certain wavelength and detect the emission at a longer wavelength); colorimetry (color detection); Raman (inelastic scattering detection of a laser); luminescence (light generation at low temperature). Also, changes in intensity, spectral shifts, time-domain parameters (fluorescence decay time), as well as polarization (with appropriate polarization-preserving fiber bundles and configuration) can all be used with optical fiber detections.

The approaches for integrating fiber optics with Lab-on-a-Chip devices can be grouped according to fiber location and are classified as: embedded fibers, proximity fibers, or wetted fibers. Table 1 provides a summary of the characteristics of embedded fiber sensors. Tables 2



On-Chip Detection Using Optical Fibers, Figure 2 Proximity fiber device with source and detection fibers above and below the detection zone on the chip (top). Example of a commercial fiber with jacketing, color coding and connectors (bottom)

and 3 lists the key parameters for proximity and wetted fiber sensors. Each of these three unique *on-chip* fiber optic sensor configurations will be described in the following.

Embedded Fibers

The most common configuration for performing on-chip detection has been the embedded fiber type of device as listed in Table 1. A typical setup, shown in Fig. 1, includes a light source and fiber for delivery, exit fiber connected to a detection system, microfluidic channel, and liquid delivery components. The fibers are usually embedded in chip materials consisting of polydimethylsiloxane (PDMS), SU-8 epoxy, polymethyl methacrylate (PMMA) or glass [3].

An *insertion guide* is used to accurately locate an etched optical fiber. Fiber distal ends are chemically etched to reduce the diameter by removing fiber cladding for easier insertion into the LOC. The plastic or rubber jacket of optical fiber should be moved before this etching. One of the keys to fabrication involves accurately setting the distance from the fiber channel to the microfluidic channel shown in Fig. 1.

Proximity Fibers

The next most popular configuration for performing on-chip detection uses optical fibers in close proximity to the detection zone as summarized in Table 2 and shown in Fig. 2. The input fiber and the receiving fiber tips are usually within 1 mm of the chip surface. In some cases, lenses and filters are used to focus and/or collect the light. Other system components such as light sources, detectors, and computers are the same as those used with the embedded fiber devices.

There are many commercial fiber types, jacketing options, and connectors which can be used such as the example shown in Fig. 2. Fiber accessories and fixtures allow one to easily connect fibers, and integrate them into experimental set-ups. Bulk fibers and fiber assembly-making kits and components are also readily available.

The main advantage of the proximity fiber detection system is that fabrication is much easier due to the fact that the fibers are not connected directly into the chip. This greatly simplifies the chip fabrication process. One disadvantage is that it is more difficult to achieve the maximum intensity of light entering and exiting the detection zone because the fiber tips are further away from the chip. Lenses and filters

On-Chip Detection Using Optical Fibers, Figure 3 Wetted optical fiber device with the end of a fiber inserted directly into the analyte flow stream

are sometimes used to compensate for this light traveling distance issue.

Wetted Fibers

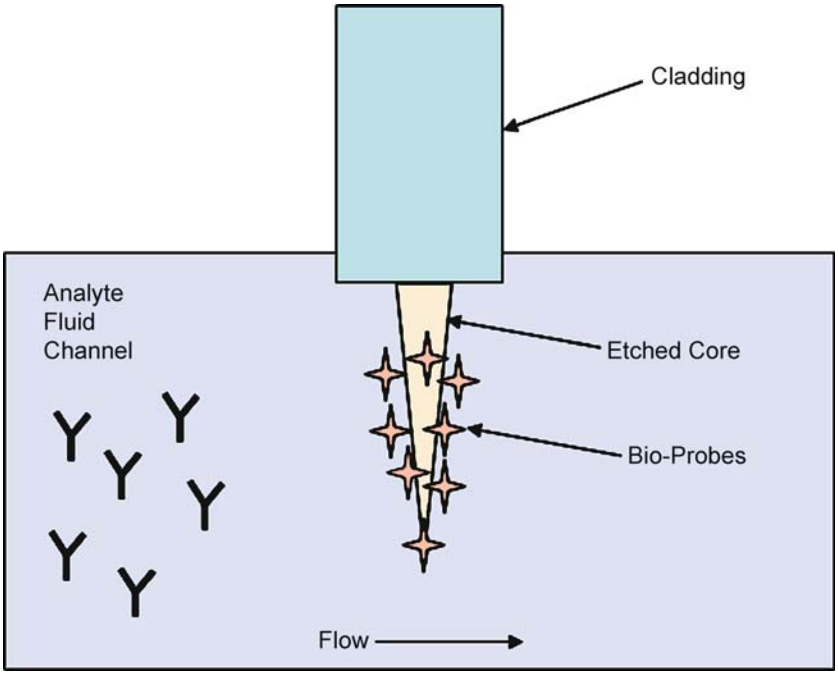
Table 3 lists another type of on-chip detection that is performed using *wetted* optical fibers. In this case, the ends of the fibers are inserted directly into the analyte flow stream as shown in Fig.3. Prior to insertion, an indicating layer of biomolecules must be immobilized as sensing elements on the fiber tips as shown in Fig. 4. The ends of the fibers are first decladded and polished, followed by incubation in a labeled antibody/protein solution. Fluorophore labeling is the most common, but chromophore or Raman reporter can also be used. This produces a sensing region on the surface of the fiber. This fluorescent indicating layer responds to the presence of analyte by changing its optical properties. The change in the indicator's properties affects the light which is transmitted back through the fiber to a detector. The change in intensity or spectral properties of the returning light correlates with analyte concentration. Similar to any optical immunoassays, labels (e. g. fluorophore) can be located not only on the fibers but within solution and/or other biomolecules (thus sandwich assay configuration). Competitive binding assay or various other assay formats are all possible in wetted fiber configuration. Wetted fiber optic sensors are created using either a single fiber or a fiber array bundle. A fiber array bundle may contain thousands of individually clad fibers, each $3-10\,\mu$m in diameter. An imaging fiber bundle is able to transmit light signals and images concurrently, while a single-core fiber can carry light, but not images.

Fiber Optics Technology

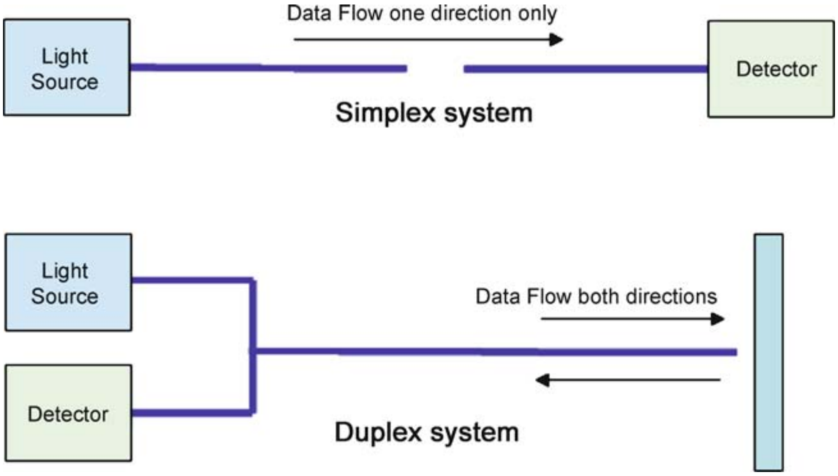
An optical fiber is simply a very thin piece of glass or plastic which acts as a pipe, through which light can pass. The light that is passed down the fiber can be turned on and off to transmit digital information, or changed in amplitude, frequency, or phase to transmit analog information. This is an important distinction, since telecommunication fibers are based in digital applications while sensor fibers are based in analog applications. On-chip bioreactions emit analog signals, not digital. This is one reason why signal attenuation is a lesser issue for sensor applications than with telecommunications.

Digital signals are sent as square waves, with high frequency components. The bandwidth of a fiber is set by the maximum frequencies it can handle. In sensor applications (analog), high frequencies are generally not an issue except when fluorescence decay time is of interest; and thus, signal attenuation due to bandwidth is typically not an issue. Also, signal attenuation over hundreds of kilometers (dB/km), which is a key parameter for telecommunications, is not a factor for LOC fiber optic sensors which usually travel less than a few meters.

Signal flow direction in fiber optics consists of simplex or duplex methods as illustrated in Fig. 5. The simplex method allows data to flow in one direction only. This is the common case where one fiber is used to transmit the light source while another fiber is used to receive and send the emitted signal to a detector. The duplex method allows simultaneous flow of information in both directions. When detection is performed using wetted optical fibers, it is usually done using the duplex method, where light delivery



On-Chip Detection Using Optical Fibers, Figure 4 An indicating layer of biomolecules are immobilized as sensing elements on the fiber tips. Here an antibody-antigen immunoassay is shown

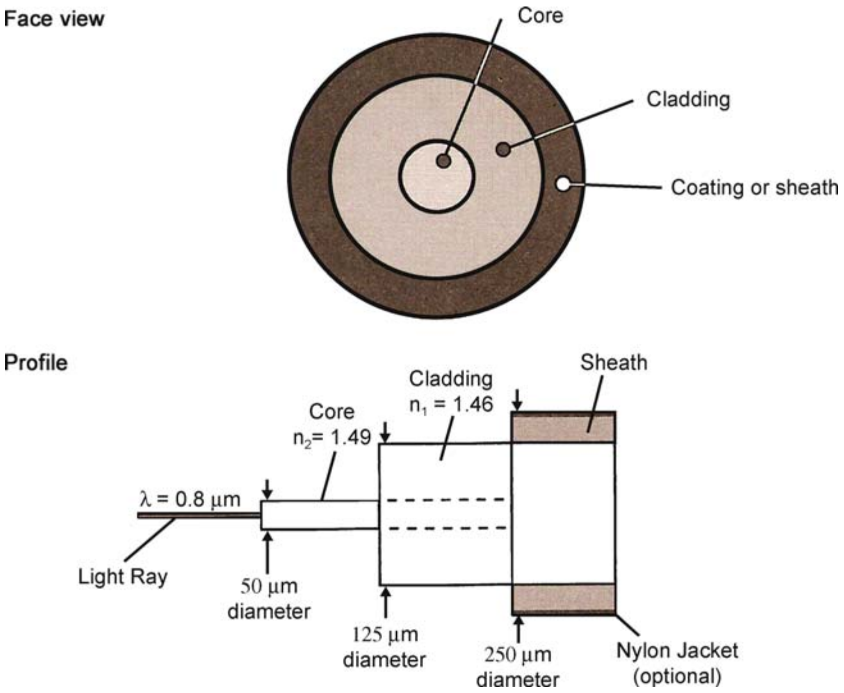


On-Chip Detection Using Optical Fibers, Figure 5 The simplex fiber arrangement is normally used for embedded and proximity fibers (top). The duplex setup is used with wetted fiber optic devices (bottom)

and detection both occur simultaneously in opposite directions. There is no problem using the same fiber for sending and receiving light waves. The larger core diameters of multimode fibers are capable of handling thousands of light modes without interference.

The optical region of the spectrum where fiber optic devices operate is from 300 nm to 2 µm wavelengths. The wavelengths used in fiber optic systems are matched to the particular characteristics of the system. Plastic fibers operate best at visible wavelengths, non-silica glass fibers are designed to operate at infrared wavelengths, and special grades of doped silica are used in the near-ultraviolet region. Most optical fibers use silica glass, which is most transparent to light in the near-infrared region from 700 – 1600 nm.

Most LOC devices require detection in the UV-VIS spectrum for biomaterial applications. These wavelengths require quartz or doped silica core fibers, since glass and



On-Chip Detection Using Optical Fibers, Figure 6 Cross section of a typical multimode, step index fiber. Some LOC detection devices employ fibers with cores up to 1mm in diameter

plastic will not transmit very efficiently below 400 nm. Doped silica fibers with high hydroxyl (−OH) content for UV-VIS, or low hydroxyl (−OH) content for VIS-NIR are often used in biosensor fibers. When working in the UV wavelengths, the cladding of the fiber must be chosen such that it will not fluoresce and create noise. The cladding material also affects the light-acceptance angle of the fiber.

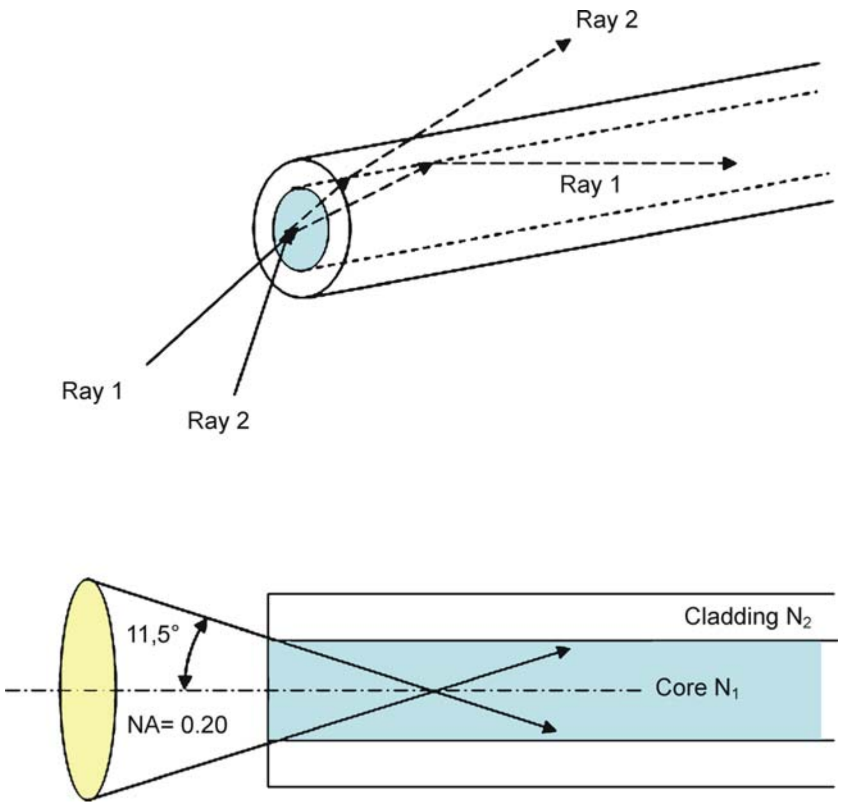
Construction of an optical fiber begins with a tube of glass consisting of a number of layers of concentric rings as shown in Fig. 6. Each ring of glass has a different refractive index. Total internal reflection (TIR) is required to send light down the center of these concentric glass tubes. To achieve TIR, the outer glass rings must have a lower refractive index than the inner glass core in which the light is traveling. The core (50 μm) and cladding (125 μm) diameters shown are typical of the fibers used in some LOC devices. TIR should be achieved for successful use of optical fibers, and there exist maximum allowable bending and strain (both extension and compression) as well as maximum/minimum operating temperatures. The ultimate tensile strength of glass is also of important interest.

Numerical aperture refers to the maximum angle of light allowed into the fiber tip. For light to travel down a fiber, it must enter and reflect off the cladding at greater than the critical angle. Due to refractive changes in the direction of light as it enters the fiber core, there is a limit to the angle at which light can enter the core and propagate down the optic fiber. Any light striking the cladding at greater than the critical angle will penetrate the cladding and leak out as illustrated in Fig. 7 (top).

For light entering within the cone in Fig. 7 (bottom), all the rays will strike the cladding at less than the critical angle and transmit down the fiber. This is referred to as the acceptance cone and the half angle (θ) of this cone is referred to as the acceptance angle. The value of the acceptance angle depends on the refractive indices of the core, cladding, and air. A light ray entering the core at an angle greater than (θ) will disperse into the cladding. The term used to specify the light collecting ability of a fiber is the numerical aperture (NA). NA is the sine of the acceptance angle θ, that is: $\mathrm{NA} = \sin 11.5° = 0.20$ for the example shown.

Optical fibers with high NAs will accept more light than fibers with low NAs. High NA fibers must be used when weaker light sources such as LEDs are used. Low NA fibers generally require more expensive light sources, such as lasers, to achieve sufficient intensity for high quality transmission.

Modal dispersion is a phenomenon which affects the clarity of light transmission. A fiber with a large diameter and high NA will have a large number of modes (rays of light) operating along its length. Optical fibers are classified according to the number of rays of light that can be carried down the fiber simultaneously. This is referred to



On-Chip Detection Using Optical Fibers, Figure 7 Light rays striking the core at less than the critical angle will penetrate the cladding and leak out (top). Light entering within the acceptance cone will strike the cladding at greater than the critical angle and transmit down the fiber (bottom)

as the *mode of operation* of the fiber. A mode of light is simply a single light ray. The higher the mode of an optical fiber, the more rays of light that can travel down the core. It is possible for a fiber to carry as many as several thousand modes or as few as only one.

An omnidirectional light source (i. e. one that radiates light rays equally in all directions) such as an LED, emits several thousand rays of light in a single pulse. Because an LED injects a broad beam angle into the core, each mode of light travels at a different angle as it propagates down the fiber, and will travel different total distances over the length of the fiber. Therefore, it takes different lengths of time for each light ray to travel from one end of the fiber to the other. The light source will launch all modes into the fiber at exactly the same time, and the signal will appear at the beginning of the fiber as a short sharp pulse. By the time the light reaches the end of the fiber, it will spread out and appear as an elongated pulse. This is referred to as *modal dispersion*. Modal dispersion increases with higher NA, while the bandwidth of a fiber decreases with higher NA.

A specific number of modes are allowed to propagate down the length of a fiber. When the core and cladding each have a constant refractive index across their cross sections, but the core refractive index is different than the cladding refraction index, then they behave like an optical waveguide. This is referred to as *step index* and in this fiber type, only a specific number of modes can propagate.

As the diameter and the NA decrease, so do the number of modes that can propagate down the fiber. The decrease in modes is affected more by reduction in diameter than by reduction in NA. As the diameter decreases to the wavelength of light, then only one mode will travel down the fiber. This state is referred to as *single mode* propagation or a *single mode* fiber.

Multimode fibers generally refer to fibers with a core diameter of 50 μm or more. Because of their large diameter, multiple modes of light are able to travel down the core. The wider diameter of the multimode fibers makes them suitable for use with LED light sources. This normally produces a lower cost system than single mode fibers, which have a small diameter and require the use of lasers. However, allowing multiple modes of light to travel down

a fiber may cause modal dispersion. The good news is that the short optical fiber lengths in most LOC systems make problems with modal dispersion unlikely.

Step and graded index fibers differ in the gradients of their refractive indices. A step index fiber has a glass core of constant cross-sectional refractive index, surrounded by a cladding of a different but constant cross-sectional refractive index. Because of this sudden change in the refractive index, light will reflect off the core/cladding interface and transverse its way down the core. The refractive index of the core (N_1) is typically 1.48 while the cladding is 1.46 (N_2). The acceptance angle (θ_a) is typically near 14°. Step index fibers used in telecommunications exhibit modal dispersion which limits their transmission bandwidth and speed. However, step index fibers are often used in chip sensor applications, where fiber lengths and data rates are much lower than in communication applications.

Graded index (GRIN) multimode fiber has a core with a gradually changing cross-sectional refractive index. The highest refractive index is in the core center and then gradually reduces, as it moves to the outer edge of the core. Because of this gradually changing refractive index, the light rays refract (rather than reflect as in step index fibers) as they move through the core, and produce sinusoidal light wave patterns in the fiber. The practical effect of this curved refractive index profile is that light rays that are traveling further from the center axis of the core will have further to travel, but are traveling through the lowest refractive index and will therefore be traveling the fastest (Snell's law). Light rays that are traveling near the center of the core are moving the shortest distance but going through the highest refractive index and therefore traveling the slowest. The result is that all the rays tend to arrive at the end of the core at the same time, which means that modal dispersion is greatly reduced in graded index fibers.

Single-mode fibers are used to reduce the number of modes traveling down a fiber and therefore reduce modal dispersion. A single-mode fiber is basically a step index fiber with a very small core diameter, generally 8 – 9 μm. To reduce the number of modes, the fiber is constructed with very little difference between the refractive indices of the core and the cladding. As the difference between the refractive indices of the core and cladding decrease, the critical angle increases. Therefore, only light approaching at a very large angle of incidence is internally reflected and all other rays will dissipate into the cladding. Because of this, only a single mode of light is able to traverse down the fiber (i. e. the fundamental mode).

When using a single-mode fiber, light must be precisely aimed down the center of the core, or light will be lost to the cladding. With only the fundamental mode traveling down the fiber, there can theoretically be no modal dispersion in single-mode fiber. The signals input at one end of the fiber appear at the output of the fiber with exactly the same shape. As optical biosensors move toward single molecule detection, single-mode fibers may be required.

Alignment of fibers is a major concern with all on-chip detection using optical fibers. There are many issues involved in aligning fibers and connecting fibers. The main concern when connecting two optical devices together is *attenuation*, the fraction of optical power lost in the connection process. Attenuation is the sum of the losses from a number of factors including: misalignment of fibers, differing core diameters, numerical aperture differences, reflection from fiber ends, spacing between the ends of the fibers, fiber tip end finish and cleanliness, and bends in the fibers. Theoretical analysis of the losses caused by these factors is complicated by the fact that the distribution of power across the face of a fiber is usually unknown and varies according to the type and length of fiber, method of excitation, etc.

Plastic fibers such as PMMA have also been used successfully with both communications and sensor applications. Plastic fibers are, however, limited to step index, multimode construction. Because of the nature of plastics, the fabrication process produces a core and cladding with significantly different refractive indices. Most plastic fibers have a core refractive index of 1.50 and a 1.40 cladding refractive index. A typical NA is 0.50, which represents an acceptance angle of 30° (an acceptance cone of 60°) for plastic fibers, which allows them to collect a great deal of light.

There are several other advantages associated with using plastic fibers. First, they are more robust than glass fibers. They can sustain significantly more shock, pressure and stress than glass fibers. Second, they are far more flexible, easier to handle and to terminate than glass fibers. Finally, they are generally cheaper than glass.

However, plastic also some disadvantages. Plastic fibers have a much higher attenuation than glass and can only be used over very short distances. Plastic has an optimum operating wavelength of 650 nm, which may not match the sensor application. Plastic fibers also have very limited operating bandwidth. Another issue for some sensor applications is that plastics are limited to much lower temperatures than glass fibers.

Light Sources

The light-emitting diode (LED) is a semiconductor device that emits incoherent, narrow-spectrum light. The color of the emitted light depends on the semiconducting material used, and can be near-ultraviolet, visible or infrared.

The laser light is monochromatic, i. e., consisting of a single wavelength or color, and emitted in a coherent beam, contrary to common light source.

A laser diode is a laser where the active medium is a semiconductor similar to that found in a light-emitting diode. Laser diodes are used in devices for optical storage, laser pointers, and fiber optics.

The quartz halogen lamp contains a tungsten filament surrounded by a halogen gas such as iodine or bromine. Halogen lamps can be run at higher temperatures, allowing for higher luminous efficacy, apparent brightness, and whiter color temperature. Because the lamp must be very hot to create this reaction, the halogen lamp's envelope must be made of quartz.

The deuterium halogen lamp is a low pressure gas discharge light source often used in spectroscopy when a full spectrum source of illumination in the ultraviolet region is needed. The origin of the continuum ultraviolet radiation extends from around 160 nm to 400 nm.

A mercury-vapor lamp is a gas discharge lamp which uses mercury in an excited state to produce light. They also offer a very long lifetime, as well as intense lighting. Like fluorescent lamps, mercury vapor lamps usually require a starter which is usually contained within the mercury vapor lamp itself.

Xenon arc lamp uses ionized xenon gas to produce a bright white light that closely mimics natural daylight. Xe lamp, however, have a significant amount of spectral fine structure in many parts of the spectrum, as this is one factor to consider when choosing between a halogen and a Xe source. The white, continuous light generated with this arc is of daylight quality and all movie projectors in theaters employ these lamps.

The incandescent tungsten lamp is a source of light that works by passing an electric current through a thin filament, heating it and causing it to emit light. This is the typical light bulb for home use.

Light Detectors

Photomultiplier tubes (PMTs) are extremely sensitive detectors of light in the ultraviolet, visible and near infrared. These detectors multiply the signal produced by incident light by as much as 10^8, from which single photons can be resolved. The PMT benefits from a combination of high gain, low noise, high frequency response and large area of collection.

The photodiode is a semiconductor diode that functions as a photodetector. Photodiodes are packaged with either a window or optical fiber connection, in order to let in the light to the sensitive part of the device. They may also be used without a window to detect vacuum UV or X-rays.

Avalanche photodiodes (APDs) are photodetectors that can be regarded as the semiconductor analog to photomultipliers.

Si PIN photodiodes feature low capacitance, which enables them to deliver a wide bandwidth with only a low bias voltage, making them ideal for high-speed photometry as well as optical communications. Some PIN diodes have a mini-lens, which increases fiber coupling efficiency and enhanced sensitivity for violet laser detection.

The spectrometer measures light over a specific range of wavelengths, from gamma- and X-rays into the far infrared. The variable measured is most often the light's intensity but could also, for instance, be the polarization state. Spectrometers are used for producing spectral lines and measuring wavelengths and intensities.

The charge-coupled device (CCD) detector array is an image sensor, consisting of an integrated circuit containing an array of linked or coupled capacitors sensitive to light. CCDs are used in digital photography, astronomy, photometry, optical and UV spectroscopy and other high speed techniques.

The complementary metal-oxide-semiconductor (CMOS) detector array is another type of an image sensor. Although less sensitive than the CCD array, it is increasingly used in sensor and Lab-on-a-Chip applications due to: much lower power consumption, much lower cost, easier compatibility with digital electronics, and the fact that for many Lab-on-a-Chip applications the background levels are sufficiently high that the higher sensitivity of the CCD does not confer a significant advantage.

Optical Filters

An optical filter is a device which selectively transmits light having certain properties (often, a range of wavelengths), while blocking the remainder. Filters are commonly used in many optical instruments including LOC sensors.

A *longpass (LP) filter* is a colored glass filter that attenuates shorter wavelengths and transmits longer wavelengths over the active range of the target spectrum. In fluorescence, longpass filters are frequently utilized in dichroic mirrors and barrier (emission) filters.

A *shortpass (SP) filter* is a colored glass filter that attenuates longer wavelengths and transmits shorter wavelengths over the active range of the target spectrum. In fluorescence, shortpass filters are often employed in dichromatic mirrors and excitation filters.

A *band-pass filter* is a device that passes frequencies within a certain range and rejects (attenuates) frequencies outside that range. The filter does not attenuate all frequencies outside the desired frequency range completely. This

is known as filter roll-off, and is usually expressed in dB of attenuation per octave of frequency.

A *dichroic filter* is a very-accurate color filter used to selectively pass light of a small range of colors while reflecting other colors. By comparison, dichroic mirrors and dichroic reflectors are characterized by the colors of light that they reflect rather than the colors they pass. Because unwanted wavelengths are reflected rather than absorbed, dichroic filters don't absorb much energy during operation and so don't become nearly as hot as the equivalent conventional filter.

Filter wheels and *filter cubes* usually contain four or more individual filters which can be rotated into position. Since all filters are the same thickness, no refocusing is required when changing filters. Filter wheels and cubes are designed to closely and rigidly couple to CCD cameras or other optical equipment.

Applications of On-Chip Detection Using Optical Fibers

Nearly all of the published studies in on-chip detection using optical fibers were conducted after the year 2000. Most of the work to date has been performed at universities in North America (Canada and United States), Europe (Denmark, Germany, Poland and United Kingdom), and East Asia (Japan, Singapore and Taiwan).

Fiber Types

There have been three main types of optical fibers used for on-chip detection as listed in Tables 1–3. The vast majority of researchers have chosen multimode fibers made from fused silica (glass).

Most of the embedded fiber devices (Table 1) contain small diameter (50 – 100 μm) multimode fibers. Many researchers further reduce the size of the fiber by acid etching to remove much of the cladding. For example, when starting with a 63 μm core and 125 μm cladding, the fiber may be acid etched to reduce the cladding size to perhaps 70 μm. This facilitates assembly of the fibers into the micro dimensions of the device. Several embedded fiber devices have been made from the singlemode type (9 μm core), but it has been challenging to deliver or gather sufficient amounts of light while being limited to a single mode and low NA. Lee et al. were able to obtain an order of magnitude lower LOD by using multimode fibers compared to singlemode (Table 1, 5th row) [6].

One advantage of using a proximity type fiber arrangement (Table 2) is that a much larger diameter multimode fibers can be used. Most of these chips are based on fiber cores from 400 μm to 1000 μm. The silica fibers usually have NAs of 0.22, while plastic fiber NAs of 0.50 are common. The proximity fibers can gather more light, but there is a greater distance between the analyte and the fiber which reduces the signal strength.

The wetted fiber types listed in Table 3 have been based on multimode fibers or fiber array bundles. In Fig. 4, the large diameter (1000 μm) multimode cores are acid etched or stretched to create a sharp probe tip. In either case, the fiber surface is treated for binding proteins or other molecular probes. Walt et al. [7] (Table 3, 5th row) developed a chip using a wetted fiber optical array of thousands of individual fibers in a coherent bundle. By etching the core at the fiber bundle's tip, an array of microwells was created and loaded with microspheres. The microspheres are coated with various sensing materials such as antibodies. Resulting changes in fluorescence intensity correspond to analyte concentration.

Lighting and Detection

The most common light source for all applications has been the blue LED (470 nm) and red LED (635 nm), generally used with multimode fibers. Lasers are used with singlemode fibers because the small core requires more intense power. For spectrophotometry, devices utilize full spectral light sources such as mercury vapor, halogen, or tungsten lamps. This allows detection of light absorbance or transmission over the spectrum.

Lenses are sometimes used to focus both source and detected light. Concave, convex, bi-convex and other converging lenses have been used. Loock et al. [8] formed a convex lens directly onto the ends of the fibers (Table 1, 8th row). Fujii et al. [9] fabricated lenses into the chip PDMS structure (Table 1, 14th row). In some cases, filters are also used to sharpen the signal. The most popular filters are the band-pass and dichroic variety.

Chip Fabrication

The chips themselves are most commonly made from SU-8 molds and polydimethylsiloxane (PDMS) which is a silicon-based organic polymer. It is optically clear, inert, and non-toxic, which makes it well suited for Lab-on-a-Chip applications. Other glasses, silicon wafers, and acrylics have also been used. Recently, Golonka et al. have used low-temperature cofired ceramic (LTCC) technology to produce electrical, optical, and fluidics within an LOC structure (Table 1, 10th and 11th rows) [10, 11].

The microfluidic channels in these LOC systems are typically 100 μm depth and width. The liquids are moved with syringe pumps, peristaltic pumps, or some type of electrokinetic method. The syringe pump generally provides a low cost, yet accurate solution.

Analyte Detection

Much of the early work in this area was done for flow cytometry applications using embedded or proximity fiber systems. These devices typically measured the counts and velocities of microspheres in liquids. These systems are able to detect 10 μm spheres at a rate of 65 particles per second (Table 1, 2nd row) [12].

Another application involves capillary electrophoresis (CE) used to separate ionic species based on their size-to-charge ratio in microchannels filled with electrolytes. Various dyes have been used such as Rhodamine B, Cy3, and Topro-5 to detect biomolecules and DNA. LOD's of 100 – 200 nM have been reported (Table 1, 5th, 8th and 13th rows) [6, 9, 13].

The most popular applications have been in the areas of spectrophotometry and/or spectrofluorometry involving the measurement of light intensity as a function of wavelength. These devices have been used to measure chemical concentrations, amino acids, and fluorescent species down to an LOD of 25 nM (Table 1, 4th row) [14].

Most recently, researchers have begun using these chips to conduct immunoassays. An immunoassay is a test that measures the level of a substance in a bio-sample, typically serum or urine, using the specific binding reaction of an antibody or antibodies to its antigen. LOC's have been used to detect protein markers for vasculitis and cancer (Table 2, 1st and 7th rows) [15, 16] at LOD's in the 100 nM range. They have also been used to detect *E. coli* and BTK-a biowarfare agent simulant (Table 3, 5th row) [7].

Future Directions for Research

Lab-on-a-Chip detection using optical fibers will be guided by two major driving forces: molecular analysis and molecular biology, and microelectronics and optical telecommunications. Most Lab-on-a-Chip technologies to date have focused primarily on molecular analysis by miniaturizing capillary electrophoresis (CE), chromatography, flow cytometry, and sensing conditions such as pH, ionic strength, and concentrations of analytes. Currently in the U.S., biodefense funding from DOD and DARPA are driving much of the LOC academic research in universities. These defense programs tend to focus on detection and immunoassays for bioterror prevention. The recent emphasis on high-throughput sequencing for genomics and proteomics has also begun to use microfluidics devices. Current commercial development, in the meantime, is driven to a much greater extent by the real need (and real market for) in vitro diagnostics and drug discovery tools. While the manufacturing technologies being developed in microelectronics will continue to pace the fabrication of microelectromechanical systems (MEMS) in the future [3].

Fiber optics technology has always been dominated by the telecommunications markets and this will certainly continue. Fibers will continue to increase in speed and bandwidth by using new methods such as dense wavelength-division multiplexing (DWDM). Future fibers will be even more pure, and conduct light and images with more clarity. Recent growth in the sensors industry has spawned several new companies which focus strictly on fibers for optical detection. While the communications industry has focused on longer IR wavelengths, the sensor fiber optics companies will work on improving light transmission down into the UV range for biodetection.

Embedded fiber optics will continue to be successful only as microfabrication methods are simplified and commercialized. The original hope of microfluidics was that photolithography and associated technologies that had been so successful in silicon microelectronics, and in microelectromechanical systems (MEMS), would be directly applicable to microfluidics. Some of the earliest work in fluidic microsystems did, in fact, use silicon and glass, but these materials have largely been displaced by plastics. For analyses of biological samples in water, devices fabricated in glass and silicon are usually inappropriate. Silicon, in particular, is expensive, and opaque to visible and ultraviolet light, and cannot be used with optical methods of detection. It is easier to fabricate the components required for microanalytical systems in elastomers than in rigid materials but these methods have not been commercialized. Exciting future research areas will involve embedding light sources and micro-detectors directly into the chip.

Proximity fiber optics should continue to grow in popularity as light sources and detectors become smaller and portable. Companies are now producing low cost LEDs, lasers, and spectrometers that make it relatively easy to set-up on-chip detection devices. These systems will require better and lower cost lenses, filters, light sources and detectors especially in the near-UV wavelengths. Again, this is because almost all research to date has focused on the IR wavelengths used for telecommunications and the internet. Future work in proximity fiber optics will focus on lowering signal-to-noise ratios and increasing the sensitivity of distinguishing different wavelengths.

Wetted fibers on-chip have only recently been attempted and shows great promise. Like embedded fibers, the wetted fibers require very sophisticated microfabrication techniques. Microfluidics has seen the rapid development of new methods of fabrication, and of components such as microchannels that serve as pipes, and other structures that form valves, mixers, and pumps that are essential elements

of microchemical ’factories’ on a chip. Wetted fibers will require easier ways of inserting and removing the fibers from the chip as well as simpler methods of preparing the fiber tips with biomolecules for detection.

An LOC system must have a number of generic components: a method of introducing reagents and samples; methods for moving these fluids around on the chip, and for combining and mixing them; and various other items such as detectors for most microanalytical work, as well as components for purification of products for systems used in synthesis. The field has, so far, centered on demonstrating concepts for these components. In the future there will be sufficient methods of fabrication, and a range of components which will make it possible to apply microfluidic systems to the resolution of problems rather than simply to the demonstration of principles [3].

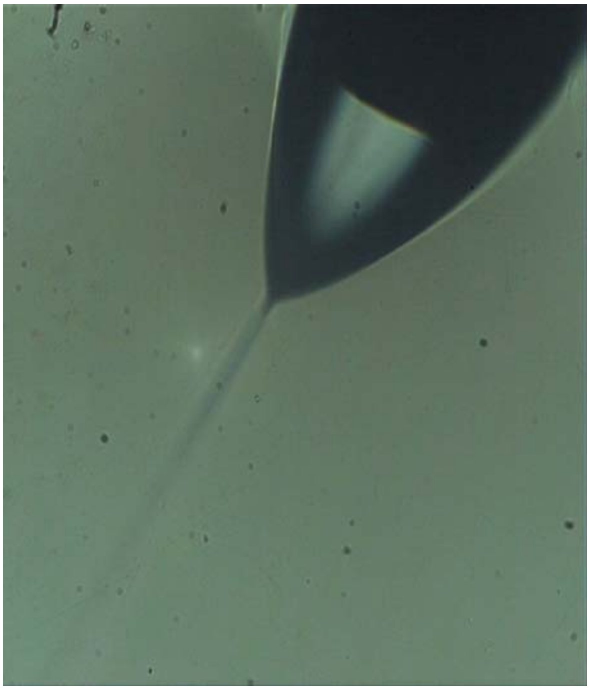
Definition

Electrospraying utilizes an applied electric field to generate micron or nanometer sized aerosol drops. If DC fields are employed, the emitted drops carry a net charge which allows electrosprays to function as ionization sources, in particular, for mass spectrometry. With electrospray ionization (ESI), interfacing between microfluidic separation technology such as on-chip high performance liquid chromatography (HPLC) and capillary electrochromatography (CEC) with mass spectrometry (MS) is now realizable.

Overview

The concept of employing electrostatic charging to atomize a liquid source was first observed by John Zeleny in



On-Chip Electrospray, Figure 1 Taylor cone formation at the tip of a 100 μm capillary across which a 3 kV DC voltage is applied. A slender jet issues from the tip of the Taylor cone as a result of Rayleigh fission, subsequently breaking up to form aerosol droplets

1914. If the liquid is flowing through a metal capillary, the surface of which is raised to a potential with respect to a grounded source placed a small distance away, the electric field acts to stretch and deform the liquid meniscus at the capillary tip. The fluid physics under the influence of an electric field in such circumstances was described by Sir Geoffrey Ingram Taylor in 1964, who observed the meniscus to deform into a sharp cone with a specific half angle of 49.3° for highly conducting liquids. This Taylor cone, depicted in Fig. 1, arises due to the separation of electrical charges within the liquid or ambient phase to form a thin polarized layer of counter-ions near the meniscus interface; these counter-ions then drift towards the tip of the meniscus by tangential electromigration.

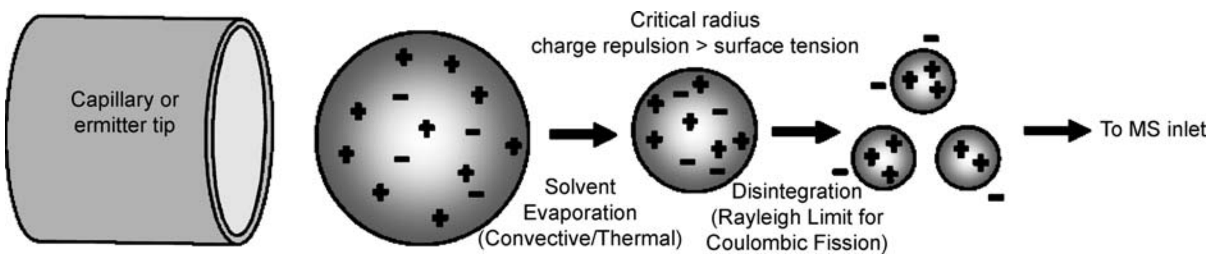
The counter-ion accumulation at the tip then creates a Coulombic repulsion force which causes the tip to disintegrate into a thin jet that emanates from meniscus when the surface tension force holding the drop together is exceeded, as shown in Fig. 1. This jet subsequently breaks up due to hydrodynamic or Coulombic instabilities to form a spray of small liquid drops. As the accumulated charge at the tip is transferred from the meniscus tip to the jet and subsequently to the drops, each individual drop carries a net charge. Since the size of the ejected drop shrinks during its flight due to evaporation, the repulsive force builds up due to the increase in the charge density. Coulombic fission then occurs once again when the Rayleigh limit

$$q > 64\pi^2 \varepsilon_m a^3 \gamma \, , \qquad (1)$$

is reached. In Eq. (1), q is the charge, ε_m the permittivity of the surrounding medium, a the drop diameter and γ the surface tension. The drop disintegrates to produce even smaller droplets, which themselves undergo similar disintegration cycles, as depicted in Fig. 2; this Rayleigh instability fission cascade eventually leads to charged drops with dimensions down to 10 nm orders.

The ability of the electrospray to produce very small, monodispersed charged drops then naturally lends itself as a powerful soft ionization technique for the mass spectrometry of large, complex and non-volatile biomacromolecules (e. g., DNA, peptides and proteins) which are otherwise denatured by other ionization techniques. Electrospray ionization (ESI) also has several advantages over matrix-assisted laser desorption/ionization (MALDI), which is another soft ionization technique. The use of lasers requires fine tuning of optical properties in order to ensure quality and reproducibility in the results; signals are dependent on the laser wavelength, pulse energy, time between pulses and impact angle, amongst others. Moreover, the inorganic salts in proteins can interfere with the ionization and hence elaborate sample preparation to remove these components is a vital step in MALDI. The small size of the laser spot compared to the sample also requires multiple laser pulses targeted at different sample regions in order to obtain a statistical average of the local concentration within the sample, which is further complicated by inhomogeneity due to partitioning of the analyte molecules as a result of non-uniform solvent evaporation. Sample dispensing onto MALDI target plates also requires the integration of complex components such as piezoelectric microdispensers or centrifugal delivery systems.

ESI was first proposed by Malcolm Dole in 1968 who noticed that the Coulombic fission cascade would eventually lead to sufficiently small drops which contained a single solute molecule that retained some of the drop charge such that a fully desolvated gas phase ion would ultimately be left once all the solvent evaporates, this mechanism being known as the charge residue model (CRM). These efforts were, however, largely unsuccessful practically due to the use of an ion-drift spectrometer to which the electrospray was interfaced. It was John Fenn, then at Yale University, who later developed a practical method for electrospray ionization mass spectrometry (ESI-MS) that allowed the identification and structure analysis of biomacromolecules of virtually unlimited molecular weights to an accuracy of 0.01% by averaging



On-Chip Electrospray, Figure 2 Schematic illustration of the Coulombic fission process occurring during DC electrospraying giving rise to successively smaller charged drops

over the signals generated by the multiple ions which are associated with the high mass-to-charge ratios of large, complex molecules [1]. In recognition of this significant contribution and its impact on genomic, proteomic and drug discovery research, Fenn was awarded the Nobel Prize in Chemistry in 2002. It should however be noted that the term *electrospray ionization* is somewhat misleading as the process is not akin to electron ionization in which electroneutral molecules are converted into ions. Instead, the electrospray essentially allows the transfer of analytes, already ionized in the liquid phase, into the gas phase [2]. Nevertheless, we will retain the term due to its widespread use in the literature.

The recent progress in micro/nanofabrication technology as well as microfluidics has spurred efforts to interface chip-based separation devices with electrospray ionization mass spectrometers. As frontiers in the ability to miniaturize the mass analyzers are being extended further, an integrated field portable microdevice that couples both on-chip separation (e. g., capillary electrophoresis, capillary electrochromatography and high-performance liquid chromatography) and analytical technology with an electrospray interface to produce a complete tool, which is both reliable and can be easily replicated, is increasingly realizable. Such a device would be extremely attractive for in-situ analysis in environmental, chemical or biological monitoring and remediation, offering the advantage of reduced analyte quantities and separation times, higher flow rate capabilities, low cost, increased precision and repeatability. At the time of writing, an ESI-MS microdevice for high performance liquid chromatography known as the HPLC-chip which is marketed by Agilent Technologies is commercially available. The HPLC-chip integrates the HPLC column with a sample enrichment column and an electrospray tip, which can then be mounted onto a mass spectrometer.

Basic Methodology

A review of DC electrospraying is given by Grace & Marijnissen [3]. It should be noted that the use of high frequency ($> 10\,\text{kHz}$) AC electric fields gives rise to completely different drop dynamics and characteristics [4], the most important distinction perhaps being the larger $1-10\,\mu\text{m}$ drops generated which are electroneutral. For the purposes of on-chip electrospray devices for analyte separation and detection, we will focus on the use of DC electrospraying henceforth as the AC electrospray has only recently been discovered and hence the use of AC fields for various applications and devices is currently work-in-progress (see, for example, [5]).

The most stable DC electrospray mode required for ionization is the cone-jet mode [3] described above and depicted in Fig. 1. The appearance of this characteristic conical meniscus and its stability has therefore been generally, and more likely than not, universally, adopted as the benchmark criterion for stable electrospray ionization. This stability is most commonly disrupted intermittently by gas bubbles aggregating into large slugs, thus temporarily causing cessation in the spraying. Once the slug is released, the spraying resumes. The formation of gas bubbles is a common problem in DC electrokinetics as a result of electrolytic reactions occurring to balance the charge induced by the applied voltage at the metal capillary, leading to a reduction in throughput and hence stable electrospray disruption due to the enormous capillary pressures. Joule heating and the generation of ionic contaminant as a result of Faradaic reactions at the electrodes are also additional problems accompanying the use of large DC voltages. Alternatively, stable electrospraying can also be disrupted by stray electric fields, mechanical perturbations (e. g., vibration) or flow variation.

The critical voltage V_c required for stable electrospraying can be estimated through a balance between the capillary stress, of order γ/R, where $R \sim 10^{-3} - 10^{-4}$ m is the principal curvature of the meniscus, of the same order as the radial capillary dimension, and the electric stress $\varepsilon_l V^2/d^2$, where ε_l is the liquid permittivity, V the applied voltage and d the electrode separation:

$$\frac{V_c}{d} \sim \sqrt{\frac{\gamma}{\varepsilon_l R}} \quad . \tag{2}$$

Typically, $\gamma \sim 10^{-2}\,\text{kg/s}^2$, $d \sim 10^{-2}\,\text{m}$ and $\varepsilon_1 \sim 10^{-10}\,\text{C}^2/(\text{Jm})$, thus suggesting that extremely large critical fields in excess of 1 kV are required.

Taylor, by considering a static balance between capillary and electric stresses, showed the existence of a conical meniscus with a half angle of 49.3° at equilibrium for a perfectly conducting liquid. In this limit, the meniscus behaves as a constant potential body and hence the field is external to the drop; the field lines intersect the interface orthogonally. The normal gas phase electric field E_n then scales as $1/\sqrt{R}$, and hence the normal electric stress $p_E \sim E_n^2$ scales as $1/R$. At every point R along the interface, the normal electric stress exactly balances the azimuthal capillary pressure $p_C \sim \gamma/R$. This exact balance and absence of a specific length scale, is responsible for the formation of a static Taylor cone [6].

The perfectly conducting limit was later relaxed to allow for the effect of finite liquid conductivity [7]. In these cases in which the liquid meniscus is assumed to be sufficiently slender such that the longwave approximation can be assumed, the field that arises is predominantly in the liquid phase, tangential to the interface. Nevertheless, this tangential liquid phase electric field E_t also scales as $1/\sqrt{R}$ and thus an exact balance between the normal electric stress $p_E \sim E_t^2$ and the capillary stress $p_C \sim \gamma/R$ again yields a stable equilibrium cone-like meniscus. The cone angle, however, depends crucially on the liquid to gas permittivity ratio $\varepsilon_1/\varepsilon_m$, wherein the Taylor angle is recovered in the perfectly conducting limit as $\varepsilon_1/\varepsilon_m \to \infty$ [6].

An alternative ionization mechanism to Dole's charge residue model (CRM) above has been proposed, in part to account for the inadequacy of CRM to account for the excess of analyte molecules over the observed charges in the electrospray flux. The CRM predicts that the relative number of drops for each species is proportional to the species relative concentration. The difficulty lies conceptually in the unlikely possibility for the successive drop subdivisions during the disintegration process to end up with the observation that all the daughter drops contained only a single analyte molecule for each of the ionizable species, especially in the presence of strong evaporation currents. Even if this were possible, a spectral peak for each species would always be obtained, which is not true. The alternative model, in contrast, proposes that the singly charged or multiply charged gas phase ions are generated by the evaporation of small, highly charged liquid drops of the analyte species [8].

On-Chip ESI-MS Interfacing

Progress in the development of on-chip electrospray interfaces for mass spectrometry has grown exponentially over the past two decades. Whilst there are many different designs and methods proposed, it is possible to summarize these developments in general into three broad categories based on the nature of the electrospray emitter type employed: Blunt edge, transfer capillary attachment, and, emitter tip. Early developmental work employed the blunt edge configuration. However, there appeared to be a subsequent parallel divergence thereafter, in which either the transfer capillary or the emitter tip interfaces were employed. Most of the recent on-chip electrospray interface designs therefore fall generally into either of these two latter categories.

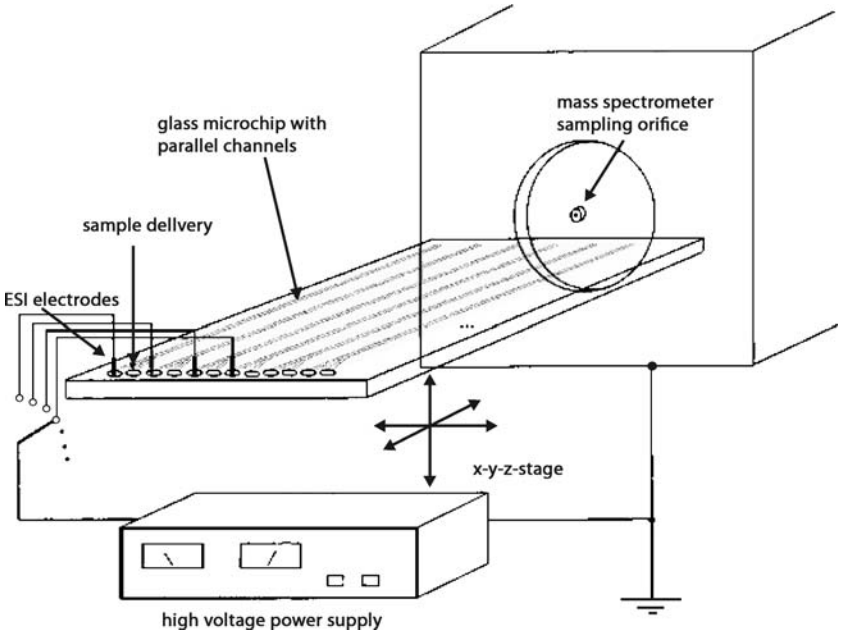
On-chip ESI-MS devices were initially fabricated onto quartz or silica substrates. In addition to problems due to the hydrophobicity (discussed below), fabrication on glass is relatively labor-intensive. The shapes and dimensions available for patterning on glass are also limited. Silicon has also been commonly used because of its amenability to fabricating relatively small high aspect ratio features such as needle tip structures. In addition, semiconductor processing techniques such as deep reactive ion etching (DRIE) can be carried out for mass production of silicon chips [9]. However, silicon being semi-conducting has the disadvantage of current leakage.

Recently, the use of polymer-based substrates such as parylene, poly(dimethylsiloxane) or PDMS, polycarbonate (PC), polyimide (PI), poly(methylmethacrylate) or PMMA, poly(ethylene terephthalate) or PET, amongst others, has become increasingly attractive due to the availability of a wide range of plastics at low costs and the relatively simple and rapid microfabrication (rapid prototyping) techniques involved. The flexibility, superior optical properties and the ability to bond readily to glass after exposure to plasma of some plastics also make these materials attractive. Plastics, and glass for that matter, however, often have to be treated with hydrophobic surfactants to eliminate wetting and capillary ballooning at emitter tips. Other methods to avoid emitter tip wetting are discussed in the next section.

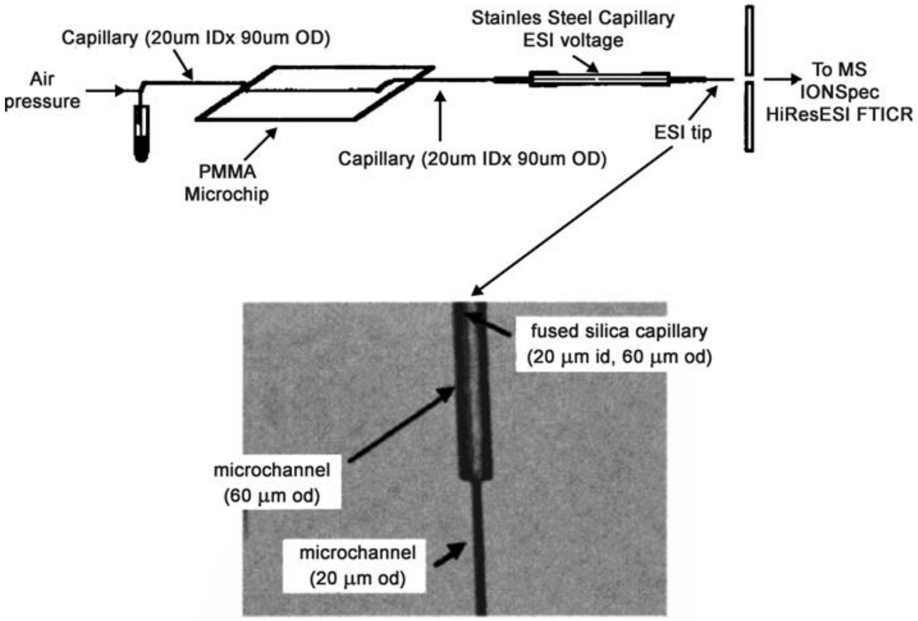
Electrospray tips from SU-8 photoepoxy have also been fabricated. Nevertheless, solvent resistance of polymer-based substrates is a critical issue, with poor resistance resulting in the swelling and distortion of the channels. A comparison between the performance of fused silica, parylene and borosilicate glass is discussed in Licklider et al. [10].

Blunt Edge Orifice

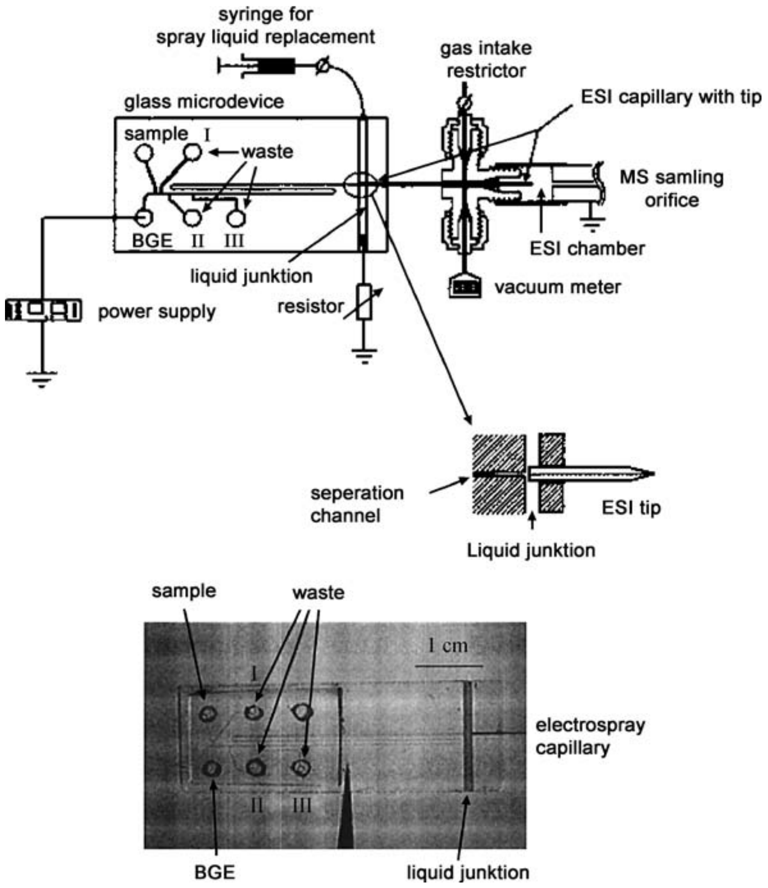
The first miniaturized on-chip electrosprays consisted of a planar glass microchip with 60 μm wide and 10 μm deep etched channels [11]. The open-end channel exit



On-Chip Electrospray, Figure 3 Schematic diagram representing the multichannel ESI-MS chip device in Xue et al. [12]. Each channel was connected to two reservoirs for sample injection and delivery. A syringe pump attached to the second reservoir of each channel was used to deliver the sample through the channels and electrodes were placed in one of each two buffer reservoirs to provide the electrical contact with the solution. The electrospray orifices consisted of the blunt edges of the open-ended channels. Reprinted with permission from [12]



On-Chip Electrospray, Figure 4 On-chip ESI-MS device employing a fused silica transfer capillary. The electrical contact was established through a stainless steel capillary connected to the silica capillary using a poly(tetrafluoroethylene) sleeve. Another fused silica capillary connected to the other end of the stainless steel capillary was used as the electrospray emitter, as shown by the enlargement in the bottom image. Reprinted with permission from [16]



On-Chip Electrospray, Figure 5 Schematic diagram (top) and image (bottom) of the ESI-MS device involving a transfer capillary and a subatmospheric liquid junction. Reprinted with permission from [17]

functioned as the electrospray orifice from which a Taylor cone was observed, thus avoiding the necessity of a dedicated electrospray tip. The coning and spraying is still possible as the electric field intensity at the exposed liquid surface was sufficiently high, above the critical value estimate given by Eq. (2). The blunt edge functioning as the electrospray orifice was formed by either breaking off the scored chip or by cutting the chip using a dicing saw. A similar but parallel multichannel electrospray microchip (Fig. 3) for increased throughput was also developed [12].

Whilst the blunt edge configuration is simple to fabricate, there were several challenges associated with such a design. The low currents associated with electrospraying are insufficient to generate electroosmotic flow (EOF) and hence required the flow to be pressure-driven. The absence of flow regulation however resulted in meniscus ballooning at the orifice which disrupted the electrospray stability and led to the formation of a dead volume; this dead volume introduces hydrodynamic dispersion and hence band broadening of the sample, reducing the efficacy of the separation. Even with application of ancillary electric potentials to drive the flow electroosmotically, the low EOF flow rate made regulation difficult. The electrical connection to the electrospray tip, established by insertion of a metal wire into the sample reservoir, also introduced flow perturbations which aggravated the problem of the lack of flow regulation.

In addition, the ballooning problem was intensified by the hydrophilic glass substrate. This was overcome by surface modification or applying a hydrophobic coating around the edges of the exit end. Nevertheless, this was only a partial remedy as it was possible that the corona discharge affected the chemical stability of the coating [13]. Alternatively, it is possible to bond a porous poly(tetrafluoroethylene) or PTFE membrane at the edge of the microchannel exit acting as the electrospray orifice. The hydrophobic membrane acts to constrain lateral dispersion of the liquid emanating from the orifice. The hydrophobic surface of such a membrane being consis-

tently hydrophobic and hence the hydrophobicity can be easily controlled [14].

The ballooning problem was also addressed by attaching a pneumatic nebulizer and introducing an ancillary liquid (e. g., acetonitrile, methanol or 2-propanol) sheath flow downstream prior to the electrospray exit [15]. This was carried out by coupling an integrated nebulizer to a subatmospheric liquid junction. The role of the nebulizer gas (e. g., nitrogen) is four-fold, directly removing the ballooning meniscus and hence minimizing the dead volume, controlling the flow rate of the ancillary sheath flow, aiding in the evaporation of the electrosprayed drops, and, providing cooling to the sheath flow at high currents. The role of the sheath flow is two-fold, providing an electrical connection and reducing the ballooning effect and hence dead volume by constraining the flow of the sample. Sheath flow interfaces also enjoy the advantage of wide flexibility in analyte solution selection and enhanced reliability. However, a major drawback of sheath flows is the dilution of the sample and the introduction of background noise from the ancillary flow, both of which compromise the detection sensitivity. The position at which the nebulizer channel merges with the separation channel is however crucial. If this is too far from the exit, the gas pressure results in a back flow whereas non-merger of the channels will result in the failure of the gas flow to disperse the liquid at the exit [15].

Subsequent developments in the on-chip electrospray then involved using either a transfer capillary or a microfabricated emitter tip as a dedicated electrospray orifice in order to more efficiently address these problems.

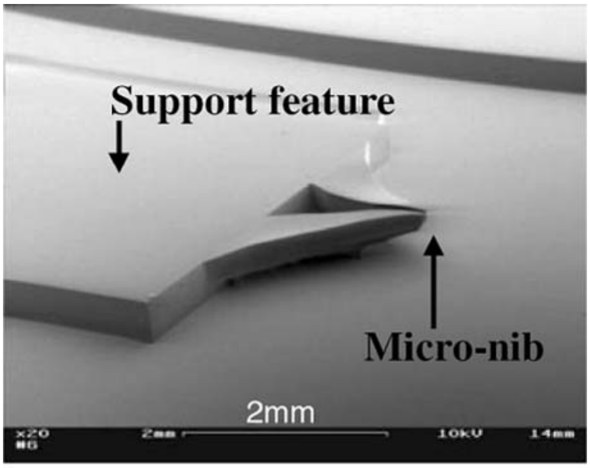
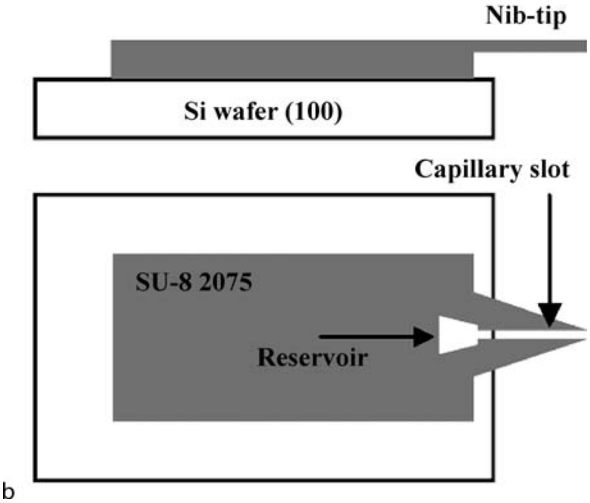
Capillary Transfer Attachment

A transfer capillary to which a high voltage is applied can be attached to the edge of a microchannel to act as the electrospray interface. This allows the orifice to be smaller in dimension than that of the blunt edge, thus increasing the stability and hence the performance of the electrospray. In addition, the use of transfer capillaries, the majority constructed from quartz or fused silica, simplifies the construction of the device. Since the capillary is external to the microchannel and chip device, the ESI can be optimized externally. The transfer capillary can also be attached to different chip devices, extending its lifetime and eliminating contamination [13]. An example of the transfer capillary is shown in Fig. 4 in which a long 20 cm fused silica capillary affixed tightly with epoxy to one end to the microchannel was connected to a stainless steel capillary at its free end with a PTFE tube, which in turn, was connected using the PTFE tubing to an electrospray tip pulled from a fused silica capillary [16].

The capillary attachment setup is, however, difficult to control and does not produce good reproducibility. To circumvent these issues, the transfer capillary can also incorporate the sheath flow and liquid junction components discussed above (Fig. 5) to provide the electrical connection, reduce the dead volume as well as to act as a buffer zone such that the separation is not affected by the nebulizer gas flow. Transfer capillaries however require time-consuming alignment and end-to-end butting; poor alignment reintroduces more dead volume instead, resulting in a reduction in the detection sensitivity and separation efficiency. Another deficiency associated with transfer capillary devices is the clogging of the capillary due to contaminants.





On-Chip Electrospray, Figure 7 Scanning electron microscopy image (**a**) and schematic plan and side views (**b**) of the nib-like in-plane electrospray emitter tip fabricated in SU-8 epoxy using double exposure lithography [21]. Reprinted with permission from [21]

Sheathless interfaces have also been developed to eliminate the dilution effect. To achieve a stable electrospray in the absence of nebulizer flow, the capillary tip is often tapered to provide a reduced orifice size. Electrical connection is provided either by applying a conductive coating (e. g., gold, carbon black or a conductive polymer) to the capillary tip, insertion of a wire electrode through a small opening drilled in the capillary wall or with an additional stainless steel capillary connected via a sleeve tubing shown in Fig. 4 [16]. The conductive layer coating is susceptible to damage due to corona discharge and deterioration due to friction. Moreover, these connections suffer the disadvantage of bubble generation due to electrolytic reactions at the electrode, which could disrupt the spraying and suppress the output signal. To avoid this, a Nafion® housing design was employed in a novel sheathless interface device which provides an escape route to relieve the flow of undesirable electrolytic products [18]. Nafion® is a conducting polymer which acts as a charge-selective salt bridge, thus permitting current penetration through the Nafion® membrane, which in itself has negligible polarization due to the small operating current. The external housing of the electrodes thus permits any gas bubbles to escape through the vent. In this same work, an efficient electroosmotic pump is also integrated into the device using silica monoliths, thus enhancing the stability of the electrospray.

Emitter Tips

Direct electrospraying via emitter tips, also known as nanoelectrospray or nanospray tips, were developed almost as a parallel technique to the transfer capillary interface in an attempt to address the problems associated with direct electrospraying using a blunt edge. The use of emitter tips has the advantage of parallelization in which multiple arrays of emitter tips (over 100 in number) can be fabricated very cheaply and attached onto a microchip, which makes them amenable to high throughput delivery [19]. In general, the development of such tips has taken two routes, namely, out-of-plane tips and in-plane tips. Early work on these emitter tips were almost always out-of-plane, in which the main flow direction and hence emitter is in a direction perpendicular to the device substrate. The first emitter tips comprised of a needle tip, about 50 μm at the large end and 5 μm at the emitting end, blunt cut to about 2 cm in length and glued on to the underside of the substrate at a drilled opening where it meets the bottom of the microchannel [20]. The next generation devices consisted of an integrated nozzle fabricated at the bottom of a liquid chamber, as shown in Fig. 6 [9]. Electrical connection was obtained through the use of a conductive coating or a conducting emitter. In another design, an array of 30 μm holes was machined into the substrate by laser ablation to function as emitters; the inherent taper of low demagnification factor laser etching processes naturally gives rise to conical orifices [19]. The surfaces of these holes were treated to increase the hydrophobicity.

In-plane emitter tips in which the tips are embedded at the end of the microchannel at the edge of the chip devices have been heralded mainly by recent advances in microfabrication technology by which low cost disposable chips are now close to reality. The smaller dimensions of these emitter tip devices were observed to produce more stable electrosprays over longer times. These emitter tip devices consist of an open capillary slot, connected at one end of

the chip to a reservoir, which tapers in diameter at the emitting end to form a nib-like structure resembling that of a calligraphic pen, as illustrated in Fig. 7 [21]. This tapered tip is intentionally designed to minimize liquid spreading and to reduce the characteristic orifice length scale and hence the critical voltage required, as stipulated by Eq. (2). In this design, a platinum wire is inserted into the nib to establish the electrical connectivity and sample delivery was achieved using capillary infusion. A drawback of this design, however, is that a large reservoir is required due to evaporation from the open channel. A star-shaped chip device containing eight arms, each with a similar open channel and tip for sequential analysis via rotation of the chip has been built [22]. Other tip designs, e. g., groove structures, triangular tips, point tips and enclosed SU-8 tips have also been proposed. To reduce contamination, the insertion of a triangular parylene sheet between a bottom substrate and a top substrate incorporating the channel and tip has been suggested to confine the liquid at the outlet.

Future Directions for Research

Although a commercially on-chip device for ESI-MS is now available, there still remains several design problems related to enhancing electrospray stability, ionization efficiency, detection sensitivity, separation efficiency, speed, accuracy and spectra quality that need to be addressed. In addition, efforts need to be concentrated to minimize and eliminate sample loss and cross-contamination. Despite significant progress, there is still some way to go before a robust, optimized, cost-effective, high-throughput microdevice providing flexibility for coupling to different MS configurations can be realized. Whilst the high duty cycle of MALDI-MS enables large number of samples deposited on a single target plate, high throughput can only be achieved on chip based ESI-MS devices through the use of multiple channels or emitter tip arrays (see previous section), which themselves are limited by the allotted chip substrate area. The use of high voltage DC electric fields is also a critical safety issue for portable field deployment of miniaturized consumer devices. A possibility around this is to explore the feasibility of employing high frequency AC electric fields [4, 5].

Perhaps the main challenge, however, is the sequential or simultaneous handling of multiple streams (multiplexing) and the integration of multistep processes to allow analyte separation and detection onto a single microchip device [23]. Miniaturization and integration of the mass spectrometer onto the microchip is one goal; some advances have been achieved in scaling down ion trap and quadrupole mass analyzers although the complexity of the tandem mass spectrometer poses a significant challenge for its reduction to a chip-based system. The other goal is upstream miniaturization and complete integration of various other processes such as flow-through sampling, and, sample preparation and enrichment. Such a total analysis microsystem would require complete compatibility and connectivity between the various microfluidic components.

Definition

On-chip micro-optical detection describes the collection of optical signals created in a micro- or nanofluidic device on the same chip. The wavelengths of the optical signals to be detected are typically in the visible or near-infrared part of the spectrum ranging from 0.4 to 2 μm. This sets the length scale for the detection elements and results in the use of micro-optical methods for on-chip detection. The detection process is an integral part of a fully integrated Lab-on-a-Chip and has to be optimized in the context of the entire chip. In this chapter, we will survey the most common approaches to on-chip micro-optical detection in the context of the complete integrated microfluidic system.

Overview

A large number of microfluidic devices with applications in analytical chemistry, biology, and biomedicine rely at least in part on optical methods for sample analysis. At the same time, the overarching goal for building microfluidic systems is to create miniaturized, portable, and self-contained Labs-on-a-Chip that perform all desired functions in as small a volume as possible. If optical analysis is to be part of the fluidic system, all optical components should be miniaturized as well. This situation is schematically depicted in Fig. 1a that shows the components of a Lab-on-a-Chip with focus on the optical parts. In general terms, light has to be brought in contact with liquid sample material. To this end, the outputs of light and fluid sources are guided via optical waveguides and fluidic channels, respectively, to an interaction region denoted by "I" where the sample analyte creates a characteristic optical signal, typically fluorescence, scattering, or absorption. This optical signal needs to be recorded by the detector, and to this end may pass additional functional optical elements such as filters, beam splitters, or gratings. Fig. 1b shows a recent example for an optofluidic chip that incorporates all these elements in a single device, resulting in almost complete integration [1]. In the remainder of this article, we will first give a brief overview of the optical components preceding the detector stage before focusing on proposed and cur-

rently implemented solutions for incorporating the detector with the microfluidic system to create a true optofluidic Lab-on-a-Chip.

Basic Methodology

Integrated Light Source

Due to the generally small amount of sample volume, optical analysis methods in microfluidic systems require only moderate to low amounts of optical power in the range from microwatts to milliwatts. These power levels can easily be achieved by incoherent sources such as light emitting diodes (LEDs). Coherent radiation as produced by a laser has, however, numerous advantages such as high spectral purity and long coherence lengths so that most studies are carried out with laser sources. The main challenge has been that the electronic properties of silicon cause it to be an extremely poor light emitter and preclude the realization of an electrically pumped laser built on a pure silicon platform. There are several ways around this limitation. Either a more efficient semiconductor material, typically alloys from III-V systems such as GaAs or InP or organic dyes that emit light in the desired wavelength range are used. Dye lasers have the advantage that they do not require a silicon-based substrate and that advanced laser structures such as single wavelength distributed feedback (DFB) lasers can be built [1, 2]. Current limitations to this technology include the need for an off-chip optical pump source for exciting the dye molecules and the additional fluidic infrastructure required to control the laser dye.

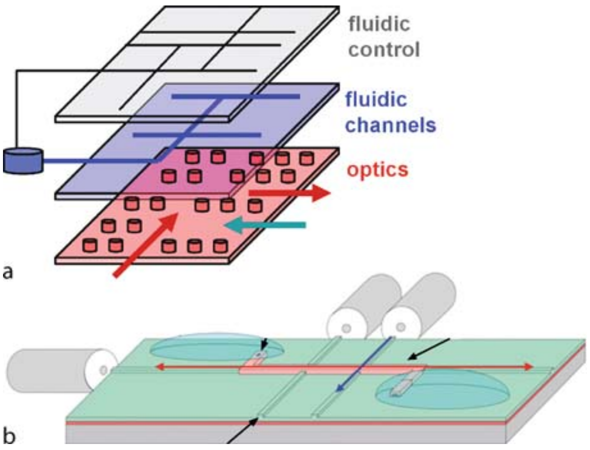
Optofluidic Architectures

Once light is generated at the source location on the chip it needs to be guided to the interaction volume to excite the particles of interest. This light transport occurs in optical waveguides and leads to two fundamentally different approaches to the optofluidic device architecture. Light can be guided using conventional index guiding based on total internal reflection from the material surrounding the waveguide core. In this case, it interacts with the fluid either via the evanescent component of the light field that extends into the liquid surrounding the waveguide, or the waveguides are intersected by the fluidic channels and light is recollected after passing the liquid. This approach is represented in Fig. 2a which shows a layered optofluidic device in which microfluidic controls, microfluidic channels, and optical structures (sources, waveguides, sensors) are vertically separated from each other [3]. This architecture is particularly suited for hybrid material approaches where the optical layer is made of different materials (e. g. silicon based) than the fluidic layers (e. g. polymer based). In the second approach, both light and liquids are guided through the same physical fluidic channels. This appears difficult to achieve at first because the low refractive index of typical analyte liquids (around 1.3 to 1.4) precludes the use of conventional index guiding as used in silica fibers. In the context of chip-based integration, two methods to solve this problem have recently been developed. Liquid-core/liquid-cladding (L^2) waveguides are based on flowing two non-mixing liquids through the same channel. If the index of the innermost liquid is higher than that of the cladding liquid, regular index guiding is possible over millimeters of length [4] and additional functionalities such as optical switching can be added. Alternatively, light can be confined in the low-index liquid using dielectric multilayer confinement based on the antiresonant reflecting optical waveguide (ARROW) principle. In this case, light that is refracted out of the liquid is efficiently reflected back into the core by several layers of dielectric materials of appropriate thickness, typically silicon nitride (SiN) and oxide (SiO_2). This principle has been implemented on silicon platforms using wafer bonding for channels with $\sim$150 μm diameter [5], and monolithic fabrication for channels with



On-Chip Micro-Optical Detection, Figure 2 (**a**) Three-layer architecture of optofluidic chip with separate fluidic and optical layers (after [3]). (**b**) Planar optofluidic architecture with integrated liquid-core ARROW waveguides (after [7]). Fluid and light (indicated by arrows) are guided through the central channel connecting fluidic reservoirs. Solid-core waveguides interface to the edges of the chip

5 – 15 μm diameter [6]. It has also been shown that the latter approach can be extended to designing 2D networks of hollow and solid core waveguides that allow for fully planar optical beam geometries as the light can be coupled in and out of the fluidic channels in different locations [7]. This scheme is shown schematically in Fig. 2b.

Integrated Optical Elements

When considering the on-chip optical detection process in a microfluidic device, it is not sufficient to consider the detector region alone. Most optical detection methods, in particular the most popular fluorescence detection schemes, require isolation of a weak generated signal from a much stronger excitation beam. In bulk systems, this separation is accomplished in the wavelength domain because the exciting and generated signals have different wavelengths. The most common wavelength selective optical elements are spectrometers, dichroic mirrors, and bandpass interference filters. If efficient on-chip detection is to occur, these elements need to be transferred to the optofluidic chip or alternative solutions need to be found.

The most versatile and sophisticated wavelength selective element is a spectrometer, and substantial efforts to develop integrated microspectrometers on a chip have been made [8]. A key figure of merit for the performance of a spectrometer is the spectral resolution $R = \lambda/\Delta\lambda$ which is defined as the ratio of wavelength λ and the 3 dB power bandwidth $\Delta\lambda$. High-performance grating spectrometers can reach spectral resolutions up to 10^6. Spectrometers work by spatially separating different wavelengths via the combination of a dispersive element and subsequent propagation. Several approaches have been taken to implement this concept on a chip. These include metal gratings and Fabry–Perot resonators as dispersive elements. Fabrication is done with MEMS-based silicon bulk micromachining which can cause compatibility problems for an optofluidic chip. All of these approaches suffer from the short separation path length on a small chip and no spectral resolutions higher than $R \sim 15$ have been achieved [8].

Perhaps a more promising approach for pre-detection signal conditioning is to emulate an interference filter on a chip. These filters are used to pass only fluorescence signals over a few to tens of nanometers while rejecting the excitation spectrum. Interference filters are characterized by the ratio of transmitted power at the excitation and detection wavelengths which is typically on the order of 10^5. It has been shown that the ARROW waveguide based optofluidic platform discussed above can be used as an interference filter [7]. The waveguiding efficiency of these structures depends both on wavelength and thickness of the dielectric cladding layers. If properly designed, the hollow channels in Fig. 2b can be designed to guide light efficiently at the detection wavelength while being extremely lossy at the excitation wavelength. This principle allows for implementation of the filter function without adding additional fabrication steps or chip area. Narrowband wavelength transmission and subsequent separation can also be achieved with interference based integrated elements including microrings or Mach–Zehnder interferometers. There, the challenges lie mainly in minimizing optical losses that occur in curved structures.

Finally, an entirely different, filterless approach can be taken. In this case, the entire optical signal reaches the detector. Its wavelength dependence is recovered by applying different control voltages to the photodetector that result in different detection depths of the detector material [9]. The spectrum can then be reconstructed because the penetration of the optical signal into the detector is wavelength dependent. This approach has been implemented using standard 5 μm CMOS technology and was verified using DNA solution with SYBR-Green labeling. It may have limited use when a large dynamic range is required, i. e. when the excitation and generated signal differ strongly in intensity as is the case when low concentrations of analyte are to be detected.

Integrated Micro-Optical Detection

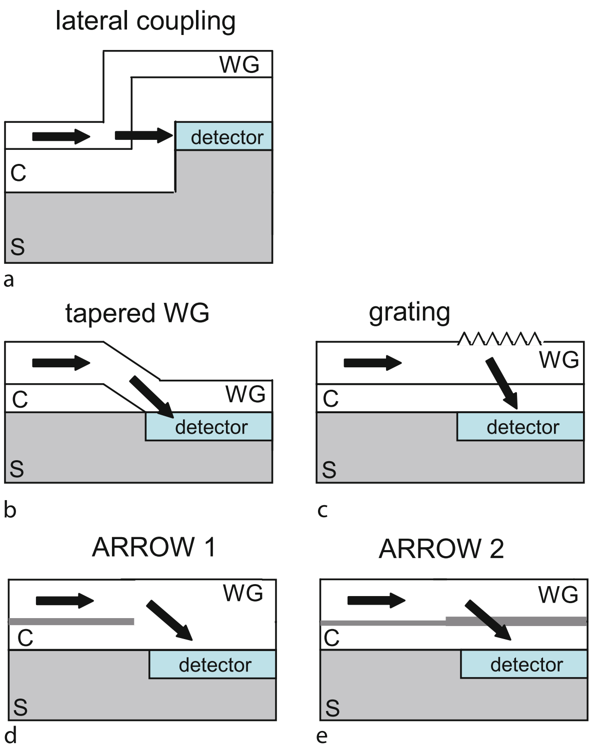
The optical detection process consists of turning light into an electrical signal that can be recorded, amplified, and stored for further processing and analysis. This signal con-

version is carried out via the photoelectric effect in which photons generate mobile charge carriers, i. e. an electrical current. In bulk detection systems, this can be done using photomultiplier tubes (PMTs) or semiconductor photodetectors. In a PMT, the photons impinge on a metal cathode to release electrons that are subsequently amplified in a high voltage cascade. In a photodiode, light incident on a semiconductor transfers electrons to a different electronic state, creating both a positive (hole) and negative (electron) charge in the process that can contribute to electrical current. If this generation process occurs inside or in the vicinity of a p/n-junction – semiconductor regions that have mostly free holes/electrons, respectively – the generated electrons and holes are separated in an applied electric field and can be detected as a photocurrent. Both photodiodes and PMTs can be extremely sensitive and reach the single photon detection limit. Semiconductor detectors with this sensitivity are called avalanche photodetectors (APDs) that include an amplification process similar to PMTs after creation of the initial electron-hole pairs.

Semiconductor photodiodes are the natural choice for building an optofluidic device with integrated on-chip detection. The immediate consequence is that the chip has to be either entirely semiconductor based or be a hybrid system with soft material fluidic components and a solid-state detection layer as shown in Fig. 2a. The detectable wavelength range is determined by the semiconductor material properties. Silicon absorbs light with wavelengths shorter than 1.1 µm and is therefore a good choice for detection in the visible and near-infrared. Longer wavelengths, in particular 1.55 µm, can be reached using different absorbing layers such as InGaAs.

The main challenges for an on-chip detection system are to guide the light to the active detector area, couple as much light as possible into the detector, and find a system fabrication process that is compatible with producing the required photosensitive p/n junctions.

Figure 3 shows different approaches that have been taken to create the optical signal in on-chip semiconductor photodiodes. Common to all of these is the principle of coupling light from the waveguides (these could be any of the types discussed above) into a detector region that consists of different materials. All of these methods were first demonstrated in solid-state integrated optical devices without fluidic components. Fig. 3a shows lateral coupling, which is perhaps the most intuitive approach as the optical signal symbolized by the black arrows remains in the same plane during the coupling process. This concept was implemented using SiON waveguides and laterally structured p-i-n photodiodes yielding light coupling efficiencies on the order of 85% [10].



On-Chip Micro-Optical Detection, Figure 3 Overview of different approaches to on-chip micro-optical detection (details see text, WG: waveguide, C: cladding)

All other methods shown in Fig. 3 utilize vertical coupling and require a way to efficiently scatter light from the waveguide into an underlying photodiode. This scattering process is cumulative and the coupling efficiency increases with the length of the detector region. In Fig. 3b, the waveguide cladding is gradually tapered until being completely absent over the detector region. Without the cladding, the waveguide becomes leaky and light is scattered into the bottom detector. In Fig. 3c, the scattering process is accomplished by a surface grating, otherwise the principle is similar to Fig. 3b. Figs. 3d and 3e are examples for variations of the ARROW waveguiding principle described earlier to accomplish efficient coupling. In Fig. 3d, the thin gray dielectric layer that ensures light confinement in the guiding region is removed over the detector and the waveguide becomes leaky. Radiation is lost quickly through the bottom interface and collected by the detector. In Fig. 3e, the thickness of the ARROW confinement layer is altered above the detector. As mentioned earlier, the ARROW guiding effect depends on the layer thickness and can vary from being highly reflective (waveguiding) to highly transmissive (leaky).

The coupling efficiencies κ of approaches 3b, 3d, and 3e can be expressed analytically as

$$\kappa = 2.17\left(\frac{\lambda}{d_C}\right)^3\left[n_C\sqrt{n_S^2 - n_C^2}\right]^{-0.5}$$

[dB · λ/m] (tapered waveguide, Fig. 3b)

$$\kappa = 0.643\left(\frac{\lambda}{d_C}\right)^3\left[n_C\sqrt{n_S^2 - n_C^2}\right]^{-0.5}$$

[dB · λ/m] (ARROW 1, Fig. 3d)

$$\kappa = 0.879\left(\frac{\lambda}{d_C}\right)^3\left[n_C\sqrt{n_S^2 - n_C^2}\right]^{-0.5}$$

[dB · λ/m] (ARROW 2, Fig. 3e),

where λ is the optical wavelength, d_C is the effective waveguide core thickness, and n_C and n_S are the refractive indices of the core and substrate layers, respectively.

Typical values for the radiation loss for all three structures are in the range of 10 dB/cm for a 5 μm thick waveguide (index 1.46) coupled to silicon (index 3.85) and several hundreds dB/cm for a 1 μm thick core. It should be emphasized that the coupling efficiency can be substantially increased by adding an antireflection layer on top of the detector that ensures efficient transmission of the scattered light into the high index silicon detection region. Experimentally, coupling efficiencies of 85% within a detector length of only 300 μm have been observed [11].

Key Research Findings

The recent development of a Lab-on-a-Chip with integrated optical detection described by Balslev et al. illustrates the combination of the individual optical and fluidic components described in the previous sections and represents the state of the art for on-chip micro-optical detection in a larger fluidic system [1]. An image of the fluidic device was already presented in Fig. 1b. It is built on a p-type silicon substrate which also contains the electrical detection layer (photodiode). Light is guided in SU-8 waveguides surrounded by SiO_2 and PMMA resist cladding layers. Sealing of the channels is provided by a borofloat glass layer on top. The device also contains a fluidic dye laser with external optical pumping, and a fluid mixer. The sample analyte is contained in a cuvette that is horizontally intersected by the SU-8 waveguides. Coupling to the photodetector is accomplished by removing the SiO_2 layer above the detector, corresponding to the tapered waveguide configuration of Fig. 3b. The photodiodes are 50 μm wide and 2 mm long and optimized for detection at 600 nm with a 1 μm deep p/n junction. They exhibit good detection characteristics with a noise equivalent power (NEP) of 7×10^{-13} W (10 Hz bandwidth) and a sensitivity of 0.39 A/W at 580 nm. The device was used for an absorption measurement on xylenol orange dye, and sensitivity to different dye concentrations was demonstrated qualitatively. Note that due to the lack of a wavelength sensitive optical element, fluorescence detection is not feasible on this chip. Such an element could be added using the techniques discussed above, e. g. a microring or Mach–Zehnder interferometer section. Also, up to now no avalanche photodiodes have been integrated on a chip. These would be required for detection on the single molecule level. This work shows that while a fully integrated optofluidic Lab-on-a-Chip has not become reality yet, this goal is now within reach. In particular, the addition of on-chip micro-optical detection represents a key step along this way.

Future Directions for Research

The large payoff for developing completely self-contained micro- or optofluidic Labs-on-a-Chip will continue to drive future research on the optical components of the system, and new developments are bound to occur in all aspects. Integration of both the light source and detector on the chip will represent major breakthroughs along this road. Research on sources will focus on electrically pumped emitters that eliminate the need for off-chip optical pumps. Electrically pumped fluidic DFB lasers, silicon lasers or bonded light emitting diodes are all candidates for suitable sources. Fully planar optical approaches based on ARROW waveguides also hold a lot of promise as single molecule detection sensitivity on a chip has already been demonstrated [6], and the concept can be extended to adding wavelength filtering and efficient detector coupling with little additional effort. Future developments in the area of on-chip micro-optical detection will likely occur in incorporating ultrasensitive avalanche photodetectors (APD) and the required circuitry on the chip [12]. This requires the use of solid-state-only or hybrid silicon-plastic chip architectures and will allow for single molecule sensitivity on a fully self-contained chip. It was discussed that for most applications – in particular fluorescence detection and Raman spectroscopy – additional optical elements such as filters with high extinction ratio must be integrated on the chip along with the detector element itself to produce a useful signal. Finally, more developments on the back-end of the detection process in the areas of on-chip signal processing and data analysis using elaborate CMOS-based circuitry can be expected.

Definition

An *optical waveguide* is a structure that guides light waves. It traditionally consists of an inner core layer, a dielectric material with high permittivity and thus high refractive index, and an outer cladding layer, a material with lower refractive index than the core. Such a structure guides optical waves by total internal reflection. Waveguides that are integrated with microfluidic/Lab-on-a-Chip devices for the purpose of delivering excitation light and/or transmitting signal light to a detector are called *on-chip waveguides*.

Overview

A critical component for almost any miniaturized analytical device is perhaps the detection system. Among the possible detection methods and principles, optical detection is the most common in modern bio/chemical analysis. In particular, fluorescence is the most frequently used optical detection method in microfluidic systems. Fluorescence occurs when a fluorophore or quantum dot relaxes to its ground state after being excited. In biotechnology applications, for example, fluorophores or quantum dots can be used to label antibodies which tag molecules of interest in order to visualize their presence. Traditionally, this approach includes bulk optical equipment such as light sources, lenses, and microscope objectives, and requires precise mechanical alignment.

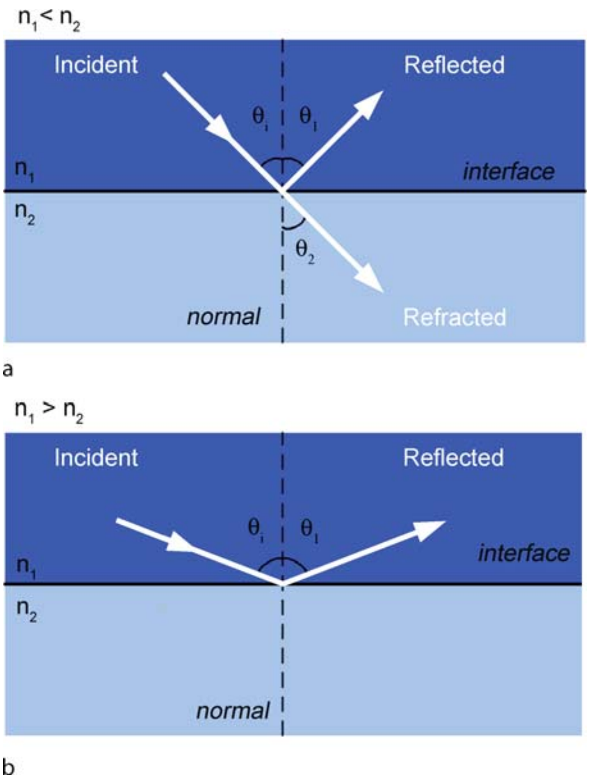
Waveguides can be integrated on-chip with microfluidic systems to improve optical detection. The general advantages of integrating waveguides on-chip are that microfluidic channels and optical elements can be aligned during fabrication, and that very compact devices can be created when light sources and detectors are integrated on-chip.

Waveguide Fundamentals

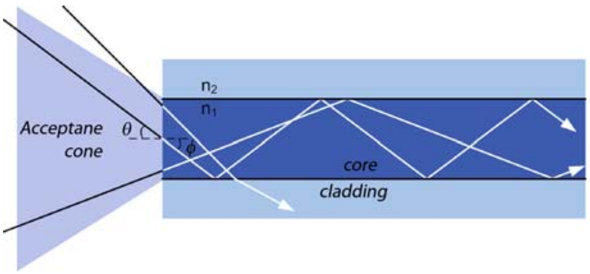
The key principle behind the waveguiding function of an optical waveguide is the phenomenon of *total internal reflection* [1, 2]. A light wave incident on an interface between two materials will refract and reflect, as schematically shown in Fig 1. Such behavior is described by Snell's law:

$$n_1 \sin\theta_1 = n_2 \sin\theta_2 \quad (1)$$

where θ are input and output angles with respect to the normal plane, and n are refractive indices of the two materials. Refractive index is a material property, defined by the ratio between the velocities of light traveling in vacuum and in the material. The refractive index of a solid material, a liquid, or a gas would thus be always greater than 1. Different



On Chip Waveguides, Figure 1 Behavior of a light wave incident on an interface with (**a**) $n_1 < n_2$ and (**b**) $n_1 > n_2$.



On Chip Waveguides, Figure 2 Total internal reflection of light in a waveguide ($n_1 > n_2$). Light entering the waveguide core within the acceptance cone is guided, while light entering at a steep angle results in coupling losses

wavelengths of light travel at different speeds through the same material, thus index of refraction of a given material is dependant on the wavelength.

Eq. 1 offers insight into the properties of optical waveguides. When the reflected angle equals 90° (i. e., $\theta_2 = \frac{\pi}{2}$), $\sin\theta_2 = 1$, and Snell's law can be rewritten as:

$$\sin\theta_1 = \frac{n_2}{n_1} \qquad (2)$$

Since the sin of a non-imaginary angle can never be greater than 1, the incidence medium must have a greater index of refraction than the transmission medium (i. e., $n_1 > n_2$) and

$$\theta_1 = \sin^{-1}\left(\frac{n_2}{n_1}\right) \qquad (3)$$

At this incidence angle, there is no longer any light transmitted though the interface and the output light would travel along the interface boundary itself. However, if the medium of incidence has a lower refractive index than the transmission medium (i. e., $n_2 > n_1$), there is refraction (external reflection). In other words, *total internal reflection* occurs when $n_1 > n_2$.

For waveguiding, the index of refraction of the core material must be grater than the index of refraction of the cladding material (Fig. 2) [1, 2]. Total internal reflection confines light in the optical waveguide core. The angle in Eq. 3 is called the angle of total internal reflection or the interface's *critical angle*. For visible light traveling from glass into air (or vacuum), the critical angle is approximately 41.5°. The critical angle for diamond is about 24.4°, which means that light is much more likely to be internally reflected within a diamond (diamonds for jewelry are cut to take advantage of this, achieving high total reflection of entering light).

A light beam propagating in waveguide core (internally) reflects off the core-cladding interface at an angle greater than the critical angle. A nearfield standing wave (called *evanescent wave*) propagates along the boundary and decays exponentially with increasing distance from the interface. Thus, as light is conducted along an on-chip waveguide, the transverse energy field extends past the waveguide core boundaries into the surrounding cladding layer.

Critical angle at the core-cladding interface at the front surface of a waveguide is the *acceptance angle*. If angle of the input light is larger than the acceptance angle, the incident light will not be totally internally reflected and will enter the cladding, causing losses (termed *coupling losses*). If the angle of the incident light is less than the acceptance angle, the light is guided.

The condition for total internal reflection at the core-cladding interface (Fig. 2) is given by:

$$n_1 \sin\left(\frac{\pi}{2} - \phi\right) \geq n_2 \qquad (4)$$

Since the angle ϕ is related to the incident angle θ by equation

$$\sin\theta = n_1 \sin\phi \leq \sqrt{n_1^2 - n_2^2} \qquad (5)$$

critical condition for total internal reflection is that:

$$\theta \leq \sin^{-1}\left(\sqrt{n_1^2 - n_2^2}\right) \equiv \theta_{\max} \quad (6)$$

where $\theta_{\max}$ denotes the maximum light acceptance angle of the waveguide and is known as the numerical aperture (NA). The acceptance angle can then be approximated by

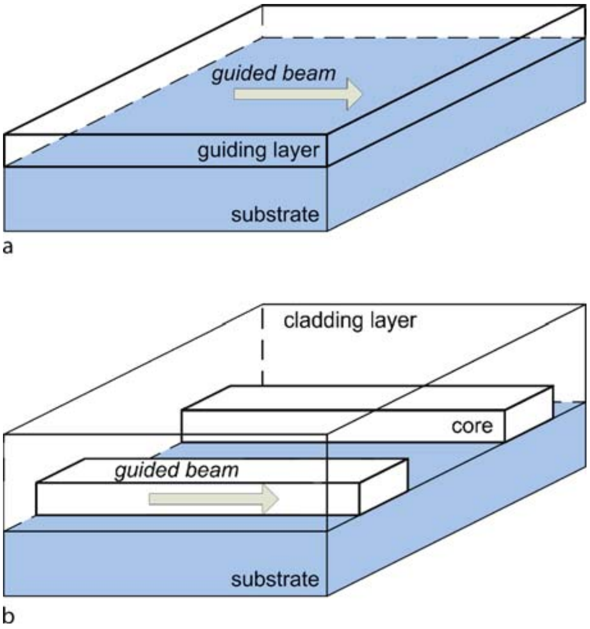
$$\theta_{\max} \approx \sqrt{n_1^2 - n_2^2} \quad (7)$$

A typical refractive index difference between the core and cladding is on the order of 0.01 or greater.

Depending on the various possible patters of propagating or standing electromagnetic fields, optical waveguides are either *single-mode* or *multi-mode* [1, 2]. Each mode is characterized by its frequency, effective refractive index, polarization, power distribution, electric field strength, and magnetic field strength. A single mode waveguide has a narrow core, typically less than 20 μm in critical dimension. As its name suggests, it has only one mode of transmission. Single mode waveguides carry higher bandwidth than multi mode waveguides but require a light source with a narrow spectral width. Using a small core and single light-wave reduces signal attenuation and distortions from overlapping light pulses and increases transmission speeds. A multi mode waveguide has a core at least 50 μm in critical dimension (100 μm is typical). Since it has higher numerical aperture, it can support more than one propagation mode. Light waves are dispersed into numerous paths, or modes, as they travel through the waveguide's core.

In optical communications, long-distance transmissions are accomplished over cylindrical dielectric waveguides (optical fibers). For on-chip integration with planar microfluidic devices, *planar optical waveguides* in the form of films or strips are required. Planar waveguides confine light in one dimension and propagate it in any direction parallel to the surface. Such waveguides can be produced by simply depositing a thin film with a higher refractive index than the substrate, trapping light inside this film.

The boundary between the waveguide core and cladding may either be abrupt or gradual. Waveguides where the refractive index changes sharply or in discrete steps are called *step-index (SI)* optical waveguides, whereas those with a gradual transition in the refractive index are called *graded-index (GI)* optical waveguides. Figure 3a shows a typical three-layer SI planar waveguide formed by depositing a think layer of material with a higher refractive index on a substrate with a lower index. The third layer is



On Chip Waveguides, Figure 3 Structures of (**a**) planar and (**b**) channel waveguides

either air or an additional lower-index cladding layer. Planar waveguides trap light in the direction of the film thickness, but allow light to spread in horizontally. To facilitate integration with microfluidic devices, 3D optical waveguides (or optical channel waveguides, Fig. 3b) that trap light in both vertical and transverse directions have been fabricated. Although waveguides come in various forms and with a variety of functions, optical waveguides that are uniform in the direction of propagation are the most basic type. Thus, the following discussion will be limited to optical waveguides in which material properties do not change in the direction of propagation.

Transmission Losses in Waveguides

Transmission loss (or attenuation) is an important characteristic of a waveguide. To measure *attenuation*, a cut back test is performed [1, 2]. Laser light is coupled into one end of a waveguide, and the other end is cut flat (e. g., with a razor blade) to allow light to exit directly to the photodetector. The waveguide length is progressively reduced (cut) and for each time the corresponding light intensity measurements are taken. Attenuation is then calculated as:

$$A = -10 \log\left(\frac{P_{\text{out}}}{P_{\text{in}}}\right) \quad (8)$$

where A is the attenuation in dB, P_{in} is the power injected into the waveguide, and P_{out} is the power measured by the

photodetector. Attenuation level of 3 dB means roughly half the power (P_{out}/P_{in} approximately equal to a ratio of 1/1.995).

One of the main causes of attenuation is absorption of energy (or photons). Absorption is caused by atomic defects which result when the waveguide is exposed to radiation, *extrinsic* absorption by impurity atoms, and *intrinsic* absorption by constituent atoms of the material [1, 2]. The dominant mechanism is extrinsic absorption, primarily by metallic ions (iron, cobalt, etc.) and OH^- ions. In early glass optic fibers, transmission distance was primarily limited by absorption by OH^- ions. These ions were introduced in the material from the presence of water or water vapor during the manufacture process. Attenuation caused by this ion is greatest at 1400 nm, 950 nm, and 725 nm, leaving *windows* for transmission between these wavelengths. Today, the vapor phase axial deposition (VAD) manufacturing method tremendously reduces the OH^- concentration in fibers. However, for waveguides microfabricated on-chip, high OH^- content can still be problematic.

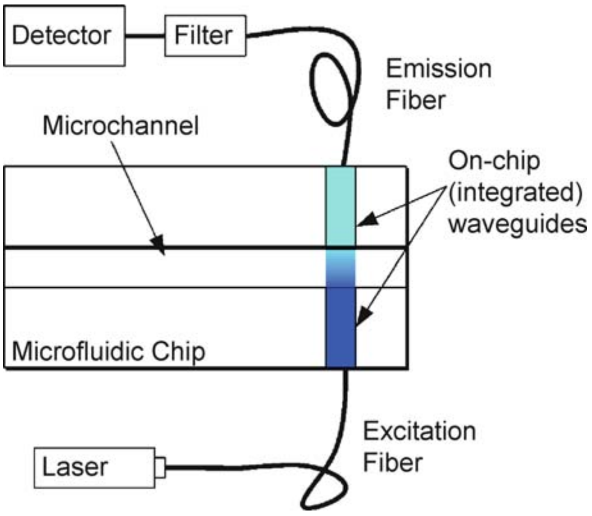
Losses in modern glass optic fibers are caused by ultraviolet absorption, infrared absorption, and scattering [1, 2]. The scattering losses, modeled by Rayleigh scattering, are caused by the interaction of the light wave with the constituent molecules which are on the order of the light wavelength. Rayleigh scattering loss is $1/\lambda^4$, so it can be reduced by increasing the wavelength. On the other hand, infrared absorption losses tend to increase with λ, and are usually the greatest at wavelengths above 1.5 μm.

Imperfections in the surface of the waveguide can also cause losses. Imperfections with dimensions of several wavelengths cause perturbation in the field, leading to coupling to higher order modes which do not have the desired transmission characteristics, and also causes power loss. Losses in modern commercial optic fibers can be kept down to as little as 0.01 dB/km, but for microfabricated waveguides losses in the order of 1 – 10 dB/cm for polymer and 0.1 – 1 dB/cm for glass cores are more common.

Basic Methodology

Overview

Generally, the motivation for integration of waveguides in microfluidic devices is to improve the detection, either by focusing the light in the channel to increase the excitation power for fluorescence measurements or by increasing the optical path length for absorbance detection. Further advantages are that optical and fluidic elements can be aligned during fabrication, reducing the number of interfaces and minimizing coupling losses, and that array of elements for multi-point/multi-analyte detection can be easily produced. In addition, on-chip waveguides can enable very compact devices when integrated with light sources and photodetectors.

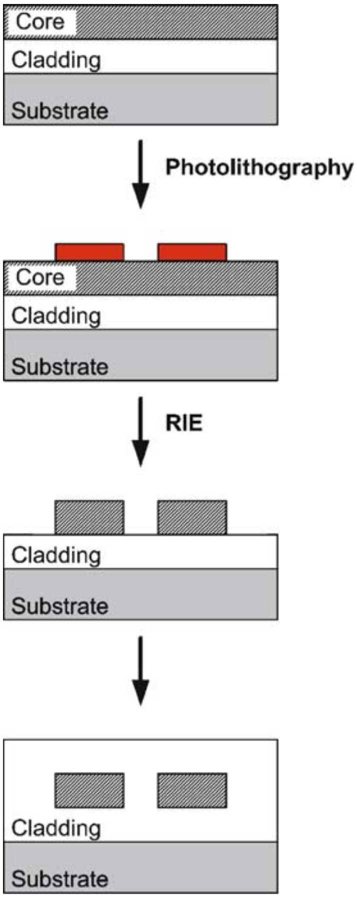


On Chip Waveguides, Figure 4 Schematic illustrating typical placement of on-chip optical waveguides in a microfluidic system

On-chip optical waveguides are placed within the microfluidic system such that the waveguide is either perpendicular or alongside microchannels. In a typical setup, illustrated in Fig. 4, light from a light source (e. g., laser or Hg arc lamp) is coupled to on-chip (integrated) waveguides via optical fiber. After light traverses the microchannel, it is transmitted by another optical fiber to a photodetector.

Alternatively, microfluidic systems can be designed to take advantage of the evanescent field by immobilizing analyte-sensitive fluorescent dye on the surface of the on-chip waveguide. In this configuration, the evanescent energy field excites the dye molecules resulting in fluorescence emission, and this emitted energy is superimposed on the transmitted light signal. Thus, the emitted signal from the waveguide contains components of the residual excitation signal and the fluorescent emission. Using filtering, chemical effects on the immobilized dye resulting in a change in fluorescent emission intensity and output spectra can allow determination of specific interactions occurring on the waveguide surface. For the evanescent waveguide sensor to operate effectively, the waveguide must confine the light by total internal reflection while allowing transmission of a substantial portion (at least 80% for short waveguide structures) of the light at both excitation and emission frequencies [3].

On-chip waveguides can be fabricated from different types of core materials. Traditionally glass has been a popular choice, but recently polymers have gained popularity



On Chip Waveguides, Figure 5 Process flow for farbciation of glass core waveguides

due to lower costs and excellent transmittance characteristics [4]. Furthermore, polymeric waveguides can now be easily integrated with microfluidic devices, which are now commonly made in polymers.

Glass core waveguides

Glass (or silica) is very well suited as a core material because of its high optical transparency, the stability of silica glass, and its chemical robustness. Silica can be thermally grown on a silicon wafer or deposited by plasma enhanced chemical vapor deposition (PECVD) from the gas phase onto the silicon wafer. Deposition rates of 160 nm/min are typical for high quality films. Figure 5 illustrates a typical process flow. To form waveguides, a bottom cladding layer consisting of pure silica glass is first deposited on top of the substrate. A core layer is then deposited on top if the bottom cladding layer. To achieve light guiding by total internal reflection, the index of the core layer is adjusted to be 1.0 – 1.5 % higher than the surrounding cladding layers. This is achieved by doping the core layer with germanium and nitrogen during PECVD deposition. The core layer is patterned using photolithography and reaction ion etching (RIE). The entire structure is then covered by a cladding layer consisting of pure silica glass. Once waveguides have been fabricated, microchannels are fabricated by etching trenches in glass and bonding with another wafer. Most of such on-chip glass waveguides are single mode, with core thicknesses of 5 – 10 μm and cladding layer thickness of approximately 10 – 20 μm.

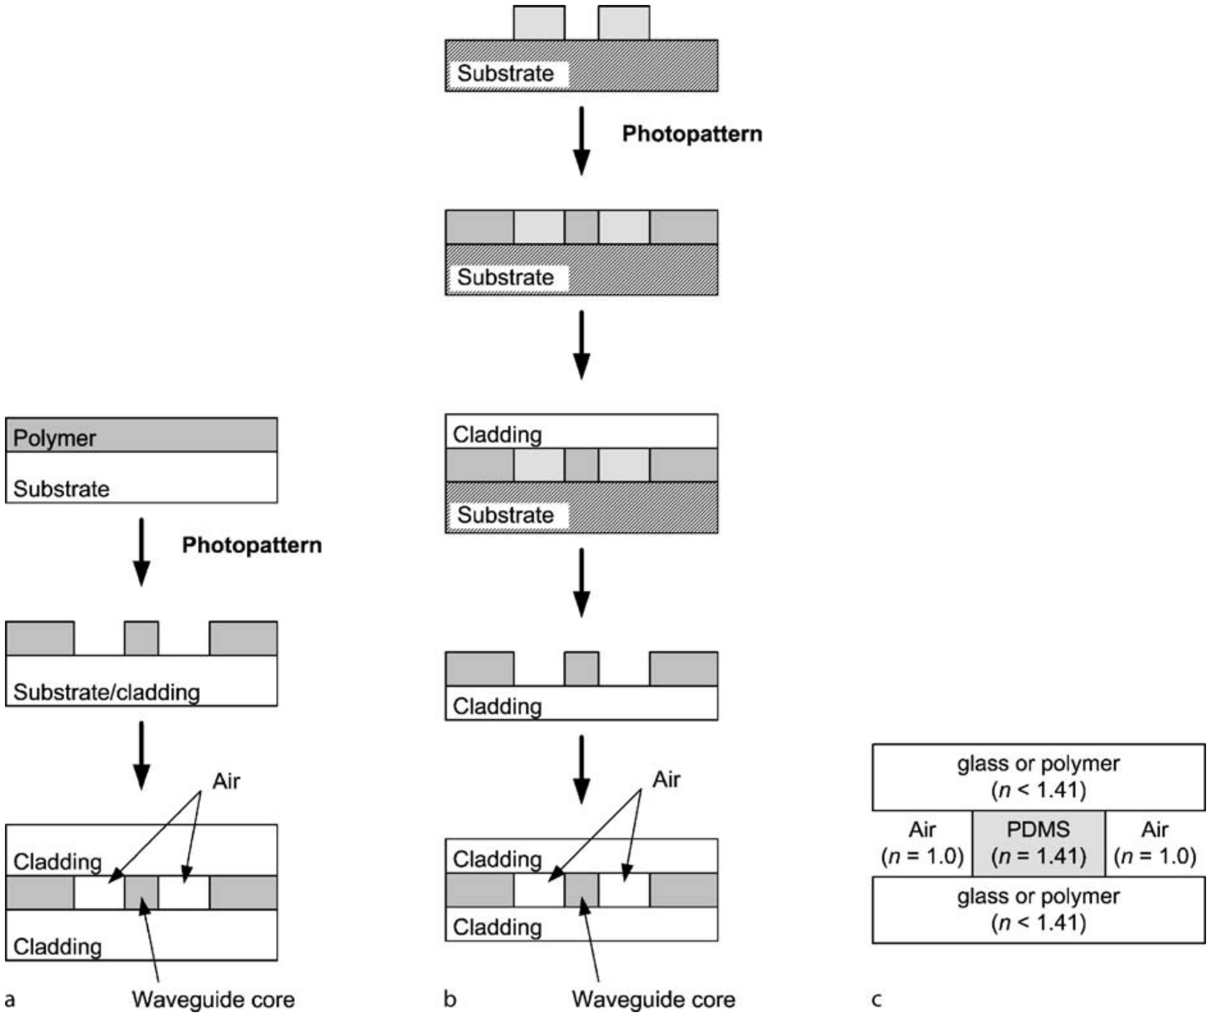
Polymer Core Waveguides

A common and simple approach to creating cladding around a polymer core is to sandwich it between two substrates. These substrates form cladding on top and bottom surfaces of the waveguide. Side cladding layers are formed by microchannels filled with air. This approach, schematically illustrated in Fig. 6, can be used to fabricate on-chip waveguides in a variety of polymers.

For a photosensitive polymer, the core is fabricated first directly on a cladding substrate. The second substrate is bonded directly on top of the polymer core (Fig 6a). The cladding is then formed by glass substrates on top and bottom, and air on both left and right sides of the waveguide. Photosensitive epoxy SU-8 (Microchem Corp.) has been growing in popularity as a core material for on-chip waveguides due to simplicity of fabrication. To fabricate waveguide core, SU-8 ($n = 1.59$ at $\lambda = 633$ nm) is simply spin-coated to a desired thickness and photolithographically patterned. Using this approach, single mode or multimode waveguides single to hundreds of micrometers in width and height can be fabricated, limited in height by SU-8 layer thickness and in width by photomask design. SU-8 waveguides, like many polymer waveguides, exhibit higher losses than those fabricated from glass. Nevertheless, unlike in optical waveguides for telecommunications, higher losses are not as problematic in on-chip waveguides for microfluidic Lab-on-a-Chip (LOC) sensing due to their short length.

For a non-photosensitive polymer, such as polydimethylsiloxane (PDMS, Sylgard 184, Dow Corning), a master is first fabricated in SU-8 by photolithography or in silicon by deep reactive ion etching (DRIE) (Fig. 6b). PDMS ($n = 1.41$ at $\lambda = 633$ nm) is then cast to form the core, followed by bonding of a cladding layer. The polymer structure is removed from the SU-8 master, and a second cladding layer is bonded. The resulting structure is schematically illustrated in Fig. 6c.

PDMS has many advantages over other core materials like SU-8 and glass. In addition to low cost, it has a very high light transmittance (> 95%) over a large frequency



On Chip Waveguides, Figure 6 Fabrication of polymer core waveguides using (**a**) photosensitive and (**b**) non-photosensitive materials. (**c**) Resulting waveguide cross-section structure

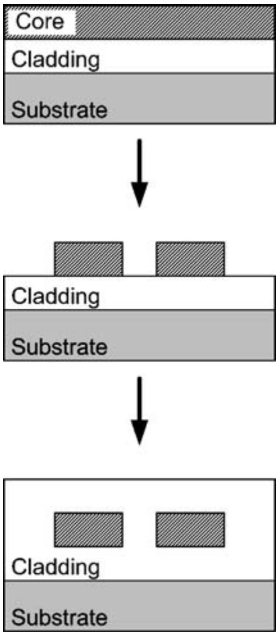
O

range. It is also biocompatible, robust, and has a rapid and repeatable mold fabrication process [5]. Even though SU-8 optical sensors designed for biochemical applications have been demonstrated successfully, the need for simpler and more biocompatible materials makes PDMS superior [6]. PDMS devices can be fabricated using soft lithography techniques [5], which do not require the use of a clean room.

Similar to glass core waveguides discussed earlier, buried waveguides can also be fabricated in polymers (Fig. 7). In this case, two different polymers with appropriate refractive indexes must be used. For example, an on-chip waveguide can be fabricated using a SU-8 core and PDMS cladding ($n_{SU-8} = 1.59$ vs. $n_{PDMS} = 1.41$ at $\lambda = 633$ nm). Alternatively, if using the same polymer for both core and cladding, differences in refractive index must be induced. For instance, curing PDMS at room temperature yields a slightly lower refractive index than curing at 150 °C ($n_{150\,°C} = 1.47$ vs. $n_{25\,°C} = 1.45$ at $\lambda = 460$ nm) [7].

Liquid Core Waveguides

As an alternative to the traditional buried channel waveguides, liquid core waveguides can be formed using microfluidic channels. In this case, microfluidic channel walls serve as cladding. By flowing liquid of higher refractive index than the microchannel material, light can be guided within the core. Liquid waveguides can also be composed of a liquid core and a liquid cladding (L^2 waveguides) [8, 9]. By selecting the inner core liquid to be of higher refractive index than the refractive index of



On Chip Waveguides, Figure 7 Fabrication of polymer core waveguides using two polymer materials

the surrounding media, light can be confined to the inner core. In these waveguides, the direction of light propagation can be easily altered by altering the differential flow rates for the liquids to steer the inner core liquid.

Key Research Findings

Mogensen et al. reported microfluidic devices for capillary electrophoresis (CE) and electrochromatography (CEC) with glass on-chip waveguides for optical detection [10]. The devices were fabricated from silicon substrates by DRIE and subsequent oxidation to form optical and microfluidic structures. Figure 8 illustrates the CEC device and shows a cross-section of an optical waveguide fabricated by oxidizing a thin lane of silicon, leaving a 22 µm wide stripe of pure SiO_2. The two air channels on both sides of the SiO_2 core constitute the lower refractive index regions of the waveguide. The depth of the air channels was ∼100 µm, which was also the depth of the microfluidic network. PDMS was used as the top cladding layer of the waveguide, due to its low refractive index and the need to seal the microfluidic channels. Light was not confined in the bottom part of the waveguide, which is a limitation of this approach (although the bottom footprint of the waveguide is small compared to the rest of the structure). Figure 8c shows the measured transmission losses for the waveguide. The propagation loss increased from about 0.2 dB/cm at 800 nm to about 0.8 dB/cm at 250 nm, which was attributed to surface scattering at the glass-air interface due to the waveguide sidewall roughness [10]. This kind of wavelength dependence is expected, since scattering generally is more pronounced at shorter wavelengths [1].

Polymers have been gaining popularity in on-chip waveguide fabrication as core and cladding materials. The use of polymers for on-chip waveguides often makes fabrication of a polymer microfluidic system substantially simpler, as both microfluidic and optical components can be fabricated in a single step. For example, Fleger et al. [11] developed a polymer microfluidic chip for capillary electrophoresis with multimode polymer waveguides for optical analytical applications. The microchannels 50 µm in width and 60 µm in depth were fabricated in polymethylmethacrylate (PMMA) using hot embossing. The on-chip waveguides were formed by fabricating 80 µm wide and 60 µm deep waveguide channels in the PMMA substrate (at the time of the microfluidic channel fabrication) and filling them with core material (NOA72, Norland Optical). NOA72 is a highly transparent UV curing adhesive, with low viscosity and good wetting of PMMA. The refractive index of NOA72 is $n=1.56$ and is suitable as a core material inside PMMA ($n=1.49$) cladding. Figure 9 shows top view and cross-section of the microfluidic channel and polymer waveguides. The transmission spectrum measured with a cooled photomultiplier (Fig. 9c) proves the suitability of the devices for optical detection in the range 440–800 nm, with a propagation loss of only 1 dB/cm [11].

Fleger et al. [12] also described a PDMS microfluidic chip for capillary electrophoresis with integrated waveguides for optical detection (Fig. 10). The waveguide core was composed of a special formulation of polysiloxane ($n=1.43$ at $\lambda=633$ nm). The waveguide cladding was formed by PDMS ($n=1.41$ at $\lambda=633$ nm) and air. Dimensions of the microfluidic channel and the waveguide channels were 70×70 µm^2; distance between the microfluidic channel and the waveguides was 50 µm. Optical loss in the whole system at $\lambda=633$ nm was approximately 1.27 dB, which included propagation loss in the 25 mm waveguides and coupling losses between the waveguides and the microfluidic channel.

Buried on-chip waveguides using the same polymer for both core and cladding can also be fabricated. Chang-Yen et al. demonstrated a method of fabricating a monolithic PDMS waveguide system using soft lithography [7]. An SU-8 master was first prepared to define waveguide core, and PDMS was cast and allowed to flow into the pattern. The excess PDMS that did not fill the SU-8 pattern was carefully removed using a razor blade. PDMS was cured

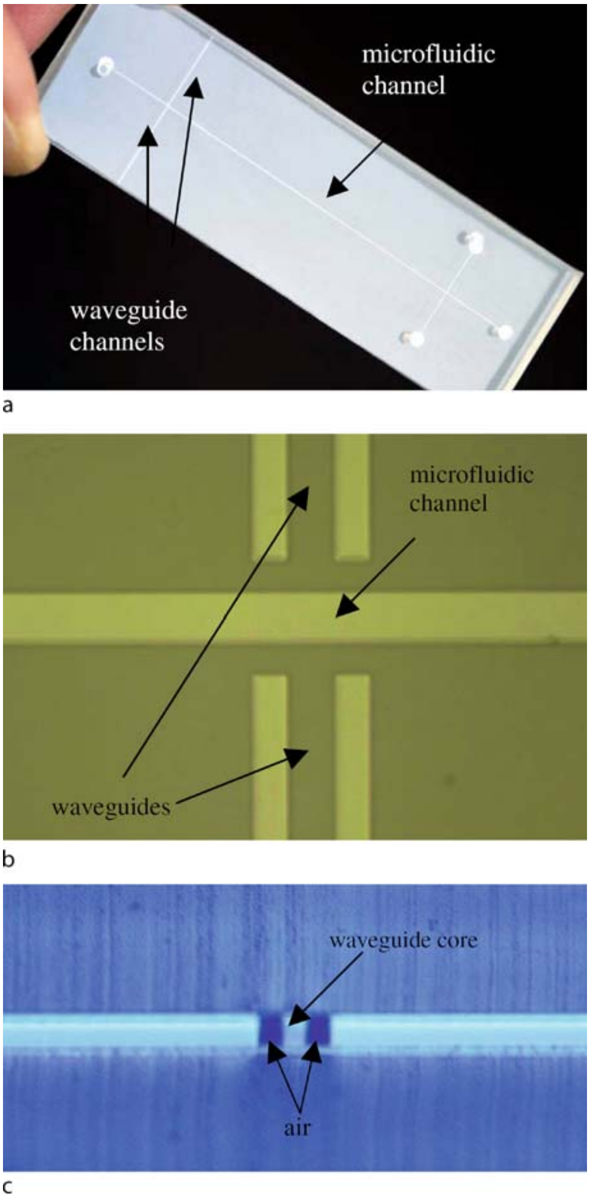
at 150 °C for 60 min, which yielded the waveguide core with $n = 1.47$ at $\lambda = 460$ nm. The baked layer was then cooled to room temperature and more PDMS was poured over it. The entire wafer was allowed to cure at room temperature to a refractive index of 1.45 (at $\lambda = 460$ nm), forming the cladding layer. A change of 0.02 in refractive index was sufficient for waveguiding. The cutback procedure was used to measure the attenuation of the waveguide demonstrated a loss of approximately 0.40 dB/cm at $\lambda = 460$ nm [7].



On Chip Waveguides, Figure 10 (**a**) PDMS capillary electrophoresis chip with on-chip waveguides. (**b**) Top view of the optical detection site, illustrating the microfluidic channel and waveguides. (**c**) On-chip waveguide cross-section. From [12]

Alternatively, photosensitive epoxy SU-8 can be used as both the core and cladding layer. The refractive index of SU-8 can be reduced by mixing it with at least 2.7% (by weight) liquid aliphatic epoxy resin DER 353TM from Dow Plastics [13]. The SU-8/aliphatic resin mixture was measured to have $n = 1.590$ at $\lambda = 633$ nm, as opposed to $n = 1.595$ for the un-modified SU-8. The aromatic groups from the aliphatic resin are absorbed in the SU-8 polymeric mesh, inhibiting high cross-linking of the SU-8. Therefore, the refractive index of the blend was lower than the pure SU-8 epoxy. The fabrication process consisted of three successive photolithographic steps to deposit sub-cladding (lower RI), core (higher RI) and top-cladding (lower RI) layers. Both cladding layers had microfluidic channels patterned in them.

Future Directions for Research

Fabrication of waveguides on-chip is important in microfluidic devices, since optical detection is used for many applications. While microfluidics has made it possible to integrate many fluidic casts on a single chip, most optical components such as light sources and sensors remain off-chip. On-chip waveguides provide an interface between these off-chip optical components and on-chip microfluidics. With the drive towards portable microfluidic systems for point-of-care diagnostics or on-site analysis, it is highly desirable to integrate these components on-chip with minimal coupling and transmission losses. This becomes especially important as limits of detection of miniaturized analytical systems improve and analyte concentrations decrease, resulting in ever smaller optical signals.

Optical Doppler tomography (ODT); Doppler OCT; Optical coherence imaging; Optical Doppler velocimetry

Definition

Optical coherence tomography (OCT) is an interferometric, non-invasive, non-contact optical tomographic imaging modality based on coherence-domain optical technology [1–6]. OCT uses the short coherence length of a broadband light source to perform cross-sectional imaging with micrometer-scale axial and lateral resolutions. Optical Doppler tomography (ODT), also named Doppler OCT, combines the Doppler principle with OCT to obtain simultaneously high resolution tomographic images of structure and flow velocity of scattering samples [7, 8].

Overview and Basic Methodology

Optical Coherence Tomography

OCT is a recently developed interferometric imaging modality that uses short coherence length of broadband light sources to perform micrometer-scale, cross-sectional imaging of biological tissue and other sample. Variations in sample scattering due to inhomogeneities in the optical index of refraction provide imaging contrast. OCT is analogous to ultrasound imaging except that it uses light instead of sound wave. The short coherence length of the broadband light source makes it possible to achieve spatial resolution one or two orders of magnitude better than what can be achieved with ultrasound. OCT was initially developed for imaging biological tissue for medical applications [2]. Since then, OCT has been used for imaging and quantifying biomaterials, microchannels, and nanostructures [3, 5, 8].

There are two basic implementations of OCT, time domain OCT (TD-OCT) and Fourier domain OCT (FD-OCT). TD-OCT is based on a Michelson interferometer with a broadband light source (Fig. 1). Light from a broadband partial coherent source is incident on the beam splitter and splits equally between reference and target arms of the interferometer. Light backscattered from the turbid sample recombines with light reflected from the reference arm and forms interference fringes. High axial spatial resolution is possible because interference fringes are observed only when the pathlength differences between the sample arm and reference arm are within the coherence length of the source. Axial scans are performed by scanning the reference arm, and lateral scans are performed by scanning the sample beam. A two-dimensional, cross-sectional image is formed by performing an axial scan followed by a lateral scan. Axial resolution is determined by the coherence length of the source, and lateral resolution is determined by the numerical aperture of the focusing lens [1–6].

Fourier domain OCT measures interference fringes in the spectral separated domain either by a spectrometer with a high speed line-scan camera (Fig. 2) or a swept laser source based system that uses a single detector [3, 6, 8]. Modulation of the interference fringe intensity in the spectral domain is used to determine the location of all scattering objects along the beam propagation direction by a Fourier transformation without scanning of the reference arm. FD-OCT has the advantages of high sensitivity and fast imaging speed. The significant increase in imaging speed and sensitivity of FD-OCT makes it possible to acquire three-dimensional OCT images with high spatial resolution.

An example of OCT applications in microfluidics is the investigation of Laminar dispersion in a serpentine

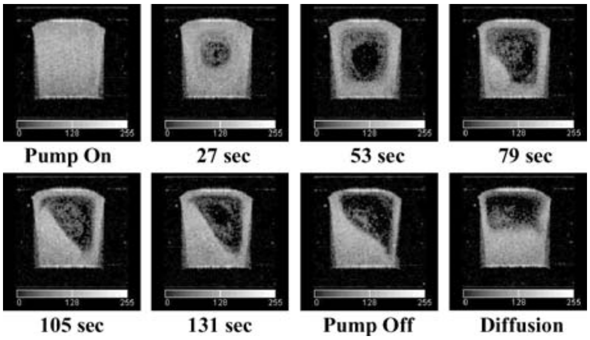
Optical Coherence Tomography and Optical Doppler Tomography, Figure 3 Picture and schematic of a meandering square micro-channel made of cyclo-olefin copolymer. It has a Y branch at the beginning and the dimension of cross-section between confluence and outlet is 600 μm $\times$ 600 μm. The radius of curvature R is 1.7 mm. The red dotted line indicates area of interest



Optical Coherence Tomography and Optical Doppler Tomography, Figure 4 OCT images of transient two-fluid mixing in a meandering square micro-channel as shown in Fig. 3. Initially, the entire channel was filled with a particle/water mixture, and the dual syringe pump (one with the particle/water mixture, and the other with water only) was turned off. As soon as the pump was turned on with a programmed flow rate, OCT images were acquired at 1 frame per second. When the initial mixing was stabilized and reached a dynamic steady state, the pump was turned off again. At the dynamic steady state, sedimentation was observed macroscopically. Stratification between the water and particle/water mixture was developed, and a clear interface was observed in the transverse plane. Secondary flow at the dynamic steady state is clearly visible. Finally, the concentration reached a static steady state where scattering particles occupied the lower half cross-section which resulted from sedimentation

microchannel with a Y-shape inlet (Fig. 3). Transient two-fluid mixing in microfluidic devices can be clearly observed (Fig. 4) [9].

Optical Doppler Tomography

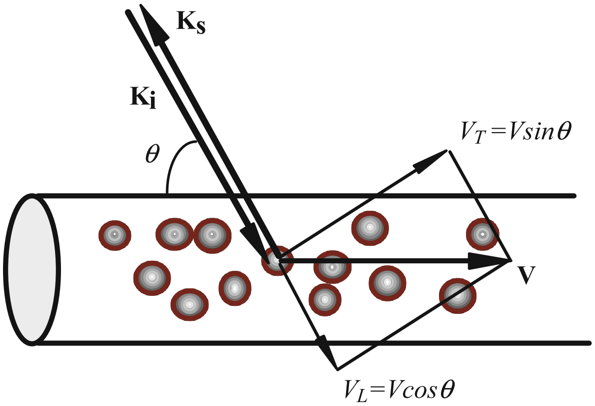
ODT combines the Doppler principle with OCT to obtain high-resolution tomographic images of static and moving constituents simultaneously in scattering samples [5, 8, 10, 11]. When light backscattered from a moving particle interferes with the reference beam, a Doppler frequency shift f_D occurs in the interference fringe:

$$f_D = \frac{1}{2\pi}(\boldsymbol{k}_s - \boldsymbol{k}_i) \bullet \boldsymbol{v}\,, \qquad (1)$$

where $\boldsymbol{k}_i$ and $\boldsymbol{k}_s$ are wave vectors of incoming and scattered light, respectively, and $\boldsymbol{v}$ is the velocity vector of the moving particle (Fig. 5). Since ODT measures the backscattered light, assuming the angle between flow and sampling beam is θ, the Doppler shift equation is simplified to:

$$f_D = \frac{2V\cos\theta}{\lambda_0}\,, \qquad (2)$$

where λ_0 is the vacuum center wavelength of the light source. Therefore, measurement of Doppler shift of the backscattered light allows quantification of flow velocity of scattering particles.



Optical Coherence Tomography and Optical Doppler Tomography, Figure 5 Schematic of flow direction and probe beam angle in ODT

The optical system of ODT is similar to that of OCT. The primary difference is in signal processing. The first two-dimensional in vivo ODT imaging was reported using the spectrogram method [10, 11]. The spectrogram method uses a short time fast Fourier transformation or wavelet transformation to determine the power spectrum of the measured fringe signal [10, 11]. Although spectrogram methods allow simultaneous imaging of in vivo tissue structure and flow velocity, the velocity sensitivity is limited for high-speed imaging. Phase-resolved Doppler OCT was developed to overcome these limitations [12]. This method uses the phase change between sequential A-line scans for velocity image reconstruction [8, 12]. Phase-resolved Doppler OCT decouples spatial resolution and velocity sensitivity in flow images and increases imaging speed by more than two orders of magnitude without compromising spatial resolution and velocity sensitivity [8, 12]. In phase resolved ODT, the phase information of the fringe signal can be determined from the complex analytical signal $\tilde{\Gamma}(t)$, which is determined through analytic continuation of the measured interference fringe function, $\Gamma(t)$, using a Hilbert transformation [8]:

$$\tilde{\Gamma}(t) = \Gamma(t) + \frac{\mathrm{i}}{\pi} P \int_{-\infty}^{\infty} \frac{\Gamma(\tau)}{\tau - t} \mathrm{d}\tau = A(t)\mathrm{e}^{\mathrm{i}\phi(t)}\,, \qquad (3)$$

where P denotes the Cauchy principle value, i is the complex number, and $A(t)$ and $\phi(t)$ are amplitude and phase term of $\tilde{\Gamma}(t)$, respectively. Because the interference signal $\Gamma(t)$ is quasi-monochromatic, the complex analytical signal can be determined by:

$$\tilde{\Gamma}(t) = 2\int_0^{\infty}\int_0^{\tau} \Gamma(t')\exp(-2\pi\mathrm{i}\boldsymbol{v}t')\,\mathrm{d}t' \exp(2\pi\mathrm{i}\boldsymbol{v}t)\,\mathrm{d}\boldsymbol{v}\,, \qquad (4)$$

where τ is the time duration of the fringe signal in each axial scan.

The Doppler frequency shift f_n at nth pixel in the axial direction can be determined from the average phase shift between sequential A-scans. This can be accomplished by calculating the phase change of sequential scans from the individual analytical fringe signal [8]:

$$f_n = \frac{\Delta\phi}{2\pi T} = \frac{1}{2\pi T}\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\left[\tan^{-1}\left(\frac{\mathrm{Im}\,\tilde{\Gamma}_{j+1}(t_m)}{\mathrm{Re}\,\tilde{\Gamma}_{j+1}(t_m)}\right) - \tan^{-1}\left(\frac{\mathrm{Im}\,\tilde{\Gamma}_{j}(t_m)}{\mathrm{Re}\,\tilde{\Gamma}_{j}(t_m)}\right)\right]. \quad (5)$$

Alternatively, the phase change can also be calculated by the cross-correlation method [8]:

$$f_n = \frac{1}{2\pi T}\tan^{-1}\left(\frac{\mathrm{Im}\left[\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\tilde{\Gamma}_j(t_m)\tilde{\Gamma}^*_{j+1}(t_m)\right]}{\mathrm{Re}\left[\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\tilde{\Gamma}_j(t_m)\tilde{\Gamma}^*_{j+1}(t_m)\right]}\right). \quad (6)$$

where $\tilde{\Gamma}_j(t_m)$ and $\tilde{\Gamma}^*_j(t_m)$ are the complex signals at axial time t_m corresponding to the jth A-scan and its respective conjugate; $\tilde{\Gamma}_{j+1}(t_m)$ and $\tilde{\Gamma}^*_{j+1}(t_m)$ are the complex signals at axial time t_m corresponding to the next A-scan and its respective conjugate; M is an even number that denotes the window size in the axial direction for each pixel; N is the number of sequential scans used to calculate the cross correlation; and T is the time duration between A-scans. Because T is much longer than the pixel time window within each scan used in the spectrogram method, high velocity sensitivity can be achieved.

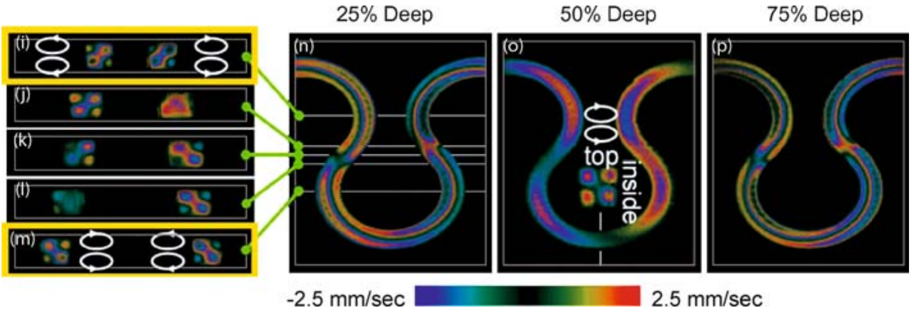
In addition to the local velocity information, the standard deviation of the Doppler spectrum gives the variance of local velocity and can be determined from the measured analytical fringe signal [8]:

$$\sigma^2 = \frac{1}{(2\pi T)^2} \times \left(1 - \frac{\left|\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\tilde{\Gamma}_j(t_m)\tilde{\Gamma}^*_{j+1}(t_m)\right|}{\frac{1}{2}\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\left[\tilde{\Gamma}_j(t_m)\tilde{\Gamma}^*_j(t_m)+\tilde{\Gamma}_{j+1}(t_m)\tilde{\Gamma}^*_{j+1}(t_m)\right]}\right), \quad (7)$$

The σ value depends on the flow velocity distribution. Variations in flow velocity will broaden the Doppler frequency spectrum and result in a large σ value. Thus, the Doppler variance image can be an indicator of flow variations and can be used to study flow turbulences. In addition, standard deviation imaging can also be used to determine the transverse flow velocity [8].

The significant increase in velocity sensitivity of phase resolved ODT makes it possible to image in vivo tissue microcirculation. Recently, the development of FD-OCT has significantly increased imaging speed and sensitivity. Combination of FD-OCT with the phase-resolved method has been demonstrated by a number of groups [8]. Because the dynamic range of the phase-resolved ODT depends on the speed of the line scans, Fourier domain ODT has an advantage over the time domain method in terms of imaging speed and velocity dynamic range [8].

ODT can provide cross-sectional imaging of channel geometry and flow velocity simultaneously. It has been used to measure osmotic mobility, quantify size of the scattering particle, and study flow dynamics of microfluidic devices of different materials, geometry, junction, and surface treatment [8, 13]. ODT has also been used to image and quantify two-phase flow and flow mixing [8, 9, 14, 15]. An example of ODT applications to simultaneously image and quantify the secondary flow and mixing pattern in microchannels is shown in Fig. 6 [15]. Aqueous suspension of polystyrene beads with a diameter of 0.2 μm and concentration of 20.5 mg/cc was injected into both inlets of the Y branch device of a meandering microchannel with a square cross section as shown in Fig. 3. The probe beam of the FD-ODT was adjusted to be approximately perpendicular to the plane of the microchannel (x-y plane). Because primary flow is in the x-y plane and the probe beam is in the z direction, ODT is not sensitive to the primary flow in such a probe configuration. Consequently, only the secondary flow will contribute to the Doppler signal. The z-component of the secondary flow velocity $V_z(x, y, z)$ was imaged and quantified with FD-ODT. Fig. 6i–m shows cross-sectional mapping of secondary flow velocity $V_z(x, z)$ in the x-z plane at different y positions as indicated. The velocity field at x-z plane shows a pair of counter rotating vortices. Since the curvature is alternating, the rotational direction of the vortices is also alternating as shown by comparing Fig. 6i–m. Figure 6n–p shows cross sectional mapping of secondary flow velocity $V_z(x, y)$ at different z positions. Alternating flow direction of the secondary flow at different depth in the x-y plane can be clearly visualized. The inset in Fig. 6o is a cross-sectional mapping of secondary flow velocity $V_z(y, z)$ in the y-z plane at the center of the channel as indicated by the white line. The velocity field at the y-z plane shows a pair of counter rotating vortices. This result clearly demonstrates that ODT can be used to image and quantify secondary flow [15].



Optical Coherence Tomography and Optical Doppler Tomography, Figure 6 ODT images of secondary flow in a meandering square micro-channel as shown in Fig. 3. The measured z components of the flow velocity $V_Z(x, y, z)$ in the area of interest was projected into different cross-sectional planes, where the z axis is perpendicular to the micro channel plane (x-y plane) and along the direction of the ODT probe beam. (**i**)–(**m**): cross-sectional mapping of secondary flow velocity $V_Z(x, z)$ at different y positions. (**n**)–(**p**): cross-sectional mapping of secondary flow velocity $V_Z(x, y)$ at different z positions (depth). Inset (**o**) is a cross-sectional mapping of secondary flow velocity $V_Z(y, z)$ at the center of the channel as indicated by the white line

Future Directions for Research

OCT and ODT are rapidly developing technologies with many potential applications for imaging and quantifying microfluidic flow dynamics in BioMEMS devices. New developments in all components of an OCT/ODT system, including light sources, detection electronics, and phase resolved processing algorithms can further increase imaging speed and sensitivity. Given its non-invasive and non-contact nature and exceptionally high spatial resolution and velocity sensitivity, OCT/ODT will be a powerful metrology tool for investigating complex flow dynamics in various bioMEMS devices that involve microfluidics.

Optical traps

Definition

Optical tweezing is the stable three-dimensional trapping of dielectric substances by the creation of strong light intensity gradients such as by focusing a laser beam to a diffraction-limited spot. Although originally created using counter-propagating laser beams, most optical tweezers today use a single beam of laser light which is focused to a diffraction-limited spot, the spot being the trapping zone.

Overview

Optical trapping refers to the manipulation of extremely small objects using forces generated by light. The field was pioneered by Arthur Ashkin in the 1970s at Bell Labs. His groundbreaking work demonstrated that forces generated by light could capture micrometer-sized particles in a stable three-dimensional trap. Although Ashkin in his early work used counter-propagating laser beams to capture such miniature particles, present day optical traps generally employ only single laser beams. What exactly causes particles to get 'caught' in laser beams depends on the size of the particle, and different theories have been developed to explain the existence of trapping forces according to particle sizes. Diverse mechanisms for the phenomenon exist because of the extremely wide range of particle sizes that have been captured. Atoms, macromolecules, micrometer-sized beads and entire cells, such as viruses, have been shown to be capable of being optically trapped. The mechanisms not only depend on the particle size but also on the wavelength of laser used.

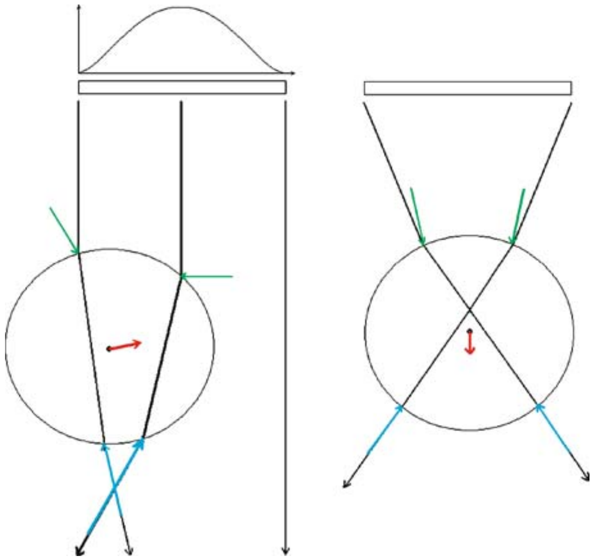
Optical trapping in all cases requires a gradient to be present across the cross-section of the light beam and wavelength control is often necessary in case of biological particles. Lasers, which are strongly monochromatic light sources with a Gaussian intensity profile across the cross-section, are ideal candidates for such purposes. The trapping of micrometer-sized particles is explained with regards to forces arising from the change in momentum of light passing through particles. The momentum change requires a force to be exerted on particles and these forces have transverse (radial) components which confine a particle to a domain. In normal circumstances such forces would be too small to be of any significance but they become increasingly important at lower length scales. These forces are usually in the piconewton range and are large enough for small particles to cause a change in their motion. Also, such a net non-zero transverse trapping force on a particle exists only for a gradient-based light source.

Application of this technology has been extremely wide and varied. The 1997 Nobel Prize in Physics was awarded to scientists who developed methods to cool and trap atoms with laser light. Researchers have used such traps/tweezers to manipulate a whole gamut of particles. The advantages laser tweezers offer over most other confining methods is the non-invasive nature and that the particles only need to have a different refractive index compared to the surroundings for the trap to work. Non-invasiveness can be a critical factor when dealing with biological particles where remote-execution is desirable.

Basic Methodology

Theoretical Principles

To trap a particle in three dimensions with a single beam requires the spatial variation of the light to satisfy two important conditions. The first requirement is that an intensity gradient in the direction perpendicular to the opti-



Optical Tweezers for Manipulating Cells and Particles, Figure 1 On the left-hand side the radial gradient force is illustrated for a particle near the axis of a Gaussian beam. The right-hand side depicts the axial gradient force acting on a particle near the focus of a divergent beam. Red lines represent the gradient forces while blue and green lines represent the forces due to refracting and reflecting rays, respectively

cal axis be present in the beam. This radial intensity gradient is responsible for trapping in the radial direction of the beam and is inherent in most laser systems. Figure 1 shows how a ray of high intensity from the core of a beam contributes a greater degree to the trapping force than a ray of low intensity. In practice, a TEM_{00} mode laser beam is used because of the Gaussian intensity gradient present in such a laser beam. The radial stiffness of the trap depends primarily on the magnitude of the radial intensity gradient. The second condition required for three-dimensional, single-beam trapping is that the laser must be tightly focused, or highly divergent, in the region where trapping is desired. A divergent beam has an intensity gradient in the direction of the optical axis due to the variation in the cross-sectional area of the beam. Trapping in the axial direction can occur near the focus of a divergent beam due to this form of spatial variation, as shown in Fig. 1. Focusing a beam to create an axial intensity gradient large enough to trap particles is easily achieved using an objective lens of high numerical aperture (NA).

Gradient Forces: Mie and Rayleigh Regimes

Optical gradient forces are the fundamental physical phenomena responsible for optical tweezers. There exist two separate theories which accurately describe the origin of the optical gradient forces for two different physical extremes. These two physical extremes, known as the Mie and Rayleigh regimes, refer to the magnitude of the wavelength of the trapping laser with respect to the characteristic size of the particle being trapped. The Mie regime assumes wavelength of the impinging laser beam, λ, is much smaller than the size of the particle, s, so that a geometric approximation of the optics and Newton's third law of motion are all that is required for a quantitative description of the gradient forces. Photons from the laser beam undergo a change in direction when they are refracted or reflected, which constitutes a change in the momentum of the photons. From Newton's third law, the material causing this direction change experiences an equal and opposite change of momentum, which manifests itself in the form of an external force acting on the material, as seen in Fig. 1. Certain rays of light will contribute disproportionately to this external force compared to others in the presence of a spatial intensity gradient. Depending on their intensity and direction before and after interacting with the specimen, each ray will contribute to the external force to a varying degree. The sum of the forces applied by each photon being scattered or transmitted by the specimen is the gradient force which acts as a potential well to trap the specimen. The differential force contribution of a ray, dF, is given by Eq. (1), where n_1 is the refractive index of the surrounding medium and c is the speed of light in a vacuum [1]:

$$dF = \frac{n_1 R\,(I \cdot dA)}{c} \tag{1}$$

In Eq. (1), I and A are the intensity and area of the incident ray, respectively, and R is either the reflectance or the transmittance of the ray in question depending on whether the ray is being reflected or transmitted as it interacts with the trapped object. In Eq. (2), the gradient force, F_∇, is found by integrating dF over the surface of the specimen [1]:

$$F_\nabla = \int_s dF \tag{2}$$

This method is particularly useful – when implemented numerically for computing the gradient force for bodies of arbitrary shape.

The other physical extreme for which an accurate theoretical treatment exists is known as the Rayleigh regime. Here the size of the specimen is assumed to be much smaller than the wavelength of light; therefore geometric approximations are no longer adequate for describing the behavior of light. Calculation of trapping forces in the Rayleigh

regime requires an electrodynamics approach to calculate the optical forces. This approach assumes the gradient force arises from the fact that a dipole in an inhomogeneous electric field experiences a force in the direction of the field gradient. In optical tweezers, the laser induces a fluctuating dipole in a dielectric particle which interacts with the inhomogeneous electric field within the beam. In the presence of an electric field gradient, a dielectric particle with dipole moment, $\boldsymbol{p}$, will experience a force given by

$$\boldsymbol{F} = (\boldsymbol{p} \cdot \nabla)\boldsymbol{E} \tag{3}$$

This is done by treating the particle as a point dipole and using Maxwell's equations to solve for the electric field within the beam. It is convenient to analyze the trapping force in terms of two separate components: the scattering force, F_{scat}, and the gradient force, F_{∇}. The scattering force arises due to absorption and re-radiation by the dipole, whereas the gradient force arises due to the interaction between the induced dipole and the electric field. The dipole moment can be calculated by

$$\boldsymbol{p} = 4\pi n_2^2 \varepsilon_0 a^3 \left(\frac{m^2 - 1}{m^2 + 2}\right)\boldsymbol{E} \tag{4}$$

where $m = n_1/n_2$ is the ratio of refractive indices. The electric field vector for the lowest order Gaussian beam approximation is

$$\begin{aligned}\boldsymbol{E} = E_0 \frac{ikw_0^2}{ikw_0^2 + 2z} \exp(-ikz) \\ \cdot \exp\left[-i\frac{2kz(x^2 + y^2)}{\left(kw_0^2\right)^2 + 4z^2}\right] \\ \cdot \exp\left[\frac{(kw_0)^2(x^2 + y^2)}{\left(kw_0^2\right)^2 + 4z^2}\right]\end{aligned} \tag{5}$$

where k is the wave number and w_0 is the minimum radius of the beam. The gradient force acting on the dielectric particle is found by substituting Eqs. (4) and (5) into Eq. (3), which yields

$$F_{\text{grad}} = 4\pi n_2^2 \varepsilon_0 a^3 \left(\frac{m^2 - 1}{m^2 + 2}\right) \tfrac{1}{2} \nabla E^2 \tag{6}$$

where a is the radius of the trapped sphere [2]. The scattering component of the optical forces must be calculated in order to find the total trapping force. The scattering force, F_{scat}, is equal to the energy density of the electromagnetic wave impinging on the scattering cross section, C_{scat}, of the sphere. The scattering force and cross-section are found using Eqs. (7) and (8) [2]:

$$F_{\text{scat}} = \left(\frac{n_2}{c}\right) C_{\text{scat}} I(x, y, z) \tag{7}$$

$$C_{\text{scat}} = \tfrac{8}{3}\pi (ka)^4 a^2 \left(\frac{m^2 - 1}{m^2 + 2}\right)^2 \tag{8}$$

The total trapping force acting on the trapped sphere is the sum of the trapping and scattering forces:

$$F_{\text{total}} = F_{\text{grad}} + F_{\text{scat}} \tag{9}$$

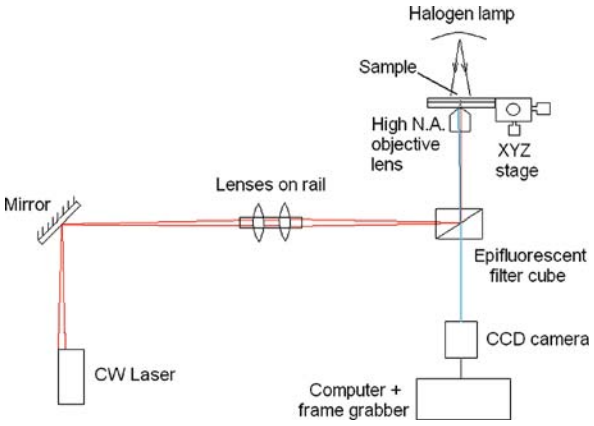
The theoretical treatments described above are very accurate for the extreme cases to which they apply. Unfortunately, most practical cases fall in the intermediate regime where the wavelength of the incident light is roughly the same size as the trapped particle. This intermediate case requires more complex theoretical models and is currently an area of interest for researchers.

Experimental Principles

As discussed earlier, single optical traps are characterized by a single laser beam focused to a high diffraction-limited spot using a high-magnification lens. The lens usually is the objective lens of a microscope, which serves to integrate the imaging and trapping systems. The imaging can serve as a data acquisition system, a monitoring system and a positioning device which helps focus the trap onto the region of interest. As stated before, optical traps have become an important tool for very diverse activities and as such have undergone numerous modifications to suit those diverse activities. The simplest form of optical trap consists of the following optical components.

Laser

The laser is the basic and most important component of the trapping system. Lasers are perhaps the most easily available sources of highly collimated, high-energy and monochromatic light beams. Also the transverse intensity gradient provides the necessary means to capture micro/nanoparticles. Being such an important component of the setup, the laser needs to be selected properly, the selection being based on a number of factors. These factors are usually output beam shape, beam astigmatism, power and wavelength. The most important requirement is that the output beam should be single mode (Gaussian TEM_{00} mode). This ensures that the beam is focused, by the objective lens, to the smallest beam diameter thus producing the



Optical Tweezers for Manipulating Cells and Particles, Figure 2 A typical experimental setup for optical trapping. The lenses on the rail focus the beam onto a diffraction-limited spot and the epi-fluorescent cube filters the unwanted part of the spectrum and hence enhances image quality

most efficient trap. Beam astigmatism also prevents convergence of the laser beam to a small spot and hence needs to be eliminated if present before the laser is deployed. The maximum power of the laser and the final output power determine the maximum attainable strength/stiffness for the laser trap. The required wattage is usually calculated allowing for the losses and taking into account the actual power required for trapping an object. The actual trapping power required might not be easy to calculate and in many cases a review of existing literature should give an order of magnitude estimate. A laser power of the order of 20 – 100 mW is usually sufficient for many basic trapping experiments. The wavelength is another important parameter when it comes to trapping biological specimens. For non-living objects any part of the spectrum works fine but the visible region is usually preferred due to the relative ease in aligning the various other optical components. There is a broad consensus that when dealing with biological elements infrared lasers should be used. The primary concern behind using a laser with an emission peak in the visible spectrum is possible "opticution" (death by light). Such opticution was first observed by Ashkin [3] when working with viruses and bacteria. Even if low-power lasers are used for trapping purposes, very high energy levels are developed due to focusing of the laser beam, and high absorption of the laser wavelength by biological specimens might lead to their extermination. There is a wide consensus that lasers in the infrared region are far less damaging to live biological specimens and the current choice of laser is the neodymium:yttrium-aluminium-garnet (Nd:YAG) laser and its close cousins [4, 5]. This is because of the low absorption of radiation of the infrared part of the spectrum by biological species in general, and wavelengths between 750 and 1000 nm are usually recommended. Nd:YAGs, although a popular choice, are more expensive compared to diode-pumped solid-state lasers. However usage of any infrared laser does not guarantee prevention of opticution and laser wavelength should be determined after a thorough literature survey.

Most of the lasers employed for trapping purposes are continuous-wave (CW) lasers but femtosecond lasers have also been shown to be effective for trapping purposes. Diode lasers are usually inexpensive but the beam quality usually necessitates correcting optics which adds to the cost and makes the optical train more complex. The output beam in the case of diode lasers is elliptical and also astigmatic. Symmetry can be restored by correcting with an anamorphic prism. Spatial filtering by pinholes or single-mode optical fibers can also achieve the same goal albeit with large losses.

Objective

The objective lens is another important component of the system and its use is primarily to focus the laser beam to a diffraction-limited spot. The objective lens is an influencing parameter with regard to the final trap stiffness and depends on its numerical aperture (NA) and transmittance. The NA is usually a measure of the light-gathering ability of a system and hence higher NA lenses are preferred. The lenses should be chosen so as to minimize the refractive index mismatch between the immersion medium and the trapping medium. Some of the higher NA lenses are oil-immersed while water-immersed lenses are also available. As aberrations have a degrading effect on the trap quality, the choice of objective lenses should be made judiciously [4]. In many trap setups the objective serves a dual purpose of trapping and viewing the particles.

Microscope

Inverted and upright microscopes have both been used for trapping purposes and usually integration with the trapping optics is straightforward. Single-beam trapping integrated with confocal microscopy has also been achieved. The microscope also serves as the imaging system which might be achieved visually or using a video-based system. Eyepieces can be used to view the sample or the light might be redirected by a dichroic to a CCD camera. Care has to be taken that the laser light is filtered out before it reaches either the eyepiece or the camera. Highly focused laser beams pose a serious hazard to the observer and hence should be removed using appropriate optical filters. Microscopes also enable different imaging techniques such as differential interference contrast and epi-fluorescence. Figure 2 shows such an arrange-

ment where an epi-fluorescent cube has been deployed for imaging. Like most other designs, it focuses a suitably expanded and shaped laser beam through a high-NA microscope objective. The laser beam is focused by an optical train to a diffraction-limited spot which is also the location for trapping particles. The optical path consists of lenses, directing mirrors and a filter cube, which is set up to specifically enable fluorescent imaging with a setup based on an inverted microscope. Bechhoefer and Wilson [6] and Smith et al. [7] discuss in detail the various practical and theoretical aspects involved in setting up a laser trap. The sample is held on an XYZ translational stage that serves to laterally displace the sample. The sample is illuminated using a halogen lamp placed directly above the sample, which can serve to provide the excitation frequency of the fluorescent microparticles. Finally, the image from the microscope is fed directly to a camera sensor. The microscope (not shown) is represented by the cube and XYZ stage.

Lenses and Other Trapping Optics

Lenses are required to expand the initial laser beam so that it totally fills the back aperture of the objective lens. Beam expanders can either be bought or constructed for specific use, by using individual lenses. The latter allows for the flexibility of a variable output if three lenses are used. Mirrors help to steer the beam. Other optics might be required depending on the specific task. Position detection might be achieved by a variety of techniques with each having its own merits and demerits. An exhaustive treatment of the same can be found in [4].

Key Research Findings

Since their invention, optical tweezers have proved themselves to be very powerful interdisciplinary tools. Today they are used extensively in biophysics, as they serve as delicate tools to manipulate and study single molecules of DNA [8, 9]. Optically trapped beads have been successfully used to measure local elasticities and viscosities, for example inside cells. Ashkin [5] provides an overview of the diverse uses of optical traps as an important tool in the important areas of research. Isolation and detection of sparse cells; concentration of cells from dilute suspensions; separation of cells according to specific properties; and trapping and positioning of individual cells for characterization are the key areas of research due to their possible impact. The non-invasive nature of particle manipulation being a key requirement, forces like hydrodynamic, optical, ultrasonic and electromagnetic have been employed for such purposes. Successful examples of the use of these optical forces for biological applications are determination of motility forces, 3-dimensional multi-gene detection and non-invasive optical sectioning of tissues [10] amongst many others.

Future Directions of Research

An optical trap behaves, at its simplest approximation, like a spring. The further a particle travels from the center of an optical trap, the greater the force it feels back to the center of the trap. Single optical traps make use of the Gaussian intensity profile in a laser to trap particles. Such traps are characterized by linear stiffness constants and hence the resulting potential well has a parabolic profile. Such systems are hence not suitable for creating arbitrary trap geometries. Fortunately recent technological advancements in holographic optical trapping have made possible generation of trap geometry based on individual preference and necessity. Optical tweezers implemented by SLMs are usually computer controllable which bestows upon them the important quality of being easily repeatable. The computer-driven liquid–crystal spatial light modulators create holograms, which correspond to various arrays of traps that can be designed, calculated and optimized on a computer. The traps can be controlled and reconfigured by writing these holograms on an SLM in real time. SLM optical traps have the advantage that they can switch traps independently. Such trapping systems show a lot of promise for future applications because of their many advantages over single optical traps.

Definition

Optofluidics is the marriage of optics, optoelectronics and nanophotonics with fluidics. Such integration represents a new approach for dynamic manipulation of optical properties at length scales both greater than and smaller than the wavelength of light with applications ranging from reconfigurable photonic circuits to fluidically adaptable optics to high sensitivity bio-detection and analysis currently under development. In this article we present a comprehensive review of some of the emerging applications and technologies for optofluidics.

Overview

The capabilities in terms of fluidic control, mixing, miniaturization and optical property tuning afforded by micro-, nano- and electro-fluidics provides an ideal platform upon which to build versatile optofluidic devices. In this article we provide a general overview of some of the emerging applications of optofluidic technology. Providing a comprehensive overview of all the research in this field is outside the scope of this review. Rather we will provide a number of representative examples of the state of the art.

Basic Methodology

The basic methodology behind optofluidics is described in detail in the ►optofluidics – fluidics enabling optics, ►optofluidics – optics enabling fluidics and ►optofluidics – fabrication and integration techniques. Here we focus primarily on providing an overview of the some of the recent applications for optofluidics and refer readers to those articles for more detailed information.

Key Research Findings

Optofluidic Particle and Cell Sorting Techniques

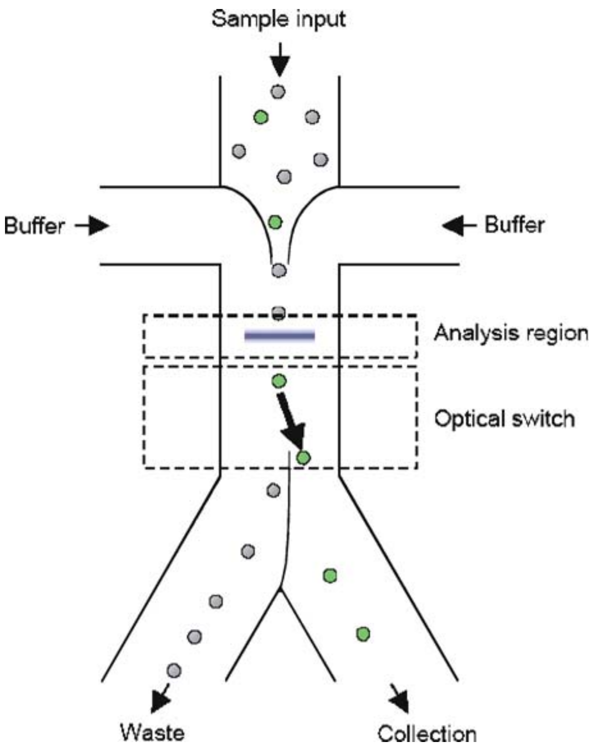
The discovery that laser radiation could transfer its momentum to microscopic particles and thus be used to manipulate them led to many innovative applications. Optical tweezing was a direct consequence of this and has been vastly refined over the years. Recently there have been various advanced implementation of such techniques to achieve optical control and sorting of particles into advanced and highly integrated microfluidic systems. These techniques range from traditional optical trapping (see a recent review by Grier [1]), to massively parallel handling of particles and cells using electro-optic tweezers, rotational manipulation of components based on form birefringence, to optical force based cell sorting. The advantage of these optical approaches lies in their ability to provide remote operation and handle individual particles directly as opposed to indirect manipulation of the surrounding flow field (as with electrokinetic and pressure driven effects).

Active Sorting

As an example of a direct device integration, Wang et al. [2] developed an optical force based cell sorting technique whereby radiation pressure was used to direct rare cells into separate streams following a green florescent protein (GFP) detection event. A schematic of the operating procedure for this device is shown in Fig. 1. The mixture of cells was made to flow through a microfluidic channel and was aligned into a narrow stream using hydrodynamic focusing. The initial alignment was such that these cells would flow into the waste outlet. Prior to this the cells were made to first pass through an interrogation region. If fluorescence was detected, indicating the presence of a target cell, the optical switch was activated and a focused laser spot was used to deflect the target cell laterally. This lateral displacement of the target cell caused it to follow a streamline which would carry it into the collection outlet. Sorting speeds as high as 200 cells per second were achieved.

Passive Sorting

Though very complex optical manipulations have been demonstrated in literature, the majority of these imple-



Optofluidics – Applications, Figure 1 Layout of the microfluidic sorting junction and the optical switch for the optofluidic cell sorter described by Wang et al. [2]. After being aligned to the center of the channel by flow focusing, cells are analyzed and then switched based on their detected fluorescence. Target cells are directed by the laser to the collection output while all other cells flow to the waste output. Figure and Caption reprinted with permission from Wang et al. [2]

mentations tend to be *binary*. This means that they rely on either the ability to trap or not trap a particle based on whether the conditions for trapping stability are met. Recently however a number of works have extended these ideas to exploit the dependence of this trapping potential on the particle properties, enabling much more advanced and subtle operations. As an example, Macdonald et al. [3] demonstrated an optical lattice technique where particles of different sizes were sorted into different streams depending on their strength of repulsion to regions of high optical intensity. The method relies upon the principle of a periodic optical gradient that is designed to deterministically guide smaller particles. The field is designed to temporarily trap small particles, while using hydrodynamic force to push particles out of the trapped state into an adjacent trapping location in the field. Careful planning of the periodicity of the field leads to a deterministic motion of smaller particles in a specified direction, while larger particles continue nearly unimpeded.

Optical Chromatography

In a series of papers, Imasaka and coworkers [4] provided the initial foundations for optically driven separation techniques, which they termed optical chromatography. The advantage of this technique lies in that it is the most sensitive technique known to date for separation of particles based on their size. Table 1 below compares various bio-analytical separation techniques, the operating principles behind the techniques and the dependence of the separation velocity on the particle radius a.
Work in this area has recently been extended by Terray et al. [5] who have recently integrated this into a microfluidic device format for pathogen detection, demonstrating very precise separation between very closely related bacteria *Bacillus anthracis* and *Bacillus thuringiensis* and millimeter scale separation. In their work a loosely focused laser beam propagates in a direction opposite to the fluid flow in the Poly(dimethysiloxane) (PDMS) channel. As a result of the difference in the optical forces on the cells they come to rest at different points along the length of the channel. At present however, such systems are practically limited by the fundamentals of the free-space optics on which they rely. Specifically, the light-particle interaction length is limited by either the focal depth or the spot size of the objective lens.

Evanescent Field Based Particle Trapping and Manipulation

Waveguide based optical structures serve to confine light within solid structures from the visible to the IR spectrum. A waveguide relies upon the principles of total internal reflection to confine light within the solid waveguide structure. Such confinement separates optical energy into guided modes and evanescent modes. While the guided modes represent the confined optical energy in the waveguide, the evanescent modes represent leaked optical energy, which exhibits an exponential decay as the distance from the waveguide surface increases. A waveguide trap/propulsion device is designed such that the evanescent mode interacts with particles to generate scattering/absorption and gradient forces which pull the particle towards the waveguide. There have been some experimental works of waveguide based particle propulsion. Gaugiran et al. [6] published a paper based on silicon nitride waveguide and demonstrated the trapping and propulsion of biological cells along these waveguides. The paper also presents the use of a finite-element analysis as a means of predicting the optical forces for a dielectric particle interacting with a waveguide. The difficulty with these waveguide techniques is that one is limited to interaction with

Optofluidics – Applications, Table 1 Comparison of Bioanalytical Separation Techniques

Technique	Operating Principle	Separation Velocity
Optical	Scattering and adsorption force dependence on particle size and refractive index. Driving force is intensity of EM field, $V_{op} \propto I$.	$V_{op} \propto a^5$ $V_{op} \propto (\varepsilon_p - \varepsilon_m)^2$
Electrophoresis	Differences in species charge to drag ratio represented by electrophoretic mobility. Driving force is electric field, $V_{ep} \propto E$.	$V_{ep} \propto \zeta \neq f(a)$ * (thin EDL) $V_{ep} \propto 1/a$ * (thick EDL)
Dielectrophoresis	Lorenz force dependence on particle size and polarizability. Driving force is the gradient of E^2, $V_{dep} \propto \nabla(E^2)$.	$V_{dep} \propto a^2$ $V_{dep} \propto (\varepsilon_p - \varepsilon_m)$
Centrifugation and Sedimentation	Differences in density. Driving force is gravitational or centrifugal acceleration field, $V_{cent} \propto g$.	$V_{cent} \propto (\rho_p - \rho_m)a^2 \approx a$
Size Exclusion Chromatography	Size dependence on permeability through packed column. Typically pressure is used as driving force, $V_{SEC} \propto \Delta P$.	$V_{SEC} \propto -\log(a^3)$ **

** Approximate, based on assumption of proportionality between hydrodynamic volume and molecular weight.

the evanescent mode which tend to be much weaker than direct interactions with the mode.

Optoelectronic Tweezers

As an alternate approach Chiou et al. [7] recently demonstrated massively parallel manipulation of single cells and microparticles using optical images. This was achieved by high resolution patterning of electric fields by projection of an optical image on a photoconductive surface. In these optoelectronic tweezers (OET), high resolution dielectrophoretic electrodes were patterned optically which enabled single cell manipulations and sorting. By varying the frequency of the AC signal applied between the two electrodes, one can switch between negative dielectrophoresis (DEP) and positive DEP regimes. Since the images used to pattern the electrodes are generated on a computer they can be dynamically modified in real-time. Thus this technique allows for highly parallel cell manipulations, sorting and trapping. The only limitation with this technique is that the resolution of the images that are projected on the photoconducting surface is fundamentally limited because of diffraction. As a result manipulation, with submicron resolution is not possible, though this is well below the precision required for cell based manipulations.

Optofluidic Imaging Techniques

At present one of the significant hindrances towards the development of fully portable, stand alone Lab-on-Chip devices, is the reliance on macroscale infrastructure such as pumps, power sources and most importantly external optics. To tackle the latter of these, Heng et al. [8] have developed an integrated optofluidic microscope (OFM) which integrates a high resolution imager, in the form of a slanted nanohole array, directly into a microfluidic network. Figure 2 provides an overview of the operating procedure for the OFM. The target object is made to flow through the microfluidic channel at a constant velocity using either electrokinetic control or pressure driven flow and confined to the center of the imager through upstream focusing. In the arrangement the imager consists of a slanted nanohole array defined in an opaque layer (typically aluminum) which spans the width of the channel. As is shown in the current arrangement the device is epi-illuminated and the transmission through the holes is monitored as the target flows over the imager. For the length of time the target flows over each individual well the transmission is reduced. Given that the flow rate is known the transmission traces can be used to reconstruct an image of the target. This technique enables the correct shape and size of the target to be extracted which should be sufficient for high speed phenotyping.

Using an entirely different approach, Kuiper and Hendriks [9] demonstrated a variable-focus liquid lens that has immense potential for application in miniature cameras and other optical devices. The lens consists of the meniscus between two immiscible liquids. In their experiment the two liquids were oil and water. By changing the curvature of this meniscus one can change the focal length of this liquid lens. To achieve this change in curvature they used the technique of electrowetting. Electrowetting refers to the phenomena of changing the interfacial contact angle between an electrolyte and solid through application of an applied potential difference. By varying this applied potential difference, the curvature of the fluidic lens could be continuously varied from convex to concave thereby adjusting the focal length of the lens.

Optofluidic Lasers

Another limitation of existing Lab-on-Chip devices is the inability to encorperate active optical components directly into the same inexpensive structure that contains the microfluidic components. As a result of the widespread adoption of PDMS as a material of choice for microfluidic systems, there has been a large thrust towards creating structures which can be easily cast into the soft elastomer fluidics and provide this more advanced functionality. One such example was presented by Li et al. [10] who demonstrated an optofluidic dye laser. In their implementation, a solution of Rhodamine 6G lasing dye in a Methanol, Ethylene Glycol solution is introduced into a microfluidic channel. The refractive index of the solution ($n = 1.42$) is slightly higher than that of PDMS (1.406) at visible wavelengths so that the dye solution and PDMS act as the core and the cladding of an optical waveguide respectively. To provide the feedback mechanism, a Bragg grating is fabricated on the sidewall of the channel. Tunable laser output can be obtained by either changing the index of the dye solution or mechanically varying the grating period. In this work, lasing was demonstrated around the 585 nm point. Such lasers would be of great interest for on-chip spectroscopy and cell sorting applications.

Liquid Core Waveguides

Liquid core waveguides are of great importance in the field of optofluidics since they allow the optical and fluidic structures to be fundamentally intertwined. Recently Yin et al. [11] have demonstrated such a liquid core waveguide which works on the principle of antiresonant reflecting optical waveguides (ARROW), see Fig. 3. ARROW waveguides with solid cores have been used for semiconductor lasers and other applications in the past. The technique uses multiple layers of materials of precise thicknesses as cladding such that an antiresonant Fabry–Perot reflector is created causing the light at the design wavelength to reflect back into the core. Silicon nitride and silicon dioxide are used as the cladding layers because of their compatibility with microfabrication techniques and the potential for integration with silicon-based electronics. The cladding layers are deposited over a sacrificial layer that is later etched away to create a rectangular shaped hollow core. This hollow core can be filled with liquids or gases and has shown exceptional promise for low level, single molecule detection in fluidic systems. The architecture is also amenable to massively parallel integration by creating numerous waveguides on the same chip.

Another approach towards creating liquid core waveguides was demonstrated by Wolfe et al. [12]. They managed to manipulate light in waveguides comprising of a liquid core and a liquid cladding. These waveguides are dynamic and can be reconfigured and adapted in a continuous manner which is a big advantage over solid-state waveguides. The liquids are introduced into a microfluidic channel in such a manner so that the higher refractive index core liquid is sandwiched between two sheaths of the lower refractive index cladding fluid. Thus the light is guided via total internal reflection within the liquid core. Since the flow is laminar the liquid-liquid interface is optically smooth resulting in low optical losses. By varying the rate of flow and the fluid compositions the characteristics of these optical systems can be tuned.

Future Directions for Research

The technologies we have described above represent, in our opinion, those which show the most promise for future commercial development. Of what we have described here liquid lenses (such as that described by Kuiper and Hendriks liquid lenses [9]) are likely the closest to being mass produced and broadly commercially available. Though less well developed at present the other optofluidic imaging techniques may also serve to solve some of the fundamental downsizing challenges (those related to imaging) which have to date largely prevented the demonstration of a truly portable Lab-on-Chip. The inherent advantages of optical chromatography coupled with the very large size of the bio-analytical separations market seem to suggest that this could hold commercial potential in the near future.

Photofluidics

Definition

Optofluidics is the marriage of optics, optoelectronics and nanophotonics with fluidics. Such integration represents a new approach to the dynamic manipulation of optical properties at length scales both greater than and smaller than the wavelength of light. Broadly speaking optofluidic devices can be split into two distinct classifications: optics enabling fluids and fluids enabling optics, the latter of which is the focus of this article.

Chemical and Physical Principles

The concept behind optical devices which incorporate liquids as a fundamental part of the optical structure can be traced at least as far back as the 18th century where rotating pools of mercury were proposed as a simple technique to create smooth spherical mirrors for use in reflecting telescopes. Modern microfluidics has enabled the development of a present day equivalent of such devices, the development of which we now refer to as Optofluidics. As will be described below, the capabilities in terms of fluidic control, mixing, miniaturization and optical property tuning afforded by micro-, nano- and electro-fluidics combined with soft lithography based fabrication provides an ideal platform upon which to build such devices.

Broadly speaking optofluidic devices can be classified into two distinct categories: *Optics enabling Fluidics* and *Fluidics enabling Optics*. As mentioned above in this article we focus on the latter of these two and refer readers to the ►optofluidics – optics enabling fluidics article within this encyclopedia for more detail. In this article we begin by describing the core fluid dynamics which describe the transport of fluids and behavior of interfaces in optofluidic devices. In the key research findings section we describe in detail the core advantages and applications of optofluidic devices (specifically looking at adaptive optics, biosensor and thermal stabilization). Following that provide a detailed example of the application of optofluidics to the tuning of photonic crystal circuits at the 200 nm scale.

The Fluid Dynamics of Optofluidic Devices

In the broadest sense, optofluidics involves the manipulation of the optical properties of a system using fluidics and conversely the manipulation of fluidic properties of a system with optics. It is thus is inherently concerned with both the optical and thermophysical properties of the fluid and the dynamics of how both the optical and flow fields change in response to external stimuli. In this section we will provide a brief overview of some of the fluids of particular interest in optofluidics and some of their important optical and thermophysical properties. The following subsection will provide a brief overview of the relevant microfluid dynamics with a focus on the issues of relevance to optofluidics.

Optofluids

Table 1 provides an overview of a small sampling of liquids of the relevant properties for a few common optofluidic liquids. Note that this represents a non-comprehensive list, other parameters of particular interest include: fluid–fluid surface tension, fluid–solid surface energy, contact angle, fluid–solid electroosmotic mobility, compatibility with soft elastomers (or other materials of interest), and numerous others.

Optofluid Dynamics

On length scales relevant to optofluidic devices (between 10 nm and 5 mm), fluid flow and species transport can be accomplished using numerous different techniques, a few of which include: traditional pressure driven flow, electrokinetic transport, buoancy, magnetohydrodynamics, capillarity, electrowetting and thermocapillarity (see Stone et al. [1] for a comprehensive overview). In general all flows can be classified as either body force driven (as in the former four of those listed above) and surface force driven (as in the latter three). Although examples exist to the contrary in general body force driven flows have been more successfully exploited in confined channel geometries, whereas free surface techniques are more popular for discrete droplet techniques. It is important to note that this statement is a general trend and by no means a rule (as capillarity, electrowetting and thermal manipulation of surface forces have all been used in channel driven geometries).

In either case fluid motion is governed by the momentum (Navier-Stokes) Eq. (1a) and continuity equations Eq. (1b) shown below,

$$\rho\left(\frac{\partial \boldsymbol{v}}{\partial t}+\boldsymbol{v}\cdot\nabla\boldsymbol{v}\right)=-\nabla p+\eta\nabla^2\boldsymbol{v}+f\,, \tag{1a}$$

$$\nabla\cdot\boldsymbol{v}=0\,, \tag{1b}$$

where $\boldsymbol{v}$, t, p, η, and ρ are velocity, time, pressure, viscosity and density respectively and f represents an applied body force. Though it is beyond the scope of this paper to provide a comprehensive review of the equations for all transport mechanisms mentioned above we will provide

a brief overview of some of those mechanisms which may be most appropriate for optofluidics.

Pressure driven flow, for which f is zero in Eq. (1a), tends to be the simplest transport mechanism to implement and is accomplished by applying a mechanical pressure difference between an inlet and an outlet port. For the simplest case of pressure driven flow in a microchannel with low aspect ratio it can be shown that the average velocity in the channel is described by Eq. (2) below,

$$v_{\text{ave}} = \frac{h^2}{12\eta}\nabla P\,, \tag{2}$$

where h is the channel height. The geometric dependence of velocity shown in Eq. (2) represents the most significant weakness of pressure driven fluidics in that as one approaches the nanoscale the flow velocity either becomes debilitatingly small or the required pressure exceedingly high.

Alternatively a different transport mechanism can be used which does not exhibit such a fundamental limitation. In electrokinetic transport results from the interaction of an externally applied electric field, $\nabla\phi$, with the net charge density ρ_e, in the electrical double layer (the body force term in Eq. (1a) becomes $f = \rho_e\nabla\phi$). The electrical double layer is a very thin region of non-zero net charge density near the interface (in this case a solid–liquid interface) and is generally the result of surface adsorption of a charged species and the resulting rearrangement of the local free ions in solution so as to maintain overall electroneutrality. In general it can be shown that for electroosmotic flow in a channel with uniform properties Eq. (1a) reduces to a flat velocity profile (as opposed to the parabolic velocity profile associated with pressure driven flow) whose velocity is described by that below,

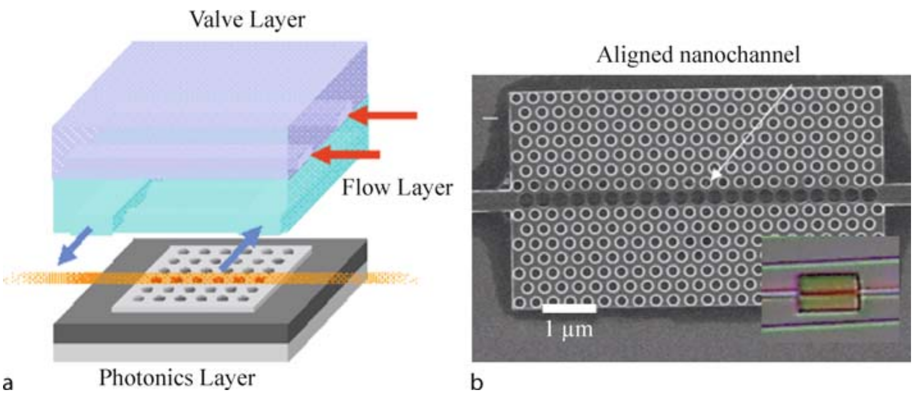
$$v_{\text{ave}} = \frac{\varepsilon_w\varepsilon_o\zeta}{\eta}\nabla\phi = \mu_{eo}\nabla\phi \tag{3}$$

where μ_{eo} is the electroosmotic mobility and ε_o and ε_w are the dielectric permittivity of a vacuum and the local relative dielectric permittivity (or dielectric constant) of the liquid respectively. In general μ_{eo} is of the order 10^{-4} cm^2/Vs and flow velocities on the order of 1 mm/s are achievable with applied potential fields of 1000 V/cm. The advantage of electrokinetic flow are that the flow velocity does not scale with channel height (outside the limit of double layer overlap and then only weakly until the extreme cases) and thus is more appropriate for nanoscale fluidics. The most significant disadvantage is that μ_{eo} is highly sensitive to the conditions at the solid liquid interface and is thus only applicable to a limited class of fluids, typically aqueous based solution. Even within this class μ_{eo} is strongly dependent with on ionic concentration and becomes exceedingly small in the high molarity (i. e. high refractive index) solutions listed in Table 1. Electrokinetics in high molarity solutions also tends to have other difficulties such as joule heating. The coupling of these effects complicates the use of electrokinetics for optofluidic devices.

As mentioned above, the other class of fluidic manipulation of particular interest in optofluidic applications are surface force driven techniques. In such techniques fluidic motion is induced applying an external perturbation to the equilibrium conditions at the interface between two phases. The normal stress conditions at the interface between two phases is described by Eq. (4) [2].

$$(p - \tau_{nn})_a - (p - \tau_{nn})_b = \sigma\left(\frac{1}{R_1} + \frac{1}{R_2}\right) \tag{4}$$

where the subscripts a and b represent the two phases τ_{nn} is the stress normal to the interface, σ is the surface tension and R_1 and R_2 are the principal radii of curvature. The applied perturbation, which most commonly is either electrically (i. e. electrowetting), thermally or chemically



Optofluidics – Fluidics Enabling Optics, Figure 1 Nanoscale Optofluidic Integration. Multilayer soft lithography is used to fluidically address and tune photonic structures at the nanoscale. (**a**) shows schematic of multi-layer soft-lithography coupling with nanophotonics. (**b**) SEM image of nanoscale precision fluidic addressability in a photonic crystal

based, induces a local change in either the surface tension or curvature (often observed as a change in the solid–fluid contact angle) which, from Eq. (4), in turn results in a pressure gradient and subsequent motion within at least one of the phases. While such techniques have proven extremely successful for both optical and Lab-on-Chip type devices, the activation energy required to overcome surface roughness tends to limit such effects to relatively large droplet sizes.

Key Research Findings

As mentioned above the focus of this section is to describe some of the core applications for optofluidic devices.

Optofluidics for Adaptive Optics

A key factor for high performance adaptive optical system is the capability to dynamically control either the physical layout or the refractive indices of the optical components. Recent advancements in optical MEMS technology [3] has provided significant functionality and flexibility to the former of these (e. g. optical switching and reconfigurable mirror arrays). Traditional techniques for manipulating the refractive index through the application of electric, acoustic or mechanical strain fields are limited in this respect by the achievable $\Delta n/n$, as is shown in Table 2. Optofluidics offers an order of magnitude jump in this quantity allowing for the development of an entirely new class of adaptive optical system in which, when combined with soft lithography based nanofluidics, the index of refraction can in principal be arbitrarily reconfigured at scales significantly smaller than the wavelength of light. At present modulation speeds for such tuning can be in the millisecond range but are ultimately limited by the viscous nature of the process and the mechanical actuation techniques that are popularly used. Alternative transport mechanisms such as electrokinetics (discussed in the following section) could be used to reduce the time response even further, though likely not to the scale required for high speed optical switching applications.

Optofluidics – Fluidics Enabling Optics, Table 2 Comparison of optofluidics with traditional optical tuning techniques

Technology	$O(\Delta n/n)$	Time response (s)
Optofluidics	**1**	$\mathbf{10^{-3}}$
Liquid crystal	0.1	10^{-3}
Injection current	0.02	10^{-9}
Temperature	0.02	1
Photorefractive	0.001	10^{-1}–10^{-5}
Electrooptic (10 kV/cm)	0.002	10^{-12}
Photoelastic/ Acoustooptic (10 W)	0.0001	10^{-6}–10^{-7}

Optofluidic Biosensors

The integration of microfluidics with optical detection techniques has been a field of active interest for several years (see Prasad [4] for an overview of optical biosensors and Erickson and Li [5] for an overview of integrated microfluidic devices). In addition to traditional florescence based detection, techniques relying on the incorporation of planar waveguides, evanescent wave fields or surface plasmons are particularly suitable for integration with microfluidics. While such techniques have proven exceptionally successful, a particularly fruitful path for future research in optofluidics is in the development of resonant cavity sensors. Such sensors can take advantage of the extremely high quality factor to mode volume ratios (Q/V) achieved in nanophotonic structures to perform single or few molecule sensing. The challenges here will be to not only develop techniques for deliver-

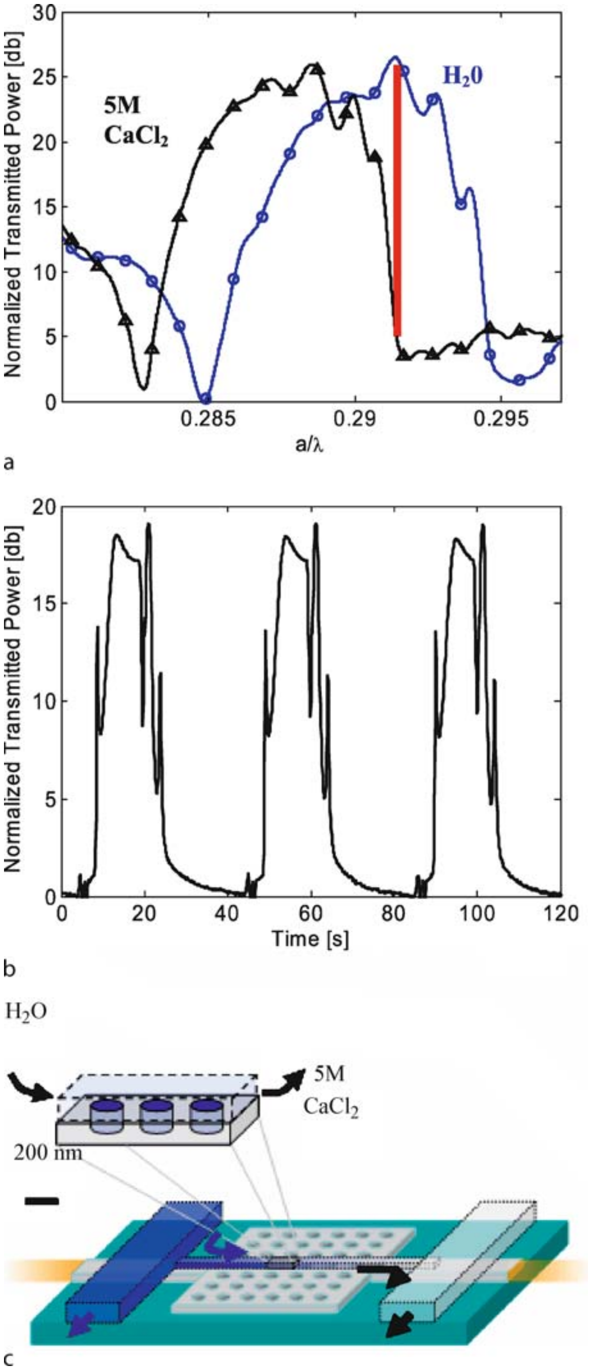
ing, attracting or concentrating bioentities into the resonant cavities, but being able to perform highly specific detection as well.

Optofluidics for Thermal Stabilization

The incorporation of liquids directly into the optical structure also has inherent advantages in terms of temperature stabilization. In general the heat transfer coefficient (which is the proportionality constant between heat rejection and surface temperature) for systems immersed in air ranges from 10 W/m^2K to 100 W/m^2K, depending strongly on the geometry and flow velocity. As a result of the higher density, specific heat capacity and thermal conductivity of water immersed systems, heat transfer coefficients typically range from 500 W/m^2K to 10,000 W/m^2K thus representing at least an order of magnitude decrease in the temperature rise for a given heat rejection requirement. It is important to note that while this represents a general rule for global heat transfer, more detailed modeling is required to accurately predict the local heat transfer enhancement.

Examples of Application

Since the emergence of optofluidics as a distinct field around 2002, a number of prominent examples of the fusion of these technologies have been developed including: liquid crystal infused photonic crystal lasers, fluid-fluid waveguides and florescent light sources, polarization independent fluidic switches, microfluidically tuned optical fibers and interferometers, and electrowetting based adaptable fluidic lenses and electronic paper. Rather than providing a cursory overview of these different devices in the limited space available here, we choose to focus on our recent work on nanofluidically tunable photonic crystal circuits [6] as a representative example. Readers looking for broader detail should consult the article within this encyclopedia entitled ► optofluidics – fabrication and integration or the recently published work by Psaltis et al. [7]. As mentioned above and shown in Table 2, at present techniques for local refractive index modulation in photonic structures are limited to the exploitation of relatively weak non-linearities, where $\Delta n/n$ on the order of 10^{-3} or lower. The consequence of this is that they require long interaction lengths, high operational power, or the incorporation of resonant elements to enhance the effect. The advantage of these techniques is that they can be, in general, applied locally to single devices (a necessity for device integration). Alternative techniques such as mechanical deformation, thermooptics, liquid crystal infusion and liquid-fluid infusion (amongst others) offer much higher effective $\Delta n/n$. At present, however, these methods rely on globally modifying the refractive index of the entire



Optofluidics – Fluidics Enabling Optics, Figure 2 TE-like transmission through photonic crystal with aligned nanochannel. (**a**) Shift in transmitted power spectrum when aligned nanochannel filled with H_20 ($n = 1.33$) and 5M $CaCl_2$ ($n = 1.44$) (**b**) Dynamic switching at $a/\lambda = 0.291$ (shown as *red line* in (**a**)) (**c**) Rendition of the switching process

device. Thus whereas local tunability over small interaction lengths requires the high $\Delta n/n$ afforded by these

global approaches, the ability to perform such manipulations with the sub-micron scale precision required for advanced photonic devices remains elusive. The development of such a technique could enable the creation of a new class of ultra-compact adaptable photonic circuits.

Nanofluidics provides a solution that enables both localized control and high refractive index modulation. As a first step in the development of two dimensional reconfigurable photonic circuits, here we demonstrate the nanofluidic addressing and tuning of individual defects within planar photonic crystals. Photonic crystals are attractive for controlling optical propagation by introducing pre-engineered defects into an otherwise regular lattice to create spectral filters, tight bend waveguides, resonant cavities and highly efficient lasers. Figure 1 outlines our approach which follows a three level nanoscale optofluidic integration architecture approach comprising of:

1. a nanophotonic level. Fabricated in silicon on insulator with the appropriate device structure.
2. a ► nanofluidic level, which serves to deliver fluids directly into the photonic structure and
3. a microfluidics control engine that performs all the major fluidic manipulations.

Assembly of the structure is performed by first defining the nanofluidic layer in positive relief on SOI and then defining the microfluidic structure on the same device using standard photolithography. At the same time a microscale valve layer is also defined in positive relief using photolithography on a separate silicon wafer. The two layers are then cast in PDMS, aligned and bonded together using standard multilayer soft lithography techniques [8]. The assembled fluidic structure is then aligned and bonded (through plasma oxidation) to the photonics layer. Using this structure fluids with different linear and non-linear optical properties can be infused directly into the nanophotonic structure with excellent precision and without significant leaking as shown in Fig. 1.

Figure 2 shows the normalized quasi-TE mode transmission through the photonic crystal with a fluidically modulated waveguide for DI ($n = 1.33$) water and 5M $CaCl_2$ ($n = 1.44$). The results show a shift in the peak transmission of the guided mode from $a/\lambda = 0.291$ to $a/\lambda = 0.289$ (corresponding to $\lambda = 1491$ nm and 1502 nm respectively) when the lower index liquid is displaced by the higher index salt solution. The high $\Delta n/n$ afforded by nanofluidic modulation demonstrated here enables consistently high contrast over a relatively wide range of wavelengths. Increasing the $\Delta n/n$ of the switching solutions would provide a greater shift in the peak transmission of the guided mode, however it would not provide for a much higher extinction ratio. Dynamic modulation of the transmitted power is demonstrated in Fig. 2 at $a/\lambda = 0.291$ by fluidically switching between the DI water and $CaCl_2$ solutions. For reasons described above, the modulation speed is inherently limited by the use of pressure driven flow. While the length of the nanochannels could be reduced the most fundamental limitation on the speed of such device is the nanochannel width section which is fixed by the lattice constant of the photonic crystal. Alternative fluidic transport mechanisms such as electroosmotic flow are mentioned above as a possibility, however here the low electroosmotic mobility of the $CaCl_2$ solution made such an approach not feasible.

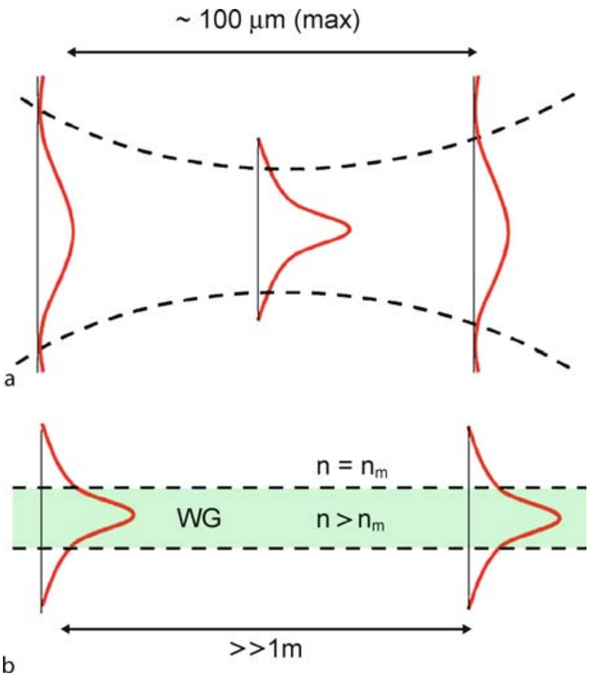
Definition

In the broadest sense, Optofluidics involves the manipulation of the local optical properties of a system using fluids and flow behavior and, conversely, the manipulation of fluids and particles within a flow through optical forces. The latter is inherently concerned with both the optical and thermophysical properties of the fluid and the dynamics of how both the electromagnetic and flow fields change in response to external stimuli. Optical forces used to manipulate fluid and particle behavior can arise either from focused beams in free space or from guided light confined to defined planar structures though total internal reflection. This emerging field of study is currently focused on the understanding of the fundamental coupling between optical dynamics and hydrodynamics, and developing methods to exploit the unique advantages optically derived forces have for micro and nanoscale systems.

Chemical and Physical Principles

The idea of using optical forces for particle manipulation was pioneered by Arthur Ashkin [1] in 1970, when he detailed the scattering and gradient force effects for small particles in the presence of optical energy. Since then, the field has developed to include many other methods to confine and move particles/fluids through the use of optical energy. The first experiments conducted using optical traps dealt with the manipulation of spherical beads within a stagnant liquid and the characterization of the forces observed acting on particles due to the presence of a focused laser beam [2]. With the development of microfluidics, experiments and studies of flow behavior could be conducted on scales similar to those on which optical phenomena occur. Thus, it becomes possible to study systems where coupled fluid and optical dynamics become important. The end goal is to develop nanoscale systems where optics can be exploited as a fundamental transport mechanism.

Free-space optical manipulation techniques in microfluidic systems have recently generated a significant amount of interest. Classically the advantage of these optical approaches lies in their ability to provide remote operation and handle individual particles directly as opposed to indirect manipulation of the surrounding flow field. The precision with which particles can be transported and separated with these optical techniques makes them particularly useful for bio-medical analysis devices. While extremely flexible and relatively easy to implement (see the section on ► optofluidics – applications and ► optofluidics – techniques for fabrication and integration), these systems are ultimately limited by the fundamentals of the free-space optics. Specifically, the light-particle interaction length is



Optofluidics: Optics Enabling Fluidics, Figure 1 Comparison between optical energy concentration for (**a**) free space and (**b**) a dielectric waveguide. WG = waveguide, n = refractive index

O

limited by either the focal depth or the spot size of the objective lens to usually a few hundred microns, as shown in Fig. 1. Using a more loosely focused lens with a larger spot size can increase the interaction length to as much as a millimeter. The intensity however scales with the square of the beam radius and as such relatively large optical power is required to perform manipulations over even these relatively small length scales.

A waveguide relies upon the principles of total internal reflection to confine light within the solid waveguide structure [3]. Though the light is confined to propagate in a single direction, an exponentially decaying component of the optical mode, known as the evanescent field, extends outside the waveguide. The degree of this extension depends on the refractive index contrast between the waveguide and the surrounding media, however is generally on the order of a few 100 nm for visible and near infrared light. The optical gradient in the evanescent field partially polarizes the particle near the waveguide, resulting in an extremely strong gradient force. This serves to attract the particle to the waveguide surface, where the electric field strength is highest. Waveguides for visible light can be fabricated from many types of materials and in different forms. For infrared light, silicon is a better material due to its relatively high transparency in the 1550 nm range and well defined fabrication methods. Planar waveguides are of

unique interest for optofluidics for the relatively simple methods for incorporating both microfluidic and optical elements on the same chip.

Optical Forces

There are three types of forces associated with electromagnetic fields, the scattering and absorption forces which account for radiation pressure, and the gradient trapping force. The scattering and absorption propagation forces can be physically described as the momentum transfer associated with the scattering and absorption of a photon from an incident electromagnetic source. For a dielectric particle, these forces can be described as an electromagnetic stress using the Maxwell stress tensor [4]:

$$\boldsymbol{F}_{\mathrm{EM}} = \oint_S \left(\langle \mathbf{T}_{\mathrm{EM}} \rangle \cdot \boldsymbol{n}\right) \mathrm{d}S \tag{1}$$

$$\mathbf{T}_{\mathrm{EM}} = \varepsilon\varepsilon_0 \boldsymbol{E}\boldsymbol{E} + \mu_0 \boldsymbol{H}\boldsymbol{H} - \frac{1}{2}\left(\varepsilon\varepsilon_0 \boldsymbol{E}\cdot\boldsymbol{E} + \mu_0 \boldsymbol{H}\cdot\boldsymbol{H}\right)\mathbf{I} \tag{2}$$

where $\boldsymbol{T}_{\mathrm{M}}$ represents the Maxwell stress tensor and $\boldsymbol{n}$ is the surface normal vector, $\boldsymbol{E}$ and $\boldsymbol{B}$ are the instantaneous electric and magnetic fields respectively, $\mathbf{I}$ is the identity tensor, ε_0 and μ_0 are the electric permittivity and magnetic permeability in vacuum and ε is the dielectric constant of the surrounding medium. It can be shown that the time averaged stress tensor then becomes,

$$\langle \mathbf{T}_{\mathrm{EM}} \rangle = \frac{1}{2}\,\mathrm{Re}\left[\varepsilon\varepsilon_0 \boldsymbol{E}(r)\boldsymbol{E}^*(r) + \mu_0 \boldsymbol{H}(r)\boldsymbol{H}^*(r) - \frac{1}{2}\left(\varepsilon\varepsilon_0 \left|\boldsymbol{E}(r)\right|^2 + \mu_0 \left|\boldsymbol{H}(r)\right|^2\right)\mathbf{I}\right] \tag{3}$$

where $\boldsymbol{E}^*$ and $\boldsymbol{H}^*$ represent complex conjugates. In Eq. (1) the integration is performed in a surface which encloses the particle of interest and returns the total electromagnetic force on the particle, including scattering, absorption and gradient forces. The latter of these physically results from the temporary polarization of a dielectric particle by the electric field. The instantaneous interaction of the dipole with a non-uniform electric field results in a force directed towards the high-intensity regions of the electric field.

Analytical Simplification: As mentioned above, the mechanism for propulsion in the proposed system is based on the summation of the scattering and absorption forces applied to a particle trapped, expressed most generally through Eq. (1) through Eq. (3) above. We can simplify these equations significantly by considering the case of a Rayleigh particle, as described by Svoboda and Block [7] (amongst others). For such a case we can derive analytical expressions for these forces given by Eq. (4a) and (4b) respectively,

$$F_{\mathrm{scat}} = \frac{8\pi^3 I_0 \alpha^2 \varepsilon_{\mathrm{m}}}{3c\lambda^4} \tag{4a}$$

$$F_{\mathrm{abs}} = \frac{2\pi\varepsilon_{\mathrm{m}} I_0}{c\lambda} Im(\alpha) \tag{4b}$$

where $\alpha = 3V(\varepsilon - \varepsilon_{\mathrm{m}})/(\varepsilon + 2\varepsilon_{\mathrm{m}})$, V is the particle volume, c and λ are the speed and wavelength of light, ε_{p} and ε_{m} are the dielectric constants of the particle and material and I_0 is the incident intensity.

Fluid Mechanics

The details of fluid mechanics on the micro- and nanoscales are well described throughout this encyclopedia and thus to minimize duplication here we will focus primarily on introducing the governing equations relevant to the remainder of our discussion. As is well known fluid motion is governed by the momentum Eq. (5) and continuity equations Eq. (6) shown below [8],

$$\rho\left(\frac{\partial \boldsymbol{v}}{\partial t} + \boldsymbol{v}\cdot\nabla\boldsymbol{v}\right) = -\nabla p + \eta\nabla^2\boldsymbol{v} + f\,, \tag{5}$$

$$\nabla\cdot\boldsymbol{v} = 0\,, \tag{6}$$

where v, t, p, η, and ρ are velocity, time, pressure, viscosity and density respectively and f represents an applied body force. Flow in channels with the low Reynolds number regime (which is almost exclusively the case in nanometer and micrometer scale confined geometries) is dominated by the diffusive transport terms, leading to the Stokes equation:

$$\nabla p = \eta\nabla^2\boldsymbol{v} + f \tag{7}$$

In optofluidic transport we are typically concerned with the interaction of the flow field with the transported species and thus the hydrodynamic quantity of interest is typically the total flow force on the particle. This is described by the integral of the normal component of the total stress tensor, $\mathbf{T}_{\mathrm{f}}$, around the particle boundary given by,

$$\boldsymbol{F}_{\mathrm{FLOW}} = \oint_s \left(\mathbf{T}_{\mathrm{f}}\cdot\boldsymbol{n}\right)\mathrm{d}S \tag{8a}$$

$$\boldsymbol{F}_{\mathrm{FLOW}} = \oint_s \left([p\boldsymbol{I} + \eta\nabla\boldsymbol{v}]\cdot\boldsymbol{n}\right)\mathrm{d}S \tag{8b}$$

where $\boldsymbol{n}$ is the surface normal. In the absence of any interaction with the confining geometry (which is commonly the case for free space optofluidics, but rarely the case for planar or waveguide based optofluidics) an analytical solution to Eqs. (8a) and (8b) is available in the form of Stokes drag law:

$$F_{\text{stokes}} = 6\pi\eta a U_0 \tag{9}$$

where U_0 is the particle velocity. Note that variants on Eq. (9) have been derived to account for the added influence of the channel side walls on the viscous drag (Faxen's law).

Key Research Findings

In this section we split recent research findings into two sections. In the first of these we will present a series of calculations illustrating the potential velocities achievable through optofluidic propulsion. In the second section we will discuss the trapping stability of a particle in an evanescent field subject to a cross flow.

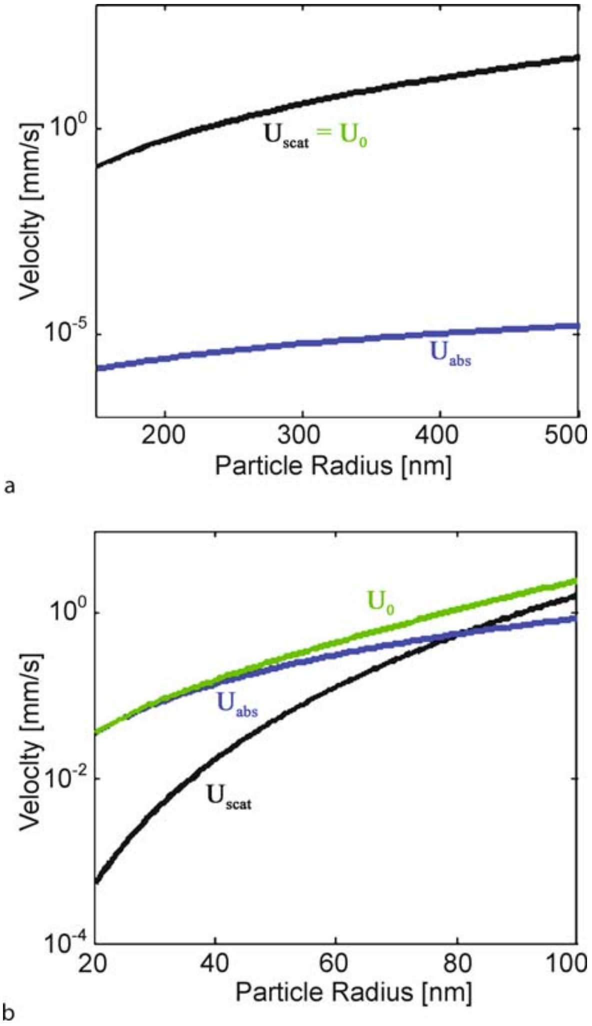
Propagation Velocity

When this particle interacts with an optical field, a certain percentage of the photons which flow through the system are either scattered (radiated in a random direction) or absorbed when they contact the particle. Each of these photons has a momentum given by Planck's constant multiplied by the frequency, $h\nu$. These scattering and absorption events result in momentum transfer to the particle and a net forward velocity which is proportional to intensity and impeded by fluid drag. By equating the scattering and absorption forces exerted by a Gaussian optical front, Eqs. (4a) and (4b) on a Rayleigh (i. e., sub wavelength) particle with Stokes drag, Eq. (9) we obtain,

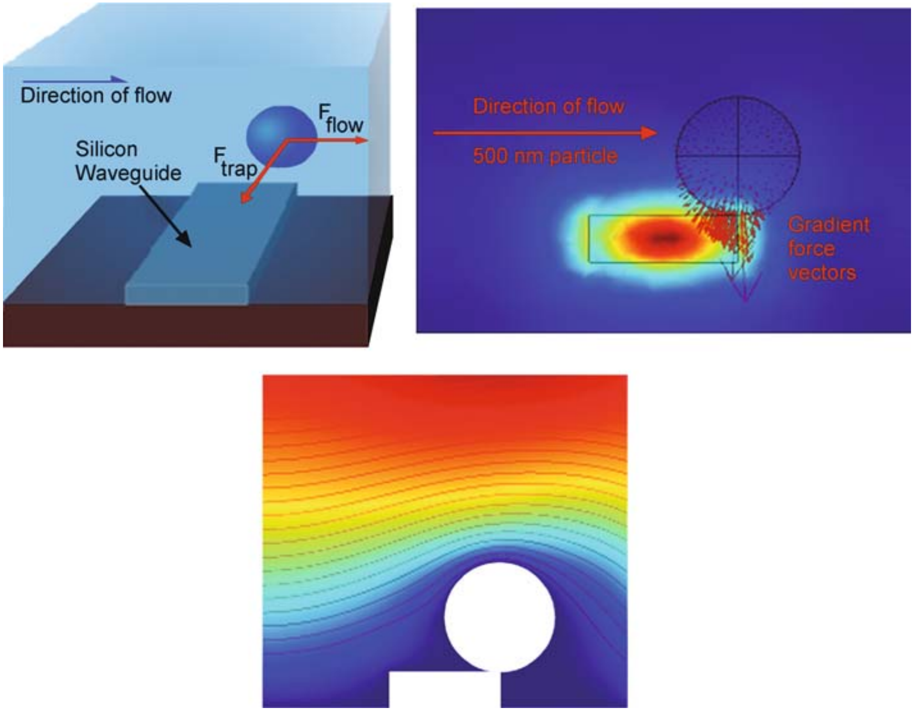
$$U_0 = \frac{\varepsilon_m I_0}{6ac\eta}\left(\frac{8\pi^2\alpha^2}{3\lambda^4} + \frac{2I\,m(\alpha)}{\lambda}\right), \tag{10}$$

In Eq. (10) the first term in brackets represents the scattering force and the second the absorption.

Figure 2 shows the computed propagation velocities from Eq. (10) for a (a) silica nano-particle ($\varepsilon_p = 2.4$), which is weakly absorbing, and (b) a gold nanoparticle, which is strongly absorbing ($\varepsilon_p = -80 + 10i$). From this figure it is apparent that at moderate optical powers, relatively high velocities are possible even at relatively long wavelengths (the scattering velocity scales with $1/\lambda^4$). Note that in the caption of Fig. 2 we refer to the peak intensity used to calculate the above ($0.8\,\text{W}/\mu\text{m}^2$) as being equivalent to 100 mW of power in a 200 nm by 600 nm silicon waveguide. For this comparison we have assumed an optimized system such that the peak in optical intensity occurs directly at the interface between the waveguide and surrounding medium (a technique developed by Ng et al. [9]). This comparison also ignores the influence of the surface on the drag force (see above) and this Eq. (10) is likely to overestimate the actual propulsive velocity for the waveguide system. This result however is accurate for the free space system and can provide some estimates of the expected performance for waveguide based propulsion. Also note that the absorption component of



Optofluidics: Optics Enabling Fluidics, Figure 2 Propagation velocity estimates for Silica (**a**) and Gold Nanoparticles (**b**) on a Silicon Waveguide. U_{abs} and U_{scat} represent the absorption and scattering components of Eq. (10) and U_0 is the summation of the two. Velocities are for calculated for a peak intensity of $0.8\,\text{W}/\mu\text{m}^2$ at 1550 nm. This is approximately equivalent to that obtainable for 100 mW of power in a 200 nm by 600 nm silicon waveguide shown in Fig. 3



Optofluidics: Optics Enabling Fluidics, Figure 3 Optofluidic architecture for waveguide based transport (**a**) diagram of fluid/electro-magnetic coupling at waveguide interface. (**b**) Cross Section of guided mode with arrows showing surface normal electromagnetic forces (Simulation is 3D). (**c**) Cross section image of the magnitude of fluid velocity along with calculated streamlines

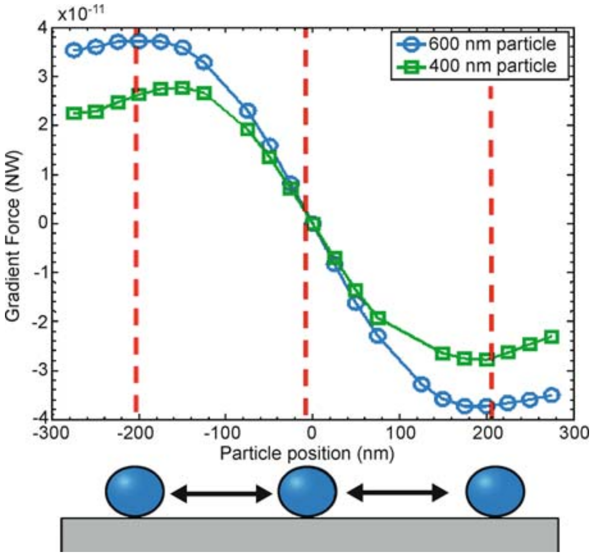
velocity for the silica particle results from the imaginary component of the dielectric constant of water at 1550 nm. For smaller absorping particles, such as gold, the scattering force becomes less significant below 100 nm and the absorption forces begin to dominate.

As mentioned above, in a waveguide system, the optical intensity (power/area) is governed by the geometry cross section of the waveguide which can be much smaller than the diffraction limit for a tightly focused free space spot (these calculations are done for the 200 nm tall waveguide shown in Fig. 3 which compares with the diffraction limited spot size which is on the order of 620 nm diameter). As such much lower optical power is required. At the same time the index contrast confines the energy over an indefinite spatial length. As this waveguide is made smaller the intensity increases and with it the net velocity. As such smaller devices have the potential for faster transport, which could impact emerging nanofluidic devices.

Particle Trapping in an Evanescent Field

Although estimates can be made regarding the propagation velocity of a particle once it has been trapped, one of the key questions which must be addressed in order for this to be a translated into a useful technology is the strength of the Lorenz trapping force compared with Brownian motion and the presence of a cross flow. We have examined this here by performing a series of numerical simulations that examine the waveguide/dielectric particle geometry shown in Fig. 3 subject to a pressure driven cross flow. As can be seen in Fig. 3b, the evanescent mode extends outside the waveguide decaying exponentially into the surrounding medium with a portion of it interacting with the particle. For the electromagnetic simulations, Maxwell's equations were solved for the electric and magnetic fields in the waveguide, and the forces on a spherical glass particle were evaluated using Eq. (1). Continuity of the electromagnetic equations are maintained for all internal boundaries, while the surrounding boundaries allow the flux of scattered light, as would be expected in a unbounded fluid medium. The inlet and outlet boundary conditions use the numerical solution from an eigenvalue solver used to determine the guided and evanescent mode profiles.

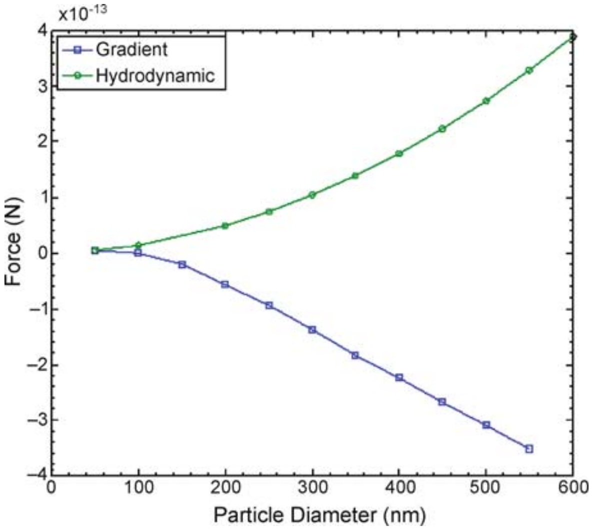
Simulation results for a glass bead of varying size were evaluated at different positions along the surface of the waveguide. The magnitude of the trapping force on a particle is determined largely by the size and position of the particle relevant to the evanescent field. As seen in Fig. 4,



Optofluidics: Optics Enabling Fluidics, Figure 4 Electromagnetic force on a particle as a function of position. Gradient force calculated for 600 and 400 nm spherical glass particles on a silicon waveguide. A critical maximum in the trapping force is observed for positions ~ 175 nm from the center of the waveguide

for a 600 and 400 nm glass bead, the strongest forces are 200 nm from the center of the waveguide. Note that the forces are directed towards the center of the waveguide, the region of highest intensity (as seen in Fig. 3b). The reason the maximum force does not correspond to the edge of the waveguide surface results from the size of the particle relative to the evanescent field and the radius of curvature of the particle. Smaller particles, and thus those which have a larger radius of curvature have a sharper peaks compared to larger particles. Additionally, the hydrodynamic force as a function of particle position can be considered. In the region from $x = 150$ to $x = 300$, where the critical trapping region would be, the hydrodynamic force on the particle remains constant with respect to position.

Simulations were conducted to determine the relationships describing the electromagnetic and hydrodynamic forces acting on a single sphere in the waveguide geometry. For particles ranging in size from 50 – 600 nm in diameter, the forces in the trapping direction acting on the particle were evaluated. Shown in Fig. 5, the gradient forces at the stable point with respect to size exhibit a near-linear relationship for particle sizes larger than 200 nm. This arises from the positioning of the particle at the edge of the waveguide, thus allowing large portions of the surface area of the particle to sample lower field intensities (in the region beyond the waveguide edge) relative to areas near the waveguide surface, creating a large gradient in the surface force profile. On the other hand, the hydrodynamic force



Optofluidics: Optics Enabling Fluidics, Figure 5 Gradient and Hydrodynamic Forces. Forces plotted for glass particle sizes from 50 to 1000 nm. Forces evaluated at edge of waveguide, as illustrated in Fig. 3

exhibits a non-integer power-law relationship. In the standard stokes drag scenario, the hydrodynamic drag on a particle has a linear relationship with respect to size, but this is in the presence of a uniform velocity field. In the presence of a parabolic flow profile, along with a waveguide geometry that serves to disturb the flow field, it is highly probable that a higher order relation exists in this case.

Photofluidic devices

Definition

Optofluidic devices integrate within themselves elements of microfluidics, optics, and electronics. Although methods for fabricating each of the components separately are reasonably well known, difficult challenges exist in developing architectures that enable the integration of all these functionalities onto a single device. Though approaches differ from device to device, the goal is to make fabrication as easy and affordable as possible. In this article we present an overview of the fabrication technologies and integration architectures for optofluidic devices. We will also discuss these techniques in the context of a sampling of the state of the art from the literature.

Overview

Choosing an appropriate fabrication process and integration architecture for optofluidic devices requires the designer to consider a number of different issues ranging from: material restrictions (e. g. optical transparency range, electrical insulation and compatibility with various fluids and functionalization chemistry), desired feature sizes (e. g. are features required on the same scale as the wavelength of light), power consumption, and of course cost (e. g. smaller feature sizes require more elaborate fabrication techniques and more careful handling and treatment of substrates increasing device cost). While these issues have been exhaustively examined independently within the electronics, optics/photonics and fluidics fields, it is unclear what the optimal device structure will be for optofluidics. For example it is reasonably well accepted that for disposable microfluidic devices, polymeric materials and fabrication techniques (such as elastomeric devices fabricated through soft lithography or hard plastic devices fabricated using embossing techniques) are likely to yield the most commercially viable products. This trend towards simplicity conflicts with the complex multilayer lithography and etching techniques commonly used in the electronics and integrated photonics industries. As such it is unclear whether the most fruitful path will be to develop a single fabrication technology that enables the incorporation of each of these elements or whether integration architectures should be developed which enable us to combine, for example, polymeric micro- and nanofluidic structures with silicon photonic devices.

The goal of this article will be to largely explore this question. In the "Basic Methodology" section below we will provide a brief overview of existing fabrication techniques, focusing on those of relevance to optical devices and microfluidics, followed by a discussion on integration techniques. To properly address integration methodology, several examples of optofluidic devices are presented in the "Key Research" section with their challenges and the advantages of techniques that were chosen.

Basic Methodology

As discussed above in this section we will begin by providing a brief review of fabrication techniques for optical and fluidic devices (we focus on these two here as they constitute the most fundamental aspects, electronics will be covered incidentally, but not directly). We will focus primarily on the different sets of tools required and, to a lesser extent, materials required for each. As will be described, the tools are closely interconnected with materials from which the components are made, as well as the sizes of features that are to be included in the optofluidic device.

Techniques for Optical Component Fabrication

Fabrication Procedures

The optical elements of optofluidic devices include such components as waveguides, photonic crystals, optical resonators and active components such as lasers. The order of magnitude of feature size for these elements can range from roughly the scale of the wavelength of light – hundreds of nanometers, to tens of microns or larger. For these smaller features (commonly required in single mode waveguides and photonic crystals for example) techniques such as electron-beam lithography (e-beam) or focused ion beam (FIB) are appropriate. Briefly for e-beam, a focused beam of high energy electrons is used to expose an e-beam resist which can subsequently be developed and the system etched so as to create features of sizes as small as tens of nanometers. Electron beam processes are well developed for silicon on insulator (SOI) type devices and represent

a good choice for fabrication of optical waveguides that include smooth bends or circular resonators. In focused ion-beam lithography, samples are bombarded with ions so as to directly etch features into the substrate. An important difference in FIB is that it has a much lower scattering, but a higher chance to damage sensitive electronics though similar feature sizes are available. The ultimate limitation of both e-beam and FIB fabrication procedures is that they are serial in nature and thus while suitable for device prototyping, they are not particularly useful for mass production. Photolithography, on the other hand, allows for much more parallel fabrication once an exposure mask is fabricated. There is a great variety of positive and negative photoresists available to achieve different feature heights. Though only cost effective for mass produced runs, state of the art fabrication lines can now reach feature sizes on the order of 100 nm and below.

Materials

The range of available active and passive optical materials is much too extensive to be described in detail and thus we will focus on the handful which are of broadest interest to optofluidics and separate them into those which are usable in the infrared and visible spectra. Within the former of these silicon specifically, silicon on insulator, tends to be the material of choice, primarily due to the well developed fabrication procedures, simplicity of integration with electronics and high refractive index. The underlying oxide layer serves to isolate the optical components but also as a convenient surface for biochemical functionalization. While generally compatible with most fluids, the conductivity of silicon can lead to some difficulties with electrically driven flow mechanisms such as electrokinetics.

A much more diverse set of materials is available within the visible regime for creating optical elements compatible with fluidics. In most cases devices are fabricated on either a glass or hard plastic base to facilitate photolithography steps and device handling; however techniques borrowed from the flexible optoelectronics communities are becoming more popular. For optical components, silicon nitrides are relatively popular due to the relatively high achievable refractive indices. Commonly however polymeric materials such as SU-8, PMMA and more recently PDMS are preferred due to the relatively easy fabrication procedures (SU-8 devices for example require only simple photolithography and developing steps, whereas silicon nitride devices require more complex etching steps) and slightly higher than glass refractive indices. Though often used to create multimode waveguides for delivering excitation light or capturing emitted light, because the index difference between these polymers and aqueous liquids, it is usually possible to create single mode devices without too much difficulty.

As mentioned above materials processing varies strongly from material to material as well. There are other numerous types or dry and wet etching that work for these different materials, each with its own unique characteristics. For example, reactive ion etches can create well defined, high aspect ratio features with straight, smooth sidewalls in numerous materials, but typically require much more handling and equipment. Wet etches are much simpler but less precise techniques that compatible with both silicon and glass materials. Because etching is time dependent, is it important to properly time the process to achieve appropriate depths. In chemical etching the materials can be layered, so that when the chemical reaches the next layer the process will stop.

In order to create micron scale mirrors or electrical functionality, evaporation of metals such as gold, chrome, titanium and silver are used [1]. The two types of vapor deposition are thermal evaporation, which works by physically boiling material, and sputtering, which includes ion bombardment. Although sputtering works on a much larger variety of materials, it is slower and more expensive than evaporation and, thus, should be used when precision counts or choice of material requires it.

Techniques for Fluidic Component Fabrication

At the onset of modern microfluidics in the early 1990's glasses, quartz and silicon were the materials of choice for microfabrication, primarily due to the well established wet etching and lithography based micromachining techniques developed by the electronics and semiconductor industries. Though silicon based devices found a variety of niche markets, particularly those that benefit from its high thermal conductivity, its high electrical conductivity proved to be a problem for the high voltages required for on-chip electrokinetic transport (as mentioned above). As such the first chips for electrokinetic processes such as capillary electrophoresis were typically constructed from glass which also offered good optical qualities, well defined surface chemistries and a high electroosmotic mobility (i. e. it supports a high ζ-potential). In general however high quality glass is reasonably expensive, at $\$\,4000/m^2$, and fabrication is very expensive, largely due to the costs associated with establishment and maintenance of clean room facilities. Additionally, usable structures must be thermally bonded to a cover plate made from a similar material at temperatures over 400°C, which precludes the possibility of incorporating a biological agent in to the chip prior to sealing.

As a result of these difficulties with traditional microfabrication materials and techniques, there has been a recent trust to manufacture microfluidic systems and biochips from low-cost polymeric materials such as poly(dimethsiloxane) (PDMS), poly(methylmethacrylate) (PMMA) and others. The primary attractiveness of these materials is that they tend to involve simpler and significantly less expensive manufacturing techniques (e. g. casting, injection and replica molding, or hot embossing), however they are also amenable to surface modification and the wide variety of physiochemical properties allows the matching of specific polymers to particular applications. While the development of these systems has reduced the time from idea to chip from weeks to days, and the per unit cost by a similar ratio, the low thermal conductivities inherent in these materials (0.18 W/mK for PDMS which is an order of magnitude lower than that of glass) retards the rejection of internally generated heat during electroosmosis (Joule heating).

Though there are many microfabrication processes for manufacturing microfluidic systems in soft polymers and hard plastics, one of the most promising is the Soft Lithography and Rapid Prototyping of Masters process developed by Professor Whitesides' group at Harvard University [2]. Through this process complex microfluidic systems can be manufactured in soft elastomer substrates (primarily PDMS) very rapidly and at a fraction of the cost or traditional glass manufacturing. After the initial investment in processing equipment, this technique can reduce the cost per custom microchannel system to several dollars per unit and reduce the lag time from several weeks (or months as outlined above) to 2 or 3 days. Briefly the process consists of producing positive, reusable, masters of the desired microfluidic design on a glass or silicon substrate, by first spin coating a film of photoresist onto the substrate, hardening it through a baking procedure, expositing it to UV light through a transparency mask containing the channel pattern, inducing cross linking of the polymers through a second bake procedure, then dissolving the unexposed portion of the film in a developer solution. PDMS replica molds of the channel design are then prepared by pouring the uncured liquid elastomer over the master and allowing it to cure in a vacuum oven. This yields a negative cast of the microchannel pattern in the PDMS slab. To form the enclosed, sealed chip the PDMS cast is typically plasma treated, aligned, and then placed in direct contact with either a glass substrate or another PDMS slab. Both the lithography mask and the final master can be reused multiple times with PDMS casting to mass-fabricate fluidic layers.

A slight extension of the above involves the use of glass or silicon as mask materials in various soft lithography techniques which can be used in fabrication of fluidic components as well as optical ones. Features as small as 30 nm can be achieved. An example is micro-transfer molding where a mold is filled with a polymer and is pushed against a substrate. The polymer is then cured forming structures on the substrate after the mold is removed. These structures of rectangular cross section can be used as waveguides in optical layers, or walls of microfluidic channels. The main disadvantage of soft lithography is its accuracy limit from thermal deformations.

Photolithography is probably the most widely used technique for making simple microfluidic devices or masters for embossing and casting of polymer devices. A combination of appropriate photoresist and an appropriate developer are needed to fabricate positive or negative relief fluidic channels. Despite its relatively low resolution achievable with photolithography, it is very convenient for channels with features sizes on the order of 2–5 μm or larger. For smaller features e-beam or FIB techniques (see above) are more commonly used. Currently there is a development to move away from placing a physical mask in proximity of the substrate with photoresist and instead use photomask created by a system of high resolution lenses. This will allow photolithography to work on non-planar surfaces.

Sealing of fluidic components to optical/electrical devices can be an issue, particularly when using pressure driven flow. High temperature bonding processes are often undesirable as they can damage electrical/optical devices or any biological functionalization which may be pre-deposited inside devices. Similarly bonding of hard fluidics (glass, silicon) to irregular surfaces is notoriously difficult. Fortunately, the technology has progressed in a direction such that a number of "optofluidically compatible" material systems have been developed. An example is wide use of PDMS because it is easy to bond with glass, silicon or other PDMS layers. Commonly air or oxygen plasmas are used to activate the bonding surface and expose the free oxygen in PDMS. Temperature treatments, such as baking or hot plates, rely on diffusion processes to bond materials. Similarly for PDMS under moderate temperatures, the polymer chains inside the two layers can inter-diffuse between themselves strengthening the bond.

Key Research Findings

Given the well developed fabrication techniques describe above, the key research directions on the fabrication side are focused on developing the techniques which integrate the optical and fluidic layers. Though this will be discussed below in the context of a series of case studies

we will also try to provide some global insight in each case. When it comes to choosing appropriate techniques and materials to fabricate these devices, it is important to make decisions based not only on equipment availability, but also on cost. Some of the devices presented below are successful because of their simplicity and cost efficiency. Here we focus on techniques for enabling the fusion of optical and fluidic layers, generally made from different materials, without deforming any of the components and preserving the function of the multilayer device.

Optofluidic Attenuator

The first device we will consider is the optical attenuator presented by Lin Zhu et al. [3]. The device is comprised of two layers, which can be used to reduce the power level of an optical signal in a waveguide. Thus, the two layers are an optical layer that contains straight waveguides with cladding, and a fluidic layer. An opening was made in the top cladding of the waveguides which is filled with a fluid from the fluidic channel on top of it. By changing the refractive index of the fluid occupying the cladding opening, it is possible to change the output power from the waveguides.

The optical layer is manufactured by first thermally growing silicon oxide on a silicon wafer to serve as the lower cladding, and then defining waveguides photolithographically in SU-8. Another photosensitive material serves as the top cladding with an opening defined by a second photolithography process. The fluidic channel is made from PDMS that is cast over a negative resist master fabricated by standard photolithography. To ensure the bonding of PDMS to the top cladding of the optical layer, the device is treated with high power oxygen plasma for 30 s and then baked for an additional 8 h. Experimental results included power output depending on the refractive index of the fluid in the channel and are in agreement with numerical simulations.

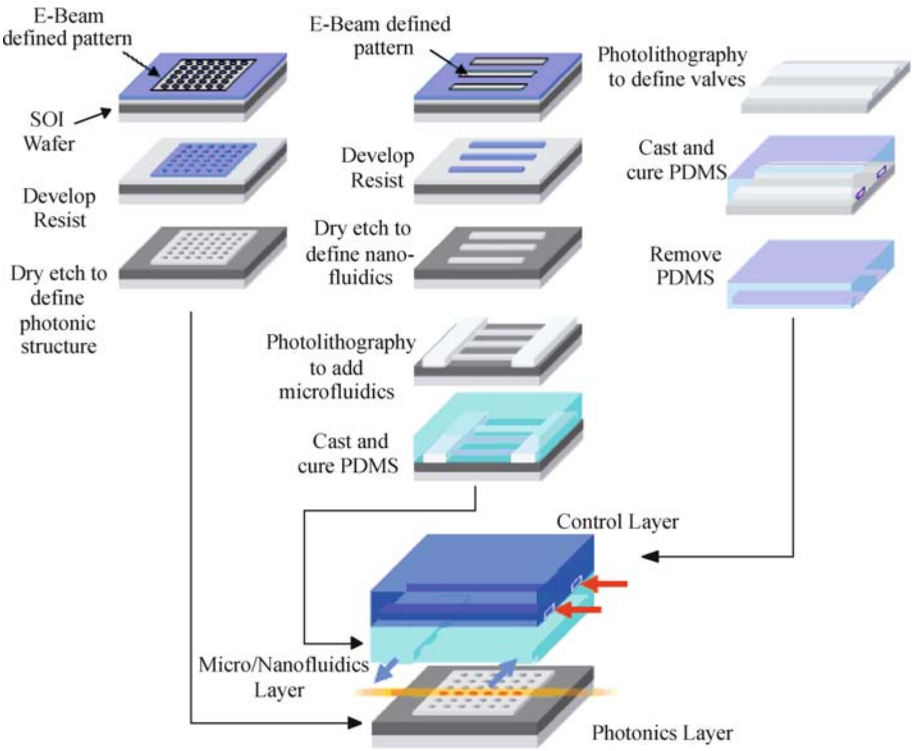
The fabrication is based mostly on soft photolithography, which is easy to facilitate and is very cost efficient. The device itself is simple to operate and reproduce. The materials used are completely inert, which is important when using chemically reactive fluids. The sizes of features make what is commonly a complex part of the fabrication process – alignment – relatively simple. Attenuation of optical signals is very sensitive to refractive indexes of the cladding materials. Thus, the main challenge in designing such a device is to allow for fabrication processes which will not only work with materials whose properties are well known, but also guarantee those properties remain relatively constant throughout the sampled volume.

Integration of Nanofluidics with Photonic crystals

A different type of optofluidic device was presented by Erickson et al. [4] and comprised of a silicon photonic crystal integrated with soft-lithography nanofluidics. A photonic crystal is a regular periodic array of varying dielectric constant that exhibits a bandgap (a range of wavelengths which cannot propagate within the structure). In the case of a silicon photonic crystal where the periodicity comprises of a series of nanoholes etched into the base silicon, the output power from the crystal and the range of the bandgap will vary depending on the refractive index of the fluids occupying the wells. The goal of the device developed in this paper was to address individual features within the photonic crystal.

This device consists of three layers: a photonic crystal layer, a nanofluidic delivery layer to deliver proper fluid into the photonic crystal structure, and a microfluidic control level to perform required fluidic manipulations. Photonic crystals have features on the order of a 100 nm and thus require electron-beam lithography for definition. The structure can then be dry etched in silicon-on-insulator substrate. In this case the nanofluidic level (which required similar feature sizes to those in the photonic crystal) was also fabricated in positive relief using e-beam lithography and the microfluidic structures (which had features closer to 10 μm) were superimposed using photolithography. Control fluidic layers were fabricated with standard soft lithography. In order to ensure that at least one channel is delivery layer is aligned with a photonic crystal, the spacing between the photonic structure is constantly varied. Immediately before the assembly of different layers, the whole device was exposed to a short duration air plasma treatment in order to aid with sealing. Figure 1 shows an overview of the device fabrication and integration techniques.

The incorporation of a multilayer microfluidic structure in this device allows for precise control of fluid delivery to the crystal. Thus, experiments require less fluid by volume and can steady state results faster (important for future sensing applications). Further integration with electric components can allow for electrokinetic trapping and other fluidic or sample manipulations. Compared to the previously discussed attenuator, this device requires a number of additional fabrication steps, including bonding between different types of materials, but it achieves versatility beyond its primary function. The final device allows for sub-wavelength usability. It is useful for very localized (sub-wavelength) control and modulation with high refractive indexes, but requires nanoscale flows, which take relatively long time to process.



Optofluidics – Techniques for Fabrication and Integration, Figure 1 Nanoscale optofluidic integration. Sample fabrication procedure for combining micro- and nanofluidics with nanophotonic structures

Label Free Biosensor

The above two devices functionally integrate optics and fluidics on the micro- and nano-scales respectively however the often cited goal of these optofluidic devices is the integration of binding reactions for biomolecular detection. An example of such a device is the label-free biochemical sensor based on a Mach–Zehnder interferometer developed by Blanco et al. [5]. A biosample occupies a chamber on one arm of the interferometer formed by a multilayer process. A waveguide in the chamber has an evanescent field which extends from it and the speed at which light passes through the waveguide arm depends on the refractive index shift caused by the presence or absence of a binding event at the waveguide surface.

The device is fabricated by bonding two separately prepared parts with multiple layers each. One part includes the interferometer with a waveguide as part of one arm. They are fabricated using photolithography on a silicon wafer. The waveguide surface has to be sufficiently pure in order for the evanescent field to interact with the fluid. Since photolithography usually leaves contaminants on the surface, the waveguide was treated with oxygen plasma. The other part consists of two temporary layers to allow for easy lift off and pealing, and an SU-8 layer on which the inlet and outlet holes are photo-patterned and developed. All of the layers of this part are transparent, so as to facilitate alignment. The materials are dehydrated on a hot plate to ensure good adhesion of the two parts.

Since the device is based on a Mach–Zehnder interferometer, the second arm is used to lower or eliminate external perturbations such as temperature fluctuations. This allows for higher accuracy and detection of smaller concentrations. The adhesion of different layers was good enough to sustain fluid pressure of up to 500 kPa. Several additional integration steps and choice of materials were made in order to satisfy this requirement. In general, this sensing mechanism is used to allow compatibility with complementary metal-oxide semiconductors (CMOS). This property, together with compactness of the device, makes it attractive for further integration with MEMs into a complete lab-on-chip device.

Integration of Fluidics and Semiconductor Lasers

The ultimate degree of optofluidic integration involves the integration of fluidics, passive and active optics, and electronics into a single device. The device presented by Cran-

McGreehin et al. [6] is an example of a device that uses electrical current to create light with wavelength of about 1290 nm. The light is trapped in waveguides and is used to optically move and trap particles in a microfluidic channel. This device can also be used for simultaneous particle detection and manipulation thought scattering and absorption forces. Such integration of microfluidics and semiconductor lasers is not done in distinct components as above. Rather a device is etched and covered with other materials to achieve proper shapes and properties in each part of the device.

The light is emitted from electrically excited layers of quantum dots. The active layer is covered with thermally grown conductive cladding on top and bottom. In order to allow waveguiding, ridges are photo-defined and etched with specific dimensions to support only the zero-order mode. To isolate adjacent waveguides, a layer of SU-8 is added and heated to reflow from the top of the ridges and harden between them. The top electrode for the electrical component is then deposited with an electron beam evaporator through a lift-off mask. The fluidic channel is etched separately to be deeper than the space between the ridges in order to accommodate larger particles. Because it is essential to isolate the pn junction from the fluid, the ridges and the contacts are covered with another layer of SU-8 polymer. This layer is also used to photo-define the walls of the channel. The last step is to deposit a thin metallic layer on the bottom of the channel to prevent particle adhesion. In order to operate, the device requires a relatively large heat sink due to heat generation from electrical currents.

This device allows for exploration of how semiconductor lasers interact with different materials. The experimental data is the power drop when the particle blocks a pair of oppositely positioned lasers. The device itself contains a large variety of fabrication techniques and materials and has a large range of applications. The advantage of this device is the ability to simultaneously manipulate and detect single particles using optical functionality. It is also likely the most prominent example of integration of different components, including electronic ones, directly into the fluidic layer instead of fabrication of different layers followed by their bonding to each other. The advantage of including so much "infrastructure" right on the device (e. g. having optical pressure generated within the microchip as opposed to using an external laser) is largely related to the idea of developing portable devices.

Future Directions for Research

What has inspired initial research in microfluidics is similarly driving the research into optofluidics today. The goal is to make smaller features going from micro- to nano-scales in order to fill the gap between top-down and the bottom-up fabrication techniques [7]. Because most devices consist of multiple planar layers, there is motivation to develop 3-D fabrication or assembly methods for both optical and electrical components. The ultimate goal is an easy and simple technique which works well with a variety of materials and on different scales. The most successful devices up to date rely on fundamental principles of both optics and fluidics in order to avoid as many of components as possible, leaving those devices only with essentials to carry out their functions.

Over/Under/Perfectly-Expanded Nozzle Flow

Definition

A comparison of the theoretical exit pressure for an isentropic nozzle with the level of the ambient back-pressure. For isentropic exit pressures below the ambient, the flow is ‘over-expanded’; for isentropic exit pressures exceeding the ambient value, the flow is ‘under-expanded’ ; when the pressures are matched, the flow is ‘perfectly expanded’.

Thermal oxidation; Oxide growth; Oxide deposition; Silicon dioxide growth

Definition

Oxidation of silicon to create a silicon dioxide layer on the silicon surface can be done either by the thermal growth methods or the undesired native growth process. The process is an adding procedure which adds oxygen to react with silicon to form silicon dioxide on the silicon surface. The process consumes silicon during the oxidation procedure. In general, the oxide layer can be grown either by wet or dry oxidation processes in a furnace at a temperature of 750 – 1100 °C. The reaction can be expressed as: $Si_{(s)} + O_{2(g)} \rightarrow SiO_{2(s)}$.

Overview

Silicon dioxide is a form of pure glass with a melting temperature of 1730 °C which is similar to fused silica. It exhibits excellent dielectric properties and has a good adhesion to silicon such that silicon dioxide is ideal to be used as a dielectric or barrier layer. Silicon dioxide is also very useful in the MEMS and semiconductor industry due to its excellent material properties. A grown oxide layer is conformal on the silicon surface, which makes it an ideal surface coating or passivation layer for MEMS structures. The electric resistivity is up to $1 \times 10^{20}\ \Omega.\mathrm{cm}$ and the energy band gap is around 9 eV. A well-grown silicon oxide layer can sustain a high electric field of up to 10^9 V/m without breakdown [1]. Further more, the ease of formation and its excellent interface with the underlying silicon material make it the most popular thin film in VLSI technology. Essentially, silicon is reactive to oxygen at room temperature such that most silicon exists in the form of silicon dioxide like quartz sand in nature. In this regard, oxidation of silicon occurs immediately to form amorphous silicon dioxide film by exposing a silicon surface to oxygen in atmospheric environment. Silicon dioxide is a dense material that fully covers the silicon wafer to prevent the inner silicon from further oxidation. The thickness of this native oxide will reach to an upper limit of about 40 Å even over a long period of time. The native oxide layer grown from air is not uniform and is usually considered a contaminant in semiconductor processing. This native oxide can be simply removed in seconds using dilute HF solution.

Alternatively, a thermally grown oxide layer is thickness-controllable and has various applications in the semiconductor industry. The thickness ranges for thermal oxide layers may vary, depending on the particular application. For example, the thickness for an oxide capacitor dielectric is as thin as several angstroms but the thickness of a field oxide layer can be up to several micrometers. Since the grown oxide layer will fully cover the silicon surface to prevent it from further oxidation, it is common to elevate the temperature to drive the oxidant molecules to diffuse across the formed oxide layer to continue the oxidation process. In general, an oven or a furnace with high-purity oxygen supplied is usually adopted for the oxidation process. The oxidant can be either pure oxygen gas or water vapor. If the growth procedure occurs with dry oxygen, then the oxidation process is called *dry oxidation*. If the oxygen is introduced to the reaction chamber with water vapor, then the oxidation process is known as *wet oxidation*. The reaction mechanism of these two oxidation approaches is different such that the growth rate and the grown film quality of these two approaches are also

different. In general, the wet oxidation process is faster than the dry oxidation process but the density of the grown oxide layer obtained is lower when using the wet oxidation process. Higher temperature will significantly increase the growth rate of the oxide layer. The equipment for performing the oxidation processes, a mathematical model for evaluating the growth rate and a well-known pattern of bird's beak effect in local oxidation of silicon (LOCOS) process are described in this entry.

Basic Methodology

Oxidation Modeling

Silicon dioxide is usually grown by consuming silicon during oxidation process at high temperature from 750 to 1100 °C. Figure 1 shows the basic process for the oxidation of silicon. For successive oxidation, oxidants must diffuse across the formed oxide layer then react with silicon at the SiO_2/Si interface. The chemical reactions for both dry and wet oxidation processes can be described as follows:

$$\text{Dry: } Si_{(s)} + O_{2(g)} \rightarrow SiO_{2(s)}$$

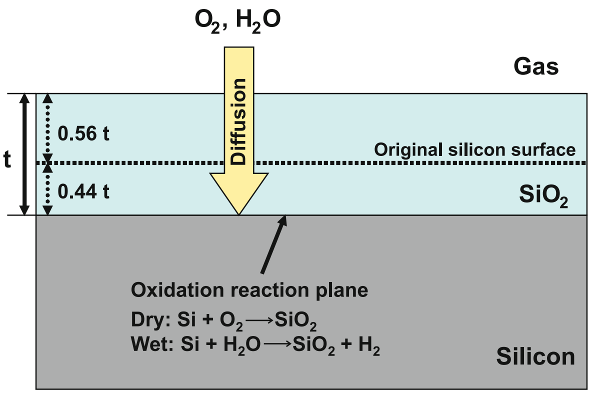
$$\text{Wet: } Si_{(s)} + 2H_2O_{(g)} \rightarrow SiO_{2(s)} + 2H_{2(g)}$$

Apparently, silicon is consumed to form silicon dioxide in both the dry or wet oxidation process. The thickness of the silicon consumed is around 0.44 of the total oxide thickness. This value can be simply calculated using the following equation:

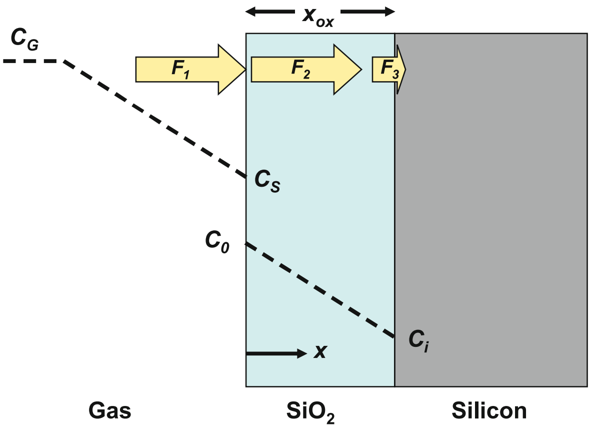
$$\frac{t_{Si}}{t_{SiO_2}} = \frac{V_{Si/mole}}{V_{SiO_2/mole}} = \frac{M_{Si}/\rho_{Si}}{M_{SiO_2}/\rho_{SiO_2}}$$

$$= \frac{28.09(\text{g/mole})/2.33(\text{g/cm}^3)}{60.08(\text{g/mole})/2.21(\text{g/cm}^3)} \approx 0.44$$

where t is the thickness, V is the volume, M is the molecular weight and ρ is the material density. The growth rate of oxide depends on the parameters for the oxidation process such as temperature, gas pressure, oxidizing condition (wet or dry), silicon crystal orientation and the dopant concentration in silicon. The model for oxide growth on silicon was first described by Deal and Grove in 1965 [2]. The Deal–Grove model describes two growth stages of the linear stage and the parabolic stage during oxidation. Figure 2 illustrates the one-dimensional model for the oxidant flux from the gas phase to the silicon surface during thermal oxidation. Three first-order equations describing the three series parts of the sample fluxes, i. e., F_1, F_2 and F_3, in the one-dimensional model are presented in Eqs. (1)–(3), where F_1 is the gas transport flux in number of molecules



Oxidation (of Silicon), Figure 1 The basic process for the oxidation of silicon



Oxidation (of Silicon), Figure 2 Flux model for oxidant diffusion from the gas phase to silicon surface during thermal oxidation

per square centimeter per second, F_2 is the diffusion flux through the oxide layer and can be expressed using Fick's first law and F_3 is the reaction flux at the SiO_2/Si interface:

$$F_1 = h_G(C_G - C_S) \tag{1}$$

$$F_2 = -D\frac{\partial C}{\partial x} = D(\frac{C_0 - C_i}{x_0}) \tag{2}$$

$$F_3 = k_s C_i \tag{3}$$

where h_G is the mass transfer coefficient (molecules per cm^2 s), C_G is the concentration of oxidant, C_S is the concentration at the surface, D is the oxidant diffusivity in the oxide (cm^2/s), C_0 and C_i are the concentrations at the two interfaces, x_0 is the oxide thickness and k_s is the reaction rate constant (cm/s). The concentration of the oxidant just inside the oxide surface C_0 and C_S can be related using

O

Henry's law:

$$C_0 = \mathrm{H}P_\mathrm{S} \tag{4}$$

where H is Henry's constant and P_S is the partial pressure of oxidant at the surface. From the ideal gas law, $PV = NkT$, Eq. (4) can be expressed as

$$C_0 = \mathrm{H} \times kT(\frac{N_\mathrm{S}}{V}) = \mathrm{H}(kTC_\mathrm{S}) \tag{5}$$

where the subscript s denotes at surface. Rearranging Eq. (5) will give

$$C_\mathrm{S} = \frac{C_0}{\mathrm{H}kT} \tag{6}$$

where k is the Boltzmann constant (1.38×10^{-23} J/K) and T is the temperature in K. C^* is defined to be the oxidant concentration in the oxide that would be in equilibrium with the bulk gas pressure P_G, which is known:

$$C^* = \mathrm{H}P_\mathrm{G} = \mathrm{H}(kTC_\mathrm{G})$$

$$\text{then } C_\mathrm{G} = \frac{C^*}{\mathrm{H}kT} \tag{7}$$

Substitution of Eqs. (6) and (7) into Eq. (1), leads to the result that

$$F_1 = h_\mathrm{G}\left(\frac{C^*}{\mathrm{H}kT} - \frac{C_0}{\mathrm{H}kT}\right)$$

$$\equiv \frac{h_\mathrm{G}}{\mathrm{H}kT}\left(C^* - C_0\right) \equiv h\left(C^* - C_0\right) \tag{8}$$

where $h = h_\mathrm{G}/\mathrm{H}kT$, which is a large value because experimental results show that wide changes in gas flow rates in oxidation furnaces, changes in the spacing between wafers on the carrier in the furnace and changes in the wafer orientation make little difference to oxidation rates. Under steady-state conditions, mass must balance such that the three flux equations representing the oxidation process must be equal. Thus $F_1 = F_2 = F_3$. Solving the two unknowns C_i and C_0 from the two equations of $F_1 = F_2$ and $F_2 = F_3$, then we have

$$C_i = \frac{C^*}{1 + \frac{k_\mathrm{s}}{h} + \frac{k_\mathrm{s}x_\mathrm{ox}}{D}} \tag{9}$$

$$C_0 = C^*\left(1 + \frac{K_\mathrm{s}x_\mathrm{ox}}{D}\right) \tag{10}$$

Substitution of Eq. (9) into Eq. (3) leads to

$$F(= F_1 = F_2 = F_3) = \frac{k_\mathrm{s} \cdot C^*}{1 + \frac{k_\mathrm{s}}{h} + \frac{k_\mathrm{s}x_\mathrm{ox}}{D}} \tag{11}$$

Let M be the number of molecules of the oxidant in a unit volume of the oxide. The rate of the thickness change of the oxide layer with time is then given by oxidizing flux divided by the number of molecules M of the oxidizing species (O_2 or H_2O) that are incorporated into a unit volume of the resulting oxide:

$$\frac{\mathrm{d}x_\mathrm{ox}}{\mathrm{d}t} = \frac{F}{M} = \frac{k_\mathrm{x} \cdot C^*}{M(1 + \frac{k_\mathrm{s}}{h} + \frac{k_\mathrm{s}x_\mathrm{ox}}{D})} \tag{12}$$

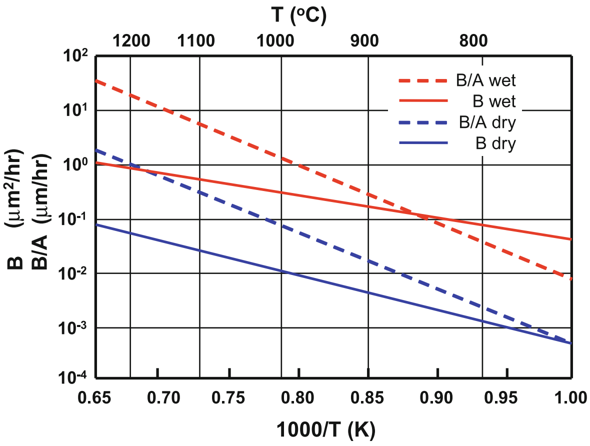
where $M = 2.2 \times 10^{22}\ O_2/\mathrm{cm}^3$ for the dry oxidation process and $M = 4.4 \times 10^{22}\ H_2O/\mathrm{cm}^3$ for the wet oxidation process. Note that $M = \text{density}/(\text{Avogadro's number} \times$ molecular weight of SiO_2). Take the boundary condition of $x_\mathrm{ox} = x_i$ at $t = 0$. The oxide growth kinetics can be obtained by integrating Eq. (12) from an initial oxide thickness x_i to a final thickness x_ox. The result is described as

$$\frac{x_\mathrm{ox}^2}{B} + \frac{x_\mathrm{ox}}{B/A} = (t + \tau) \tag{13}$$

where

$$A = 2D\left(\frac{1}{k_\mathrm{s}} + \frac{1}{h}\right),\ B = \frac{2DC_\mathrm{A}}{M} \text{ and } \tau = \frac{x_i^2 + Ax_i}{B}$$

The terms B and B/A can be referred to as the parabolic and linear rate constants for describing the oxide growth kinetics. The physical meanings of the rate constants B and B/A are the oxidant diffusion and interface reaction rate, respectively. The corresponding values for B and B/A for dry and wet oxidation of ⟨111⟩ silicon are plotted in Fig. 3. For ⟨100⟩ silicon, these values should be divided by 1.68. These expressions are better fit for the cases of a very



Oxidation (of Silicon), Figure 3 Plot of B and B/A versus temperature for dry and wet thermal oxidation of ⟨111⟩ silicon

thin oxide layer and in dry O_2 conditions. Solving Eq. (13) leads to the relationship between the oxide thickness and the growth time:

$$x_{ox} = \frac{A}{2}\left\{\sqrt{1+\left[\frac{t+\tau}{A^2/4B}\right]}-1\right\} \tag{14}$$

Considering two limiting cases of $t \to 0$ (small x_{ox}) and $t \to \infty$ (large x_{ox}), we have the following expressions corresponding to Eq. (14):

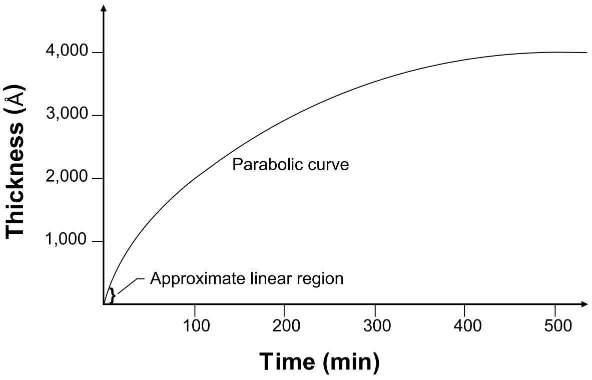
$$x_{ox} \to \frac{B}{A}t \quad \text{when} \quad t \to 0$$

and

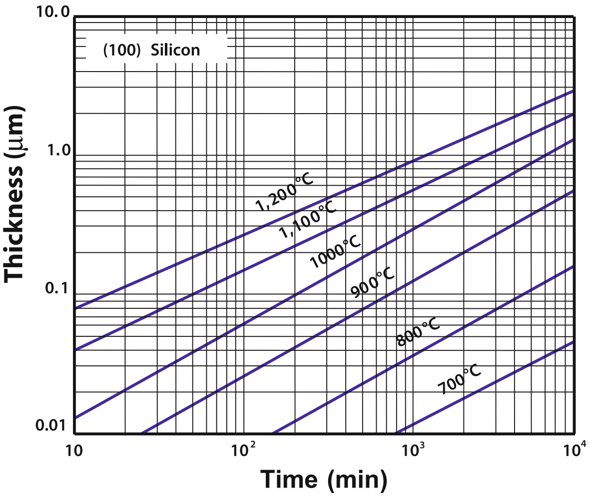
$$x_{ox} \to \sqrt{Bt} \quad \text{when} \quad t \to 0$$

It is clear that the thickness of the grown oxide layer varies linearly with time at the initial stage of oxidation. In this stage, the oxide growth rate is controlled by the reaction occurring at the SiO_2/Si interface and is called the *reaction rate-controlled region*. The linear stage of oxide growth is valid up to about 150 Å of oxide thickness [3]. The growth of the oxide layer slows down after the linear stage because the oxidant must diffuse across a longer distance to reach the interface where the oxidation reaction occurs. The equation generates the shape of a parabola such that it is called the parabolic stage. In the parabolic stage, the growth rate of oxide is controlled by the mass transportation of the oxidant and is called the *diffusion-controlled region*. Figure 4 illustrates the general curve for both the linear and parabolic stages for dry oxidation at 1100 °C [4]. It is noted that the linear stage is only at the very beginning of the thermal oxidation process.

In practical applications, it is not necessary to calculate the thickness of the grown oxide layer using the kinetic model described above. Users can simply obtain the approximate thickness from a chart which plots the oxide thickness for oxidation versus temperature and time, as an example shown in Fig. 5. Another simple way to estimate the thickness of the grown oxide layer is to use the well-developed simulator available on the internet [5]. In addition, the dopant concentration in silicon is also a factor that influences the growth rate of oxide. Here also a minor parameter which may affect the oxide growth rate is doping during the oxidation process. In general, heavily doped silicon oxidizes at a faster rate than a lightly doped substrate. In the parabolic stage, boron doping will oxidize faster than phosphorus. However, the growth rate shows little difference in the linear rate constant between boron and phosphorus doping [6].



Oxidation (of Silicon), Figure 4 Linear and parabolic stages for dry oxidation process at 1100 °C



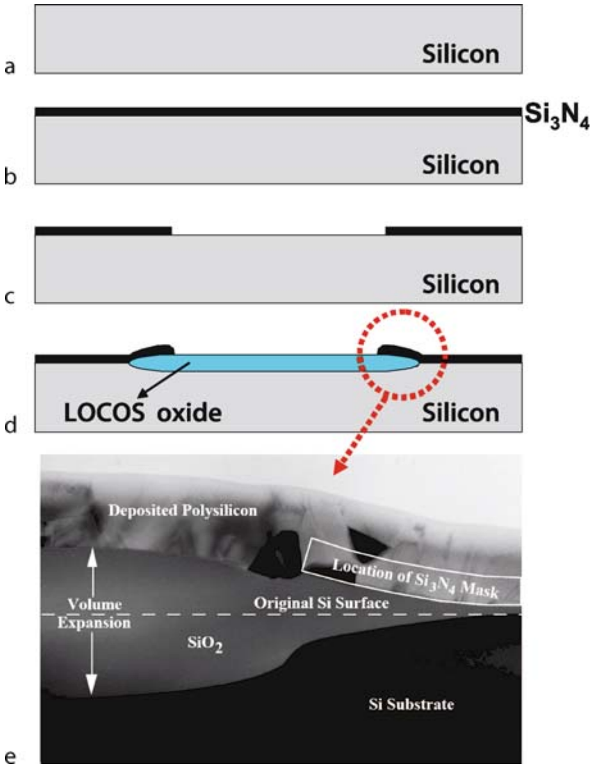
Oxidation (of Silicon), Figure 5 The thickness of a grown oxide layer for different temperature and time

In summary, the growth of thermal oxide follows a linear growth stage up to about 150 Å, followed by a slower parabolic growth stage. The chemical reaction for the thermal oxidation of silicon consumes silicon and oxidant and the growth rate of the oxide layer is faster when using wet oxidation. Factors including dopant concentration, crystal orientation, pressure and temperature may affect the oxide growth rate during oxidation.

LOCOS Process

The abbreviation LOCOS stands for *local oxidation of silicon*, in which selective areas on a wafer are oxidized for electrical insulation purposes in semiconductor technology. This process is used for isolating two adjacent devices with a feature size of greater than 0.25 μm.

0



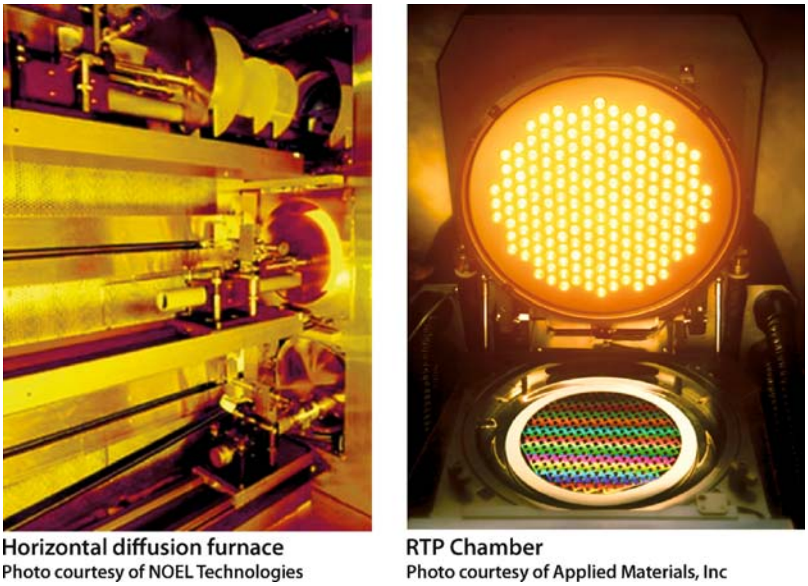
Oxidation (of Silicon), Figure 6 (**a–d**) Schematic of a typical LOCOS formation process. (**e**) SEM image of a LOCOS structure. Note that the silicon nitride layer on the right-hand side was stripped and a polysilicon layer has been deposited on top of the structure to provide better contrast in the image. (Image courtesy of J. Bravman, Stanford University.)

Figure 6 presents a simplified schematic for the LOCOS process. A deposited silicon nitride layer is patterned and etched to expose the selective area for the oxidation process. The patterned Si_3N_4 layer serves as the oxidation barrier (Fig. 6a–c). There is a slight lateral growth of the oxide beneath the nitride oxidation barrier because the oxidants move in all directions when diffusing through the grown oxide. Since the oxidation is an adding procedure and the grown oxide is thicker than any silicon consumed, the oxide grown beneath the nitride layer serves to push up the nitride edge (Fig. 6d). The LOCOS process results in a non-planar Si/SiO_2 interface between the nitride oxidation barrier and oxidized regions. This phenomenon is known as the *bird's beak effect* due to its shape. The bird's beak effect is an undesired by-product of LOCOS processes since it increases the area required for building a semiconductor device. Figure 6e illustrates a SEM image showing the cross-section of a LOCOS process, the bird's beak shape being clearly observed in the image.

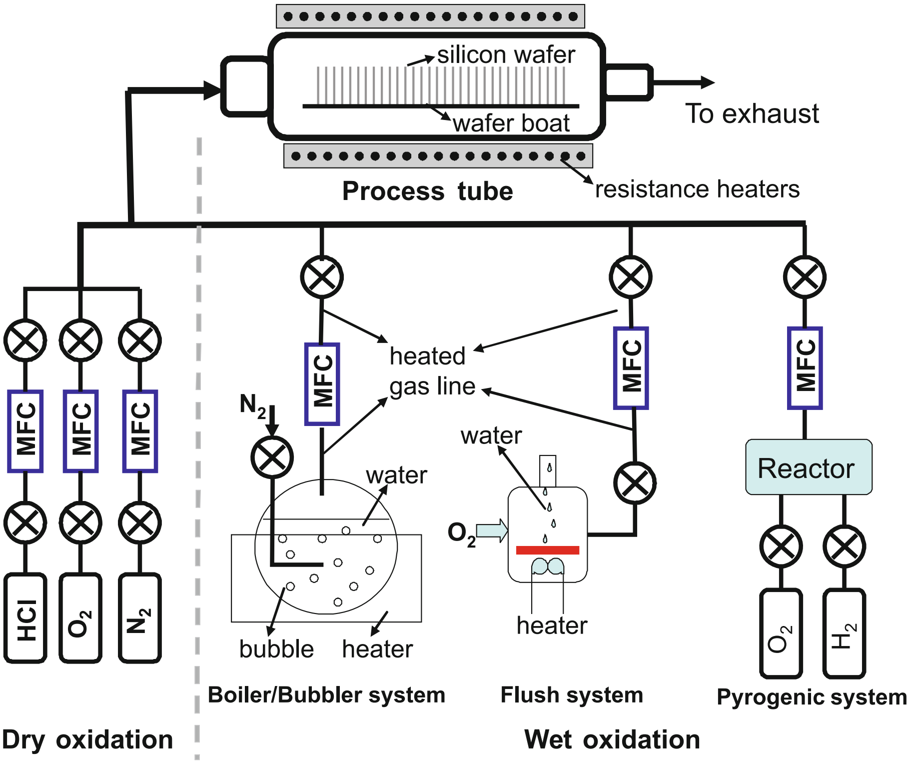
Furnace Equipment and Oxidation Processes

Furnace equipment serves as a workhorse in thermal processing and is among the simplest type of processing equipment in the semiconductor industry. The equipment is conceptually constituted of an oven capable of temperatures from 600 to 1200 °C and a simple gas distribution system capable of introducing the oxygen or water molecule oxidants. Since the growth rate of the oxide layer is highly dependent on the temperature, precise temperature control is essential for oxidation furnaces. Modern furnaces are easy to handle up to several hundred 8 in. wafers, with a temperature uniformity of ±0.5 °C [7]. There are three basic types of furnace, horizontal furnace, vertical furnace and rapid thermal processor (RTP), used for thermal processing. Figure 7 shows two images of a conventional horizontal furnace and a RTP chamber. Simple construction and ease of maintenance are the major advantages of the horizontal furnaces such that they are popular in academic institutes and industries which require only small production volumes. The horizontal furnace is so named because of the horizontal position of the quartz tube where wafers are located and heated. This furnace was largely replaced in the early 1990s by the vertical furnace in the semiconductor industry, mainly because the vertical construction is easier to automate, has improved operator safety and reduces particular contaminations [8]. Oxidation processes operated in the horizontal and vertical furnaces are batch processes, which are capable of processing large quantities of wafers (tens to 200 wafers) in one process cycle. The furnace process is considered a hot-wall procedure such that it requires more thermal budget for heating the furnace.

Figure 8 illustrates schematically the setup of a typical oxidation furnace which shows the conceptual configurations for both the dry and wet oxidation processes. The main body of the system is a quartz process tube surrounded by a resistance heating element which can be controlled to produce multiple heating zones. It is common to form three to seven symmetric hot zones over the process tube. The temperature zones thus formed facilitate control of the furnace tube to attain a flat zone near the middle of the tube where the thermal oxidation takes place. The outer zones are designed to help compensate for heat losses out of the ends of the tube. The wafers are normally loaded into the furnace on quartz *boats* which hold 10–50 wafers in parallel. The boats are carried into the center section of the hot zones by the operator or the loading system. The wafers are normally loaded at a moderate temperature (600 – 800 °C) in order to prevent crystallographic defects caused by large thermal gradients across the wafers; thermal budget for this process can be saved as well. Nowa-



Oxidation (of Silicon), Figure 7 Images of a conventional horizontal furnace (left) and a RTP chamber (right)



Oxidation (of Silicon), Figure 8 Schematic for the conceptual construction of an oxidation furnace

days, these furnaces are most commonly operated at atmospheric pressure. However, if necessary, one is able to increase the tube pressure to increase the growth rate of oxide film.

Dry Oxidation

The furnace structure for the dry oxidation process is simple and straightforward. Usually, high-purity oxygen gas is used to oxidize silicon. Nitrogen gas in the oxidation system is used as the process gas during system idle, temperature ramping, wafer loading steps and chamber purging, because nitrogen does not react with silicon at the processing temperature. In dry oxidation, the process gas is usually introduced into the furnace with a trace amount of hydrogen chloride gas. The existence of chloride ions during oxidation is very important because chloride ions react with the mobile metallic ions, such as sodium ions, to form immobile chloride compounds. The undesired oxide charge occurring at the Si/SiO_2 interface can be neutralized by the use of HCl gas. In addition, the existence of hydrogen chloride will also allow some chlorine atoms to be integrated into the oxide film and bind with silicon at the silicon–oxide interface. This process minimizes the number of dangling bonds and improves IC device reliability. Another important advantage of adding chloride ions to the thermal oxidation process is that they tend to increase the oxidation growth rate by about 10 – 15% [9]. However, the concentration of chlorine ions should not be high (usually $< 3\%$); otherwise the electric properties (e. g., bias voltage) of the electronic device would become unstable. Instead of using toxic and corrosive HCl gas, chlorine compounds such as dichloroethylene (DCE) or trichloroethylene (TCE) can be used to introduce the chlorine ions into the process tube [10]. Oxide films grown by dry oxidation have better quality than films grown by wet oxidation. Therefore, high-quality thin oxide layers such as gate oxide, screen oxide or pad oxide are usually grown using the dry oxidation process.

Wet Oxidation

The wet oxidation process uses water molecules instead of dry oxygen as the oxygen source to oxidize silicon. As a matter of fact, water molecules contact the silicon furnace in a normal wet oxidation process. Water molecules dissociate at high temperature and form hydroxide (HO) prior to reaching the silicon surface. Hydroxide has faster diffusion mobility in silicon dioxide than pure O_2, which explains why wet oxidation has a higher growth rate than dry oxidation. Wet oxidation is used to form thick oxides such as the LOCOS oxide, masking oxide and field oxide. As shown in Fig. 7, several systems have been used to deliver water vapor into the process tube. The boiler system is the simplest setup which vaporizes ultra-pure water then drives the water vapor in to the process tube via heated gas lines. However, it is difficult to have precise control of the vapor flow with this method. In addition, the water in the boiler is not *fresh* after a long boiling procedure and contaminants may be dissolved in the water. A modified setup is called a bubbler system which flows nitrogen gas into a hot water bath to generate wet nitrogen bubbles and carry vapor into the process tube. This scheme is the most commonly adopted in academic fields due to its simple structure and more precise flow control than a boiler system. The flush system is an alternative choice for introducing water vapor in to the process tube. This system uses small water droplets on a quartz hot plate, which vaporizes the water. The vaporized steam is then carried in to the process tube by flowing oxygen gas. However, this method has the problem that the steam generation is not a steady process. In order to have better control of the vapor flow rate, a pyrogenic system called *Dryox* was developed, which burns hydrogen gas to generate water vapor right at the inlet port of the process tube. The vapor flow can be precisely controlled since no liquid and vapor handling is required in this system. However, it needs extreme care to handle this process since hydrogen gas is flammable and explosive. The pyrogenic reaction is operated at a temperature of about 400 °C at which hydrogen automatically reacts with oxygen and forms water vapor. The typical mixing molar ratio for hydrogen and oxygen is 1.8 : 1 to 1.9 : 1, in order to completely consume the hydrogen gas [9]. Otherwise, hydrogen can accumulate inside the process tube and cause an explosion. A burn box and a scrubber system for exhaust gas treatment are necessary for operating a pyrogenic system.

Rapid Thermal Process (RTP)

The rapid thermal process (RTP) is a method which heats a single wafer to a temperature range of 400 – 1300 °C in a very short time under atmospheric conditions or at low pressure. This process is usually referred to as rapid thermal oxidation (RTO). The RTP has a gas handling system, an optical pyrometer for fast temperature measurement and a computer for controlling process operation. In order to achieve this fast heating process, a tungsten halogen lamp array located nearly at the top and bottom of the wafer is used as the radiant heating source. The temperature ramp up and down in a furnace is typically about 20 °C/min or less. Alternatively, the RTP can incorporate a fast-heating system which provides ramp-up rates up to 250 °C/min. In order to keep the temperature uniformity across the reaction surface, the RTP usually treats a single wafer at a time. The wafer-to-wafer uniformity of a RTP system is also better than that of a conventional furnace system. The silicon wafers are

heated by selectively absorbing radiation from the lamps, which produce short-wavelength radiation. The energy from the lamps is mainly absorbed by the silicon but not the chamber wall such that the RTP is considered as a cold-wall process. In this manner, heat-generated contaminants from the chamber wall can be reduced. The RTP also uses less thermal budget than a furnace system but the throughout is an issue. More importantly, the oxidation process achieved using the RTP can minimize dopant movement in wafers due to the shorter process time. This advantage makes the RTP ideal for processes like the barrier-layer formation and the oxide reflow process.

Future Directions for Research

Oxidation processes have been studied for more than 50 years and they still attract lots of interests from researchers who are working in this area. For example, in order to prevent gate leakage and dielectric breakdown, growth of thinner and denser dielectric layers with high dielectric constant for gate structures is an ongoing trend. The RTP will play a more important role in the semiconductor process since it offers better process control, less thermal budget, less processing time and better wafer-to-wafer uniformity. The RTP incorporated with on-line film monitoring, rapid thermal annealing and even rapid thermal chemical vapor deposition (RTCVD) processes has shown its potential for fabricating high-quality thin films with various material choices. Finally, an automation system to handle the multi-function RTP system is essential for improving the throughput of this system.

Electronic packaging; IC packaging; MEMS packaging

Definition

Packaging provides electrical or mechanical access to microdevices from the outside world. Packaging also provides protection to microdevices from being damaged by the elements, such as dust, moisture and chemicals from the environment.

Wire bonding is a technology that connects microdevices to the outside world electrically using small metal wires.

Overview

Historically, packaging technology was developed by the integrated circuit (IC) industry. When semiconductor microdevices such as transistors are fabricated on a semiconductor wafer, electrical signals can only be accessed through many micrometer-sized metal lines and contacts using specialized equipment such as a probe station, equipped with an optical microscope and micromanipulators with fine tungsten needles. In order to provide low cost, general access to the microdevices, semiconductor wafers are first diced into small chips (or dies) and small metal wires are used to connect the metal contacts to a *carrier case*. The carrier case has millimeter-sized pins that can be accessed using standard circuit boards.

In IC packaging, the carrier case also provides a moisture barrier. Often, failure in a microdevice is the contact between the metal wires and the metal contacts on the substrate due to moisture-induced corrosion. For microelectromechanical system (MEMS) devices, moisture presents more of a threat than for conventional IC devices [1]. Many micromechanical MEMS components (such as a microcantilever beam) are positioned a few micrometers from the substrate. Moisture condensing on the surface of the substrate will pull down the MEMS devices due to surface tension. The micromechanical component will no longer be functional.

For microfluidic devices, packaging not only provides electrical access to the metal electrodes in the microchannels, but also provides mechanical access. Small tubing is used to connect the fluid ports on the microfluidic device to syringe pumps or other external devices.

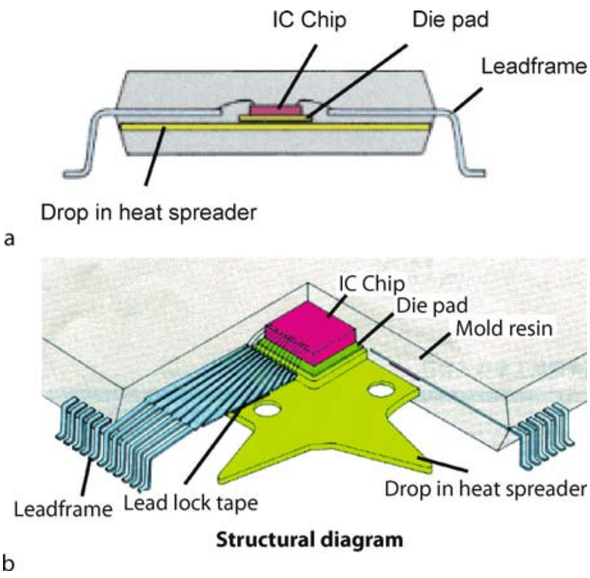
Wire bonding is a technology that uses small gold or aluminum wires with a diameter around 20 to 50 μm to build electrical connections to the MEMS/IC devices. The wires are fed through a small aperture on the tip of an ultrasound actuator (or horn). The tip presses the wire to the metal contact surface on the device substrate. Ultrasound energy is applied to vibrate the tip, making the wire rub against the metal contact surface. The vibration-induced friction can (1) create a clean interface between the wire and the metal surface and (2) provide thermal energy that bonds the wire to the metal surface.

Basic Methodology

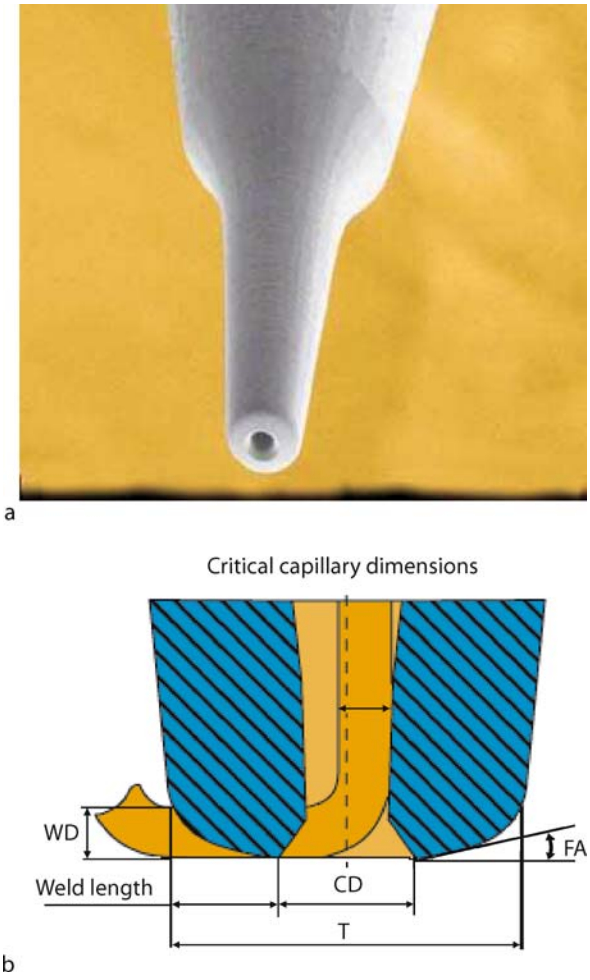
DIP (Dual In-Line Package)

DIP technology uses moisture-resistant plastic compounds to encapsulate MEMS/IC devices [2]. As shown in Fig. 1a (Courtesy of Shinko Electric Industries Co. Ltd), the two row of pins commonly seen in IC devices that extended out from the plastic body are used for electronic connections, hence the term *dual in-line*.

After IC devices are manufactured on a substrate wafer, a dicing saw is used to break the wafers into smaller chips. The chips are then bonded to a metal frame (called a lead frame) using epoxy. The lead frame is often made of Cu – Ni – Fe alloys with a thermal expansion coefficient matched with that of the silicon substrate as well as of the plastic compound. Wire bonding is used to connect con-



Packaging (and Wire Bonding), Figure 1 (**a**) Cross-section of a DIP package; (**b**) exploded view of a QFP package



Packaging (and Wire Bonding), Figure 2 Ultrasound horn for wire bonding

tact pads on the device to the lead frame. The device (and the lead frame) is then put into a mold. The plastic compound, with a thermal expansion coefficient matched with silicon, is molded around the device/lead frame to form a protective case.

Many other variations of DIP technology are readily available, such as SH-DIP (shrink DIP), SIP (single in-line package), SOP (small out-package) and QFP (quad flat pack, as shown in Fig. 1b (Courtesy of Shinko Electric Industries Co. Ltd)). The basic techniques are the same as DIP but the variants provide different form factors and different arrangement of the pins.

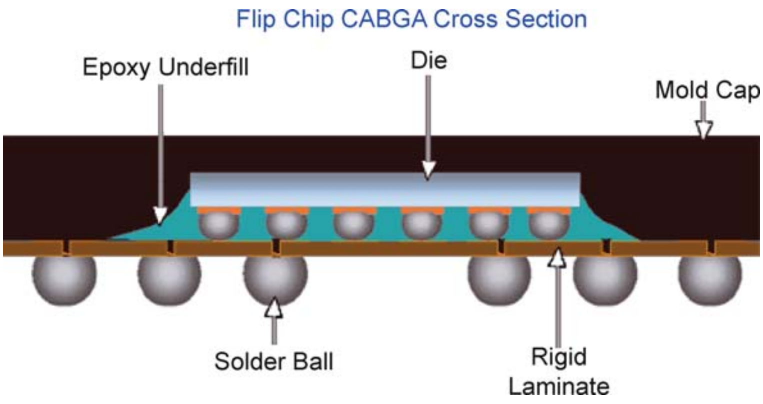
Wafer Bonding

MEMS devices need to be separated from the substrate using a wafer dicing machine before they can be packaged. However, unlike IC devices, water used in the dicing operation will destroy micromechanical components. Moreover, DIP technology cannot be used since the molding process will also destroy the micromechanical part of the MEMS devices.

The wafer bonding technique has been used to encapsulate MEMS devices before the dicing process. Wafers (silicon or glass) with recessed microcavities are used to bond to the MEMS device wafer. The microcavity provides a protection cap to the micromechanical component. The hermetic sealing between the bonded wafers will prevent water (during dicing operation) from coming into the cavity. It will also delay moisture diffusion from the environment into the cavity. Furthermore, the strength of the sealing will need to be high enough to sustain the subsequent molding in a DIP process.

Anodic Bonding

Anodic bonding has been widely used to form a pressure reference chamber in silicon pressure sensors. Borosilicate glass wafers with a thermal expansion coefficient matched with silicon are often used to bond with silicon wafers using a strong electric field and high temperature. The glass wafer is first chemically etched or sand blasted to form small cavities. Each cavity will accommodate one or more MEMS devices. The glass wafer is made contact with a silicon surface on a hot plate at 400 °C. An electric field is applied between the glass and the silicon such that sodium ions drift away from the glass–silicon interface.



Packaging (and Wire Bonding), Figure 3 Flip-chip technology for electric interconnection

Dissolved oxygen in the glass moves towards the glass–silicon interface and forms silicon dioxide that bonds the silicon surface and glass wafer (also silicon dioxide).

Silicon–Silicon Wafer Bonding

A clean and polished silicon wafer can be bonded to another silicon wafer at room temperature [3]. Two bonding mechanisms exists: (1) hydrophilic silicon surfaces will allow hydrogen bonds to form between two wafers with thin silicon dioxide layers and (2) hydrophobic silicon surfaces will allow van der Waals interactions between two clean silicon surfaces. Thermal annealing at high temperature ($> 1000\,°C$) is then required to permanently bond the silicon wafers.

Wafer Bonding with Intermediate Layers

Wafers can be bonded using intermediate layers such as metals to form hermetic seals. Polymers, in general, do not provide water-tight sealing, and are hence less important in the field of MEMS packaging. Soft metals such as indium can be bonded with silicon with a gold passivation [4]. Aluminum has been used to bond with silicon dioxide [5] and silicon nitride [6] to form hermetic seals.

Fluid Interconnects for Microfluidic Devices

In Lab-on-a-Chip applications, not only electrical, but also mechanical access (fluids) needs to be realized to the outside world. Flexible tubing such as polyimide tubes is often used to connect the small opening in microfluidic chips [7]. The sealing between the tube and the device opening has to be leak-tight. Most methods involve the use of placing a tube into the small fluid access via and sealants, such as polysiloxane [14] or polydimethylsiloxane [8], are then poured in to form seals. However, the sealants must not clog the tubing.

Many fluid interconnect techniques have been demonstrated to address the issues with the blocking of the tubing as a result of sealant application. These methods include the use of polymer membranes that prevent the seal from clogging [9] and the use of thermal shrink plastic tubing [10]. The published methods have been demonstrated in research and academic settings; much is still needed to be done for industry-relevant scale [15].

Electrical Interconnection

Wire bonding has been used in IC packaging for many years. Ultrasound energy is used to bond small metal wires on the metal pads on silicon wafers. As shown in Fig. 2a (Courtesy of Dr. I.W. Qin, Advanced Packaging, PennWell, Inc.), an ultrasound horn has a small opening at its tip. A small metal wire is fed through the opening, as shown in Fig. 2b (Courtesy of Dr. I.W. Qin, Advanced Packaging, PennWell, Inc.). The horn then makes contact with the surface and bonds the wire to the surface using ultrasound energy. The pitch size is often determined by the precision of the ultrasound horn placement, the size of the ultrasound horn and the size of the metal wires. As IC and MEMS I/O densities increase, it is becoming more and more challenging for wire bonding technology to meet the need of high-density I/O.

Other electric interconnection techniques such as wafer bumping and *flip-chip* bonding have emerged [11]. As shown in Fig. 3 (Courtesy of Amkor Technology, Inc.), small metal balls (Ag/Sn or Sn/Pb) are directly electroplated on the metal pads of the device chip. The chips are then "flipped over" and bonded to a printed circuit board (PCB) or a substrate with prefabricated metal connections. An epoxy underfill is then used to fill the space

between the chip and the PCB. A plastic compound is then molded over the chip for protection.

Packaging Reliability and Testing

A major characteristic of a MEMS or IC package is reliability. One often asked question is "how long will the device be operational"? From a packaging perspective, the protection and electrical/mechanical interconnection must withstand the elements. For example, for an accelerometer, the moisture from the environment must be stopped or delayed by the packaging seal so that the accelerometer sitting in the package will function properly. Furthermore, the temperature cycling often seen in automotive applications may raise concerns over the electric interconnection. The metal-to-metal contacts may form intermetallic compounds that are thermally mismatched with the surroundings and cracks will form when the package goes through temperature cycling. The metal contact resistance will then increase and eventually form an open circuit.

Many testing methods are available to evaluate the reliability of an IC/MEMS package. For example, if the dominant failure mode of a MEMS device is water condensation in the package, *autoclave* tests are available to test the reliability of the devices [1]. In an autoclave test, pressurized water is used to fill bonding imperfections and small crevasses that may exist in a package to accelerate the device failure.

Key Research Findings

In recent years, low-cost, localized "welding" has demonstrated reliability and possibilities for packaging of MEMS devices [5, 12]. One of the emphases has been on vacuum packaging for MEMS resonators and gyroscopes for high quality factor performance in a vacuum. Vacuum packaging for MEMS resonators using aluminum-to-silicon nitride bonding was shown to maintain the vacuum level in a harsh environment (130°C, 2.7 atm and 100% relative humidity) for a long period of time [6]. A specialized metallization process was also demonstrated to produce a vacuum package [13].

Future Directions for Research

Due to the diversity of MEMS devices, MEMS packaging methodology is device and application dependent. Compromise solutions between cost, reliability and process compatibility need to be considered.

Particle Image Thermometry

Definition

Particle Image Thermometry (PIT) is a method to determine two dimensional temperature fields of fluids. The particles carry the temperature information and are seeded into the fluid. Thermochromic Liquid Crystals (TLCs) are often used for that.

Particle Image Velocimetry (PIV)

Definition

PIV is used to estimate two-dimensional velocity fields of fluid flows. The fluid is seeded with ► tracer particles (able to follow the flow) whose motion gives information about the motion of the fluid. Therefore two images taken at two times are divided into ► interrogation areas. The interrogation areas belonging together are correlated (image processing algorithm) which leads to a pixel displacement. With the time interval between the capture of the two pictures, the pixel displacement, and the pixel length the velocity of the considered interrogation area can be calculated.

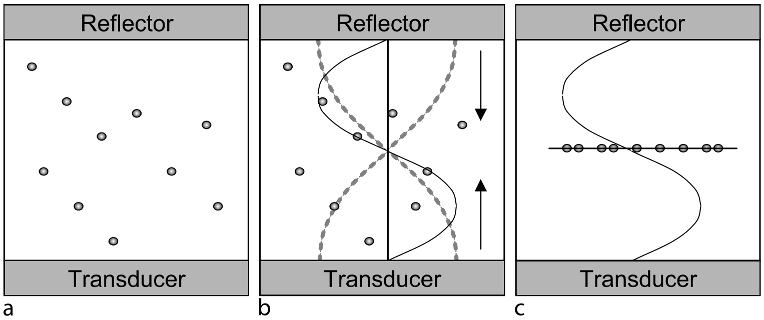
Definition

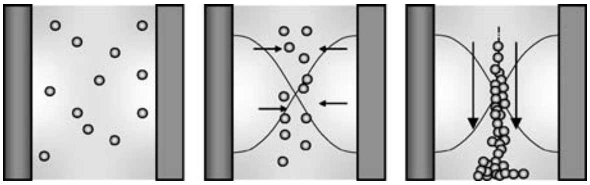
Ultrasonic fields, particularly standing waves or pseudo standing waves, can be used to manipulate particles within fluids. Typically particles in aqueous media will move to pressure nodes of the field, which can be planes, lines or points, depending on the standing wave geometry. By control of the standing wave patterns, it is possible to agglomerate particles, separate particles from the medium, wash particles from one fluid to another or fractionate populations of particles. In this article, techniques that have been used in microfluidic applications will be discussed, although many of the techniques can also be used at the macro scale.

Overview

It has been known for many years that acoustic standing waves can influence the behaviour of particles in either a liquid or gaseous medium. This effect relies on acoustic radiation forces that act on particles and other acoustic discontinuities (such as second phase fluids) within an ultrasonic field [1]. These forces are generally larger



Particle Manipulation Using Ultrasonic Fields, Figure 1 Movement of particles within an ultrasonic standing wave (USW). (**a**) Before a standing wave is generated, particles are evenly distributed throughout the fluid (**b**) a standing wave is excited by driving a transducer at a thickness resonance of the fluid layer, generating a pressure node in the centre of the fluid layer (dotted grey lines). A net force profile is established as per the solid line (in the direction of the arrows) (**c**) particles aggregate at the pressure node, driven by the force



Particle Manipulation Using Ultrasonic Fields, Figure 2 Enhanced sedimentation. Particles within an ultrasonic field (left) are agglomerated by the field (centre) and then tend to sediment under gravity (right)

in an ultrasonic standing wave (USW) than in a progressive wave and so it is mainly standing waves that are used for particle manipulation. The magnitude of this force is dependent upon the distance from the node of the standing wave and causes particles to move to the nodal plane. Use in microfluidic systems concentrates on active dimensions comparable with an acoustic wavelength. Acoustic frequencies of a few megahertz have wavelengths of the order of a few hundred micrometres. For example, a 3MHz acoustic wave in water has a wavelength of 500 μm. Many of the devices to be discussed here actually use sub-wavelength active dimensions and so it can be seen that ultrasonic waves of this order of frequency are compatible with the dimensional scale typically used in microfluidic systems. Consider the system represented in Fig. 1, in which particles within a fluid are bounded by an ultrasonic transducer and a reflective boundary. If the transducer is driven so as to excite a resonance frequency of the cavity (in this case, a half wavelength mode as shown by the pressure profile) a standing wave will be set up, with associated pressure maxima and minima. Particles will, in general, be transported towards pressure nodes within the field, by radiation forces. Figure 1b shows the relative magnitude and direction of the force across the depth of the chamber. The arrows show the net force direction, and the black curve gives an indication of relative magnitude. The dotted curve shows the acoustic pressure profile (in this case a half wavelength) with a resulting node in the centre of the fluid layer.

The magnitude of the force seen by the particles is dependent on

- the radius of the particle
- the energy density in the standing wave
- the distance of the particles from the nodal plane
- the acoustic contrast factor of the particles.

This last factor is a function of the differences in mass density and compressibility of the fluid and the particle.

By considering these factors, it can be seen that particles can be either all concentrated in one place, or by making use of the different size of particle populations and a competing force such as viscous drag, fractionated by size. It is also possible, by making use of acoustic contrast factor variations to fractionate similar sized populations.

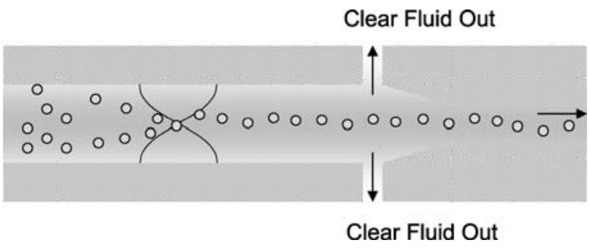
Basic Methodology

Particle Concentration or Filtration

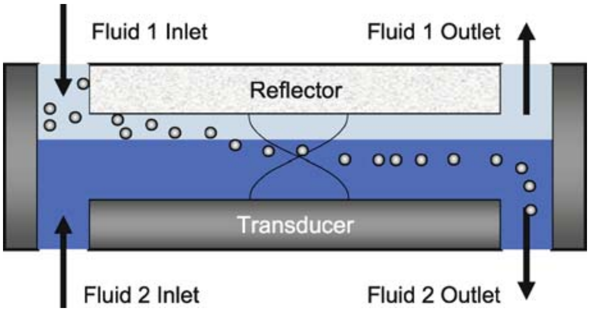
An obvious application of this technique is in a particle concentration or filtration system. There are two main approaches adopted

- Particle agglomeration
- Flow through separation.

In a particle agglomeration system (see [2]), devices are typically operated in a vertical direction (see Fig. 2). Particles are driven to the standing wave nodes by the acoustic radiation forces, and start to form agglomerates. Agglomerates form due to secondary radiation forces (see *key research findings*). As agglomerates grow, the relative importance of gravitational forces over viscous drag forces grows until the clumps of particles are able to sediment under gravity. Alternatively, once particles have been



Particle Manipulation Using Ultrasonic Fields, Figure 3 Flow through concentration based on technique described by Hawkes and Coakley [3]



Particle Manipulation Using Ultrasonic Fields, Figure 4 Particle Washing by forcing particles from one medium to another under laminar flow conditions

trapped, the field can be removed and the particle agglomerate falls.

Although as described, this technique has obvious application in batch processing, it can be modified to work as a flow-through device.

Flow-through systems are used in a continuous mode of operation in which a mix of fluid and particles is pumped through the device and the ultrasonic standing wave field concentrates the particles into a nodal plane. In this way a barrier-free filter is created.

This allows concentrated particles to be drawn off from the centre of the flow and clarified fluid to be drawn from either the upper or lower outlet, or from both as shown in Fig. 3. In this configuration, a mixture of particles and fluid are input from the left and flow through the device. In the main chamber an acoustic field concentrates the particles into a nodal plane in the centre. Clear fluid is then drawn out through the top and bottom outlets while the concentrated particles are allowed to proceed to the third exit.

This approach relies on the particles remaining at the centre of the channel due to the ordered nature of the highly laminar flow in a microchannel. The device developed by Hawkes and Coakley [3] was fabricated using traditional techniques and a microfabricated device has been developed using channels that are wet etched into silicon and Pyrex layers anodically bonded together [4].

An alternative technique that sorts particles into discrete patterns within a microchamber has been used by Neild et al. [5]. In the devices used by this group, acoustic energy is coupled into a fluid by first exciting flexural waves in a glass plate that bounds the fluid. Changing the excitation frequency, and in some cases using different transducers to excite the plate, allows particles to be aligned and manipulated within the fluid. Work described in reference [5] uses the acoustic pattern to align particles prior to further manipulation by a mechanical microgripper.

While most work has used planar resonators, it is also possible to manipulate particles in alternative geometries such as cylindrical tubes [6].

Particle Washing

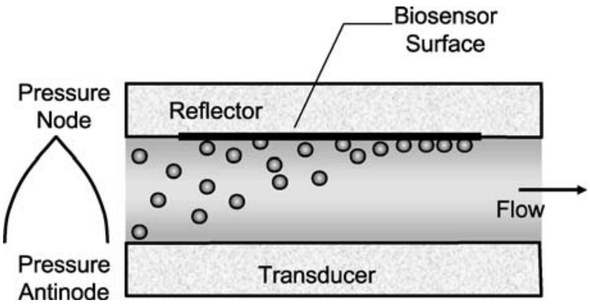
Applications have also been developed whereby particles can be driven acoustically from one fluid to another, making use of the laminar flow inherent in microfluidic systems. This precludes turbulent mixing, and so fluids can be in physical contact with minimal mixing. Figure 4 shows the principle. A fluid with particles in is fed in through fluid 1 inlet, and the acoustic force drives the particles from fluid 1 to fluid 2. Fluid 2 can then be withdrawn from outlet 2 with the particles. The ability to wash cells and particles and to move them from one medium to another is a critical element of many forms of analysis and hence an important component of a Lab-on-a-Chip toolbox.

A microfabricated device that works in a manner similar to that shown in Fig. 4 has been developed by Peterson et al. [7]. Three inlet and three outlet channels feed a single parallel sided channel anisotropically wet etched into a silicon substrate. This channel is excited at its half-wave resonance by a transducer mounted in the plane of the silicon, perpendicular to the axis of the standing wave. Similar devices have been used by the same group for a number of applications, including the separation of lipids from blood (in which the lipids move to the pressure antinode and the red cells to the pressure node) and fractionation of different size beads.

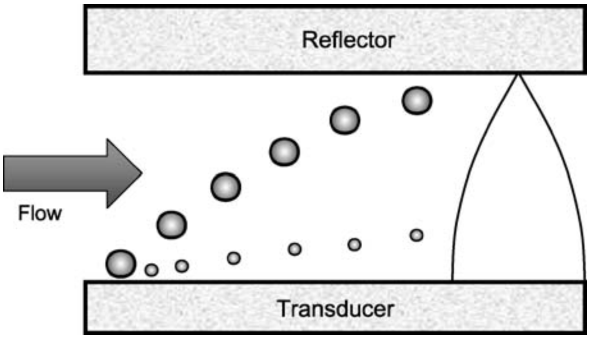
Biosensor Performance Enhancement

Ultrasonic particle manipulation can also be used to enhance biosensor performance, by using the ultrasound to drive the particles of interest to the biosensor surface. In this implementation (Fig. 5), a resonant reflector layer is used to generate a pressure node at a boundary, (effectively creating a quarter wave resonance within the fluid layer), rather than in the centre of the chamber, as previously described.

Such a device was demonstrated by Martin et al [8], who forced spores in a 135 μm deep chamber on to an antibody



Particle Manipulation Using Ultrasonic Fields, Figure 5 Enhancing biosensor performance based on technique of Martin et al [8]



Particle Manipulation Using Ultrasonic Fields, Figure 6 Fractionation of particles, making use of the net larger force on larger particles

coated surface and increased the capture of those spores by a factor of 70 when compared with the same system without ultrasonic actuation. This has the potential to overcome the diffusion limit on detection in microfluidic biosensor systems and significantly increase sensor sensitivity.

Fractionation

A further illustration of the use of ultrasonic fields is shown in Fig. 6. This demonstrates the principle of particle fractionation using acoustics. Different sized particles of the same material will experience different magnitudes of force within the same field. Thus larger particles, experiencing a larger force, will move more rapidly to the nodal plane. As long as the lateral flow is balanced against the vertical particle movement, the population of particles will be fractionated as shown. If the residence time in the field is too long though, all the particles will end up at the nodal plane.

Again, a quarter wave structure is used here to spread the particles across the width of the chamber, and the pressure profile is shown in the diagram. This requires the whole particle population to be input at the bottom of the channel, requiring some pre-conditioning of the particle distribution before the particles are introduced to this device, as the particles are driven from bottom to top in this case.

Key Research Findings

Calculation of Radiation Forces within the Fluid Layer

For a more detailed description of the background, including key references, see Gröschl's 1998 paper [1]. King provided the first comprehensive calculation of acoustic radiation forces on a small particle within a standing wave in 1934. This theory was developed for rigid spheres in an inviscid fluid and predicts that particles will move toward either the node or antinode of the field depending on the ratio of the fluid and particle densities. When the ratio of the incompressible particle density to the fluid density is less than 0.4, the acoustic force will act towards the pressure antinode. If the density ratio is above 0.4 (which is the general case for real particles) the acoustic radiation force will act towards the pressure node of the standing wave. King's predictions have been shown to be in good agreement with experimental results for solid spheres suspended in a gas, but are subject to significant errors for spheres which are not rigid in comparison to the fluid medium, which is the case of bubbles within a resonant field.

In the light of this, King's theory was extended by Yosioka and Kawasima to allow for compressible spheres in 1955. They demonstrated that the time-averaged acoustic radiation force on a spherical particle of radius a, at position x within a one dimensional standing wave of acoustic energy density ε is:

$$F(x) = 4\pi k\varepsilon a^3 \Phi(\beta\rho)\sin(2kx) \tag{1}$$

The *acoustic contrast factor*, $\Phi(\beta\rho)$ is given by:

$$\Phi(\beta\rho) = \frac{\rho_p + \frac{2}{3}(\rho_p - \rho_f)}{2\rho_p + \rho_f} - \frac{\beta_p}{3\beta_f} \tag{2}$$

where β and ρ are the compressibility and the mass density of the fluid and the particle, indicated by subscripts f and p respectively. The wave number, k is equal to $2\pi/\lambda$ where λ is the wavelength of the standing wave.

For most applications of interest, including cells in aqueous solution, the acoustic force will act towards the pressure node, however in the case of bubbles that are smaller than resonant size, and certain two-phase fluid mixtures, the bubble, or second phase fluid, will experience an acoustic force acting towards the pressure antinode.

Particle Positions Under Gravity and Other Forces Yosioka and Kawasima also considered the direction in which an acoustic force will act on a particle in suspension. The equilibrium position of a particle within the

field will be determined by the resolution of this acoustic force and any other forces acting on the particle. Typically this would be gravity, although it applies to any force. In the case of a planar resonant field in which the positive x-axis points vertically upwards, the particle will be in equilibrium when:

$$3k\varepsilon\Phi(\beta\rho)\sin(2kx) = (\rho_p + \rho_f)g \quad (3)$$

The equilibrium position, for this case (in which the particle is small compared to the acoustic wavelength) is independent of the size of the particle, but dependent upon the acoustic contrast factor and the strength and frequency of the ultrasonic field. This offers a means of characterizing the acoustic field, the pressure amplitude of which is often difficult to determine in microsystems, by balancing acoustic and gravitational forces on an acoustically levitated particle. Particles that are not neutrally buoyant will have a minimum acoustic energy density required to hold the particle against buoyancy forces.

In many applications, including the manipulation of biological cells, particles are close to neutrally buoyant and the equilibrium position given by Eq. 3 will be very close to the pressure node. However for heavy particles, or for bubbles, this buoyancy offset may be significant.

Lateral Forces Real standing wave fields do not only exhibit pressure variations along the axis of the standing wave. They also have variations in the lateral directions leading particles to move not just to the axial pressure nodes, but also to particular points within those energy nodal planes. The practical effect of this is that instead of having a homogeneous layer of particles, the layer can organise itself into stripes, or striations, or other patterns. These inhomogeneities in the field may be caused by a number of phenomena including a decrease in acoustic energy towards the edges of axial fields, near field effects [9] due to geometric interference patterns, multi-dimensional acoustic modes within the enclosure, the coupling of structural (for example bending) modes into the fluid or inhomogeneity of the ultrasonic source.

In some cases these lateral variations provide a desirable feature of the device operation, particularly in systems designed to trap particles, while in others, the variations are not desirable and may be detrimental to the device performance, such as flow through concentrators. In real devices lateral forces may well exist due to a combination of the above causes. The magnitude and distribution of the lateral forces within resonators has been measured and shown to compare well with calculations using Gorkov's formulation for radiation forces (described by Gröschl in [1]).

Secondary Radiation Forces In addition to the axial and lateral radiation forces attributable to the primary acoustic field, secondary acoustic forces are produced between particles themselves. These particle-particle interactions, known as Bjerknes forces, aid the formation of aggregates within a standing wave, but such effects are negligible until the particles are in close proximity.

Some Practical Considerations

The Influence of Particles on the Field Resonant chambers for particle manipulation (including microfluidic chambers) are designed to provide specific acoustic characteristics. However, the chambers must work when filled with a fluid-particle mix which will have acoustic characteristics that differ from the particle-free fluid. Many applications will need to work over a range of particle concentrations that will modify the acoustic field. In cases where the particles are very different acoustically from the fluid medium, agglomerations can cause localized breakdown of the acoustic field resulting in a disruption of the ordered collection of particles at the pressure nodes.

Temperature Changes The temperature of an acoustic resonator will typically rise during use due to energy dissipation in the transducer and acoustic absorption within the layers of the resonator. The temperature rise will depend on the input power, the size of the resonator, the transducer material, and the material characteristics of the resonator layers. Hence there are significant differences in the thermal behaviour of resonators reported in the literature, with, for example, Hawkes and Coakley [3] reporting less than 1 K temperature increase in micro-scale chambers, while at the other extreme, Doblhoffdier et al. [2] required an integrated cooling circuit to avoid significant temperature rises in their rather larger chamber designed for the retention of mammalian cells.

Cell Viability Many of the uses envisaged for USW manipulation of particles are based upon manipulation of biological cells and so cell viability after treatment with ultrasound becomes an important issue. This has been reported on by several studies which have found that viability is maintained. For example Doblhoffdier et al. [2] suspended mammalian cells in a large resonator at different power levels and reported no significant loss in viability.

Hultström et al. [10] trapped cells in a 260 μm deep microfluidic chamber constructed from glass and PDMS. It was demonstrated that cell viability was not significantly impeded by 75 min exposure to a 0.85 MPa 3 MHz USW field. Indeed, tests on the cells following exposure

suggested that the exposure to ultrasound enhanced the cells' ability to proliferate. The same group has demonstrated the ability of ultrasound traps to enhance bioanalysis in a number of different microchambers and has constructed microdevices that integrate ultrasonic and dielectrophoretic manipulation.

Future Directions for Research

Radiation forces as generated by low MHz ultrasonic standing waves offer a method of manipulating particles in a fluid, with particular application at the microscale. This gives tremendous potential for trapping and manipulating larger particles and groups of particles, perhaps prior to finer manipulation from other techniques. In addition, the evidence that ultrasound can manipulate and control the position of cells without adversely affecting cell viability suggest that ultrasonic standing waves hold significant potential in the manipulation of biological cells. The field is still relatively immature and requires work on the characterisation and optimisation of chambers and defining the scale limits of manipulation in practical devices.

Microfluidic mixer; Micromixing chip; Micromixer; Passive mixer

Definition

A passive micromixer is one of the microfluidic devices. It utilizes no energy input except the mechanism (pressure head) used to drive the fluid flow at a constant rate. Due to the dominating laminar flow on the microscale, mixing in passive micromixers relies mainly on chaotic advection realized by manipulating the laminar flow in microchannels or molecular diffusion with increasing the contact surface and time between the different fluid flows.

Overview

Microfluidic devices have had a considerable impact in the fields of biomedical diagnostics and drug development, and are extensively applied throughout the food and chemical industries. The very small scale of the flow

channels in microfluidic systems increases the surface to volume ratio, and is therefore advantageous for many applications. However, the characteristic Reynolds number ($\mathrm{Re} = l\rho v/\eta$) of liquid flows in such microchannels is very small. For example, the Reynolds number in a typical water-based microfluidic system with a channel width of 100 μm, a liquid flow rate of 1 mm/s, a fluid density of 1 g/cm^3 and a viscosity of 0.001 N s/m^2 is of the order of 0.1. In such low Reynolds number regimes, turbulent mixing does not take place, and hence species mixing occurs primarily as a result of diffusion, which is an inherently slow process. Consequently, the aim of microfluidic mixing schemes is to enhance the mixing efficiency such that a thorough mixing performance can be achieved within shorter mixing channels, thus reducing the characteristic size of microfluidic devices. Furthermore, developing efficient mixing schemes is essential to increase the throughput of microfluidic systems in general and to realize the concept of micro-total-analysis systems and Lab-on-a-Chip systems in particular.

In micromixers, two operating parameters are of importance: the Reynolds number Re and the Péclet number Pe. The Reynolds number, given by

$$\mathrm{Re} = VL_h/\upsilon \quad (1)$$

represents the ratio of momentum to viscous friction, where V is the average flow velocity, L_h is the hydraulic diameter and υ is the kinematic viscosity. A turbulent flow can be indicated by a high Reynolds number above a critical value (around 2300 on the macroscale). In most cases of microfluidics, a laminar flow can be expected with a low Reynolds number. The Péclet number, given by

$$\mathrm{Pe} = VL/D \quad (2)$$

represents the ratio of the mass transport due to convection and that of diffusion, where L is the mixing path and D is the diffusion coefficient. Convection is dominant at higher Péclet numbers.

The theory reported on mixing began with Einstein's investigation of Brownian movements [1]. The common mixing methods are the generation of chaotic advection and turbulence. Fluid motions vary irregularly so that quantities such as pressure and velocity show a random variation in space and time. The random movement quickly disperses the mixed components. Chaotic advection can be generated by stirring the flow, which is very effective for low Reynolds numbers. The concepts of splitting, stretching, folding and breaking up play an important role in the mixing quality.

In contrast to the passive mixing schemes presented above, in which the microchannel configuration is specifically designed to increase either the contact area or the contact time (or both) of the multiple species, active mixing schemes improve the mixing performance by applying external forces to the sample flow in order to accelerate the diffusion process. Typically, active schemes are implemented by incorporating some form of mechanical transducer within the microfluidic device using microfabrication techniques. It has been shown that microfluidic mixers which use embedded ultrasonic transducers to generate acoustic waves to stir the samples are capable of achieving a high mixing performance. However, the acoustic vibrations also generate considerable heat, which is undesirable since it may lead to unwanted reactions between the samples. Various microfluidic devices with embedded microelectrodes designed to mix the sample fluids dielectrophoretically have been presented. It has also been shown that the use of embedded electrode pairs to change the surface energy of the microchannel walls provides an efficient means of enhancing species mixing by inducing local instabilities in the flow stream. Compared to other active mixing schemes, the use of embedded electrode pairs has the advantage that moving components are not required, and hence the resulting microfluidic devices are not only cheaper, but also more reliable.

Besides chaotic advection, molecular diffusion is another important form of mass transfer in passive micromixers. In such scales where the flow is strictly laminar, the mixing is entirely ensured by molecular diffusion between layers of different concentrations. Consequently, when the thickness of each fluid layer is larger than the characteristic diffusion length, an effective and rapid mixing is difficult to achieve. The diffusion length is often approximated by $\sqrt{Dt}$, where t is the residence time of the species. To overcome the limitations by integrating particular designs of microchannels on the basis of different fluidic mechanisms, the most common approach is based on increasing the contact surface between the different fluids and decreasing the diffusion path between them. In general, passive micromixers can be categorized as lamination, chaotic advection and special designs, based on the arrangement of the mixed phases.

Basic Methodology

Theory of Lamination

Mixing in general follows a two-step sequence. The first is segmentation where a heterogeneous mixture of substantially homogeneous flows of the two fluids is formed by convection; the second is interdiffusion of molecules between nearby flows. Segmentation procedures, well

known from the macroscopic world, such as stirring or creation of turbulent flow, cannot be scaled down to microsystems with dimensions so small that Reynolds numbers exceeding 2000 (the limit for turbulent flow) are not feasible.

Perfect lamination can be obtained in a flow with a sufficiently low Reynolds number provided that the channel system guiding the fluid is designed in such a way that the pressure gradients in the flow channels will force the two fluids to laminate. Figure 1 shows a generic channel arrangement laid out in a free three-dimensional space. When considering symmetry it is obvious that a perfect lamination and a split into two channels is obtained. Depending on the flow direction, either horizontal (Fig. 1a) or vertical (Fig. 1b) lamination will be the result [2].

A detailed theoretical description of flow and diffusion phenomena in the laminar regime is very useful during design and testing of mixers for microsystems. The fully developed velocity profile for laminar flow in a straight channel of rectangular cross-section of dimensions $W \times H$ is easily found by numerical methods. For channels having width (W) significantly larger than height (H) the velocity profile turns out to be very close to parabolic in the direction of the short dimension and almost similar to H from the channel walls. This is also expected intuitively, as the distance to the nearest walls is the only physically important parameter for laminar flow. In Ref. [2], it was found that the peak velocity (v_{peak}) in the middle of the channel is related to the average velocity (v_{average}) (as calculated from the volume flow rate) as

$$v_{\mathrm{peak}} = \frac{3}{2}\left(\frac{1}{1-0.62H/W}\right) V_{\mathrm{average}} \tag{3}$$

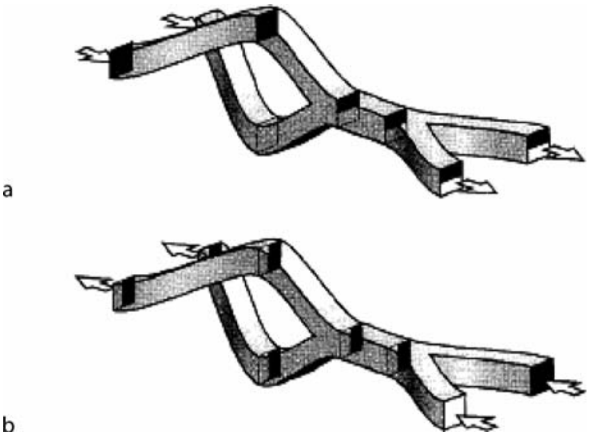
within 1.5% when $W \geq 3H$.

When solving the diffusion problem for a laminated structure, it is useful to consider Fourier expansion of the initial concentration profile, as it is well known that the time evolution of the concentration profile is given by the time evolution of each of the Fourier components. Each Fourier component κ decays exponentially during the diffusion process with a time constant τ_k given by

$$\tau_k = (2\pi)^{-2}\frac{L_k^2}{D} \tag{4}$$

where L_k is the *wavelength* of the Fourier component and D is the diffusivity.

This explains concisely what is also expected from quantitative arguments that a 2^n-layer structure can mix 4^{n-1} times faster than a 2-layer structure, as the wavelength of the Fourier component of longest wavelength and thus slowest decay rate scales with the layer thickness [2].



Passive Micromixers, Figure 1 A generic two-input two-output mixer including lamination and splitting shown in free three-dimensional space. (**a**) Horizontal lamination and (**b**) vertical lamination [2]

Meanwhile, the Fourier argument makes a small but important detail of mixing by lamination very clear: The lamination has to be symmetric, i. e. the top- and bottommost layer should be of only half thickness compared to the other layers. Otherwise, i. e. if the lamination is asymmetric, the Fourier expansion of the initial profile will contain a component with a wavelength twice the channel dimension, no matter how thin the laminated layers are. The component will sooner or later become dominant because of its slow decay, and only a minor benefit is obtained by lamination. The qualitative counterpart of this argument is that, unless the outermost layers are of half thickness, half of their content of the diffusing species has to be distributed over all of the inner layers before full mixing is achieved. When being of only half thickness, they are balanced by their neighboring layer as are all the other layers.

However, a simple cascade of two-input two-output mixers results in an asymmetric lamination. Symmetric lamination can be obtained with a modification of the first mixer into a three-input two-output mixer which builds up a $(H/4, H/2, H/4)$ type of laminate. This initial mixer can be followed by as many regular two-input two-output mixers as desired for the particular application.

Micromixers Based on Lamination

In miniature flow systems with Reynolds numbers varying from 2 to 100, flow structures can be artificially induced which assist in flow segmentation through inertia effects. Wu et al. [3] presented an analytical model of diffusive

mixing in microchannels. The dimensionless analysis generalizes the solution for different channel sizes and different diffusion coefficents by varying the Peciet numbers. It could be seen that the nonlinear model described well the diffusive mixing process in the microchannels and the mixing performance was improved with lower Peciet numbers due to the stronger diffusion effect. Another lamination micromixer using inertia forces was reported in the literature, involving a coaxial mixer containing an inner core liquid stream with a low flow rate and an outer flow stream with a higher flow rate.

Jacobson et al. [4] proposed micromixers for electrokinetically driven parallel and serial mixing. To simplify the voltage control hardware, electrokinetic mixing is effected using a single voltage source with the channels dimensioned to perform the desired voltage division. In addition, the number of fluid reservoirs is reduced by terminating multiple buffer, sample or analysis channels in single reservoirs. The parallel micromixer (Fig. 2a) was designed with a series of independent T-intersections, and the serial micromixer (Fig. 2b) was based on an array of cross intersections and sample shunting. The parallel micromixer has the advantages that each set of channels is independent of the others. Consequently, a failure in one set of channels does not affect the operation of the others. The dynamic range of the serial micromixer is larger especially if the sample shunting is carried out with additional cross intersection added to the channel manifold beyond the fifth cross intersection. Wong et al. [5] presented a micro T-mixer fabricated on a silicon substrate and bonded to a Pyrex glass plate (Fig. 3). The experimental results revealed that a mixing channel with a hydraulic diameter of 67 μm and an applied pressure of 5.5 bar were sufficient to result in complete species mixing in less than 1 ms following the initial contact between the two species flows with Reynolds numbers of 400 – 500.

Micromixers Based on Intersecting Channels

Micromixers with intersecting channels can be used to split, rearrange and combine component streams in order to enhance their mixing. He et al. [6] proposed a picoliter-volume mixer (Fig. 4) with intersecting channels of various lengths and a bimodal width distribution. In the proposed design, all of the channels running parallel to the flow direction had a width of 5 μm, while those intersecting the parallel channel network had a width of 27 μm and were aligned at an angle of 45°. The microchannels were designed such that the two species streams merged into one larger stream and then flowed together along a mixing channel of length 300 μm. The results showed that this configuration enabled a complete species mixing within a distance of 200 μm, representing a considerable

Effect of mixing is evaluated by bringing in two fluids from channels A and B, and flowing to D. Channel C is not used in this work [6]

improvement compared to the mixing distance of 3000 μm required to fully mix the two streams in a conventional straight channel. Melin et al. [7] presented a micromixer in which a constantly changing, time-dependent flow pattern was created within a two-sample liquid plug as the plug passed through a planar mixer chamber. It was shown that the micromixer created a larger mass transfer within the liquid plug than that achieved in many of the passive devices presented previously. The proposed mixing chamber comprised a main meandering channel with perforated walls, which formed connecting channels between parallel segments of the main meandering channel. In the mixing process, two discrete liquid samples are fed into the mixing chamber in a laminar manner. When the liquid wets one side of the first perforated wall segment, it enters the perforation, but is prevented from exiting by surface tension effects. However, as the bulk of the liquid proceeds to the next main channel segment, the other side of the perforated wall becomes wetted. As a result, the liquid/air interface at the exit of the perforation is replaced by a liquid/liquid interface, and hence the liquid flows freely through the perforation. The same phenomenon is repeated in each of the main channel segments as the liquid flows progressively through the mixing chamber. The resulting constantly changing flow lines within the liquid plug cause a self-folding effect within the plug which yields a significant improvement in the mixing performance.

Micromixers Based on Zigzag Channels

Mengeaud et al. [8] presented a 100 μm wide zigzag microchannel integrating a "Y" inlet junction (Fig. 5). The effect of the periodic step value (s) on the mixing efficiency was investigated in a series of experimental trials. The results indicated that for $\mathrm{Re} = 0.26$, the mixing efficiency increased from 65% to 83.8% when the geometry ratio was increased from 1 to 8. For low values of s/w, the number of angles increases, resulting in an increase in the effective width and a reduction in the effective length. For low Reynolds number flows, it was found that the most efficient zigzag configuration, corresponding to $s = 800$ μm, gave a mixing efficiency of 83.8%. For $\mathrm{Re} = 267$, the mixing efficiency increased rapidly to 98.6% as the geometry ratio was increased to 4, but reduced slightly to 88.1% as the geometry ratio was further increased, thus indicating the existence of an optimal zigzag geometry. After the research, the zigzag passive micromixer showed a modified Tesla structure. The species streams flowed close to the angled surface as a result of the Coanda effect, and this effect was used to guide the fluid streams such that they collided with one another. Mixing cells in opposite directions were then used to repeat the transverse dispersion caused by the flow impact. In the micromixer, one of the fluids was divided into two sub-streams and one of these two sub-streams was then merged with the second fluid stream from the main channel in the micromixer. The two streams were then

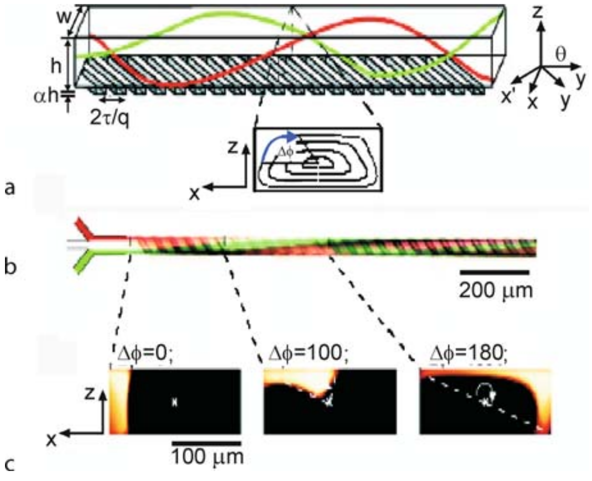
mixed with the second sub-stream, resulting in a strong impact around the sub-channel of the micromixer.

Micromixers Based on Three-Dimensional Serpentine Structures

The three-dimensional serpentine micromixer was designed to induce a chaotic mixing effect. It was found that the mixing efficiency of the serpentine microchannel was twice that obtained in a conventional straight microchannel. Liu et al. [9] fabricated a three-dimensional serpentine micromixer (Fig. 6) featuring a "C"-shaped repeating unit designed to induce chaotic advection. Mixing in the serpentine channel relies on the flow field being sufficiently three-dimensional, with secondary flows stretching and folding the fluid, greatly increasing the interfacial area across which diffusion occurs. The results showed that for flows with a Reynolds number of 70, the mixing efficiency in the serpentine channel was 16 times better than that in a conventional straight channel and 1.6 times better than that in a zigzag channel.

Micromixers Based on Embedded Barrier

Based on the combination of multilamination and chaotic advection effects, Kim et al. [10] developed barrier embedded micromixers for pressure-driven flow in which chaotic flow was induced by applying periodic perturbations to the velocity field via periodically inserted barriers along the upper surface and helical-type flow structures were induced by slanted grooves on the lower surface of the microchannel. Observations using a confocal microscope revealed cross-sectional mixing behaviors in several locations of the micromixer. The proposed design was validated experimentally at a flow rate corresponding to a Reynolds number of 2.28 (corresponding to $Pe = 1.24 \times 10^4$ with a Rhodamine diffusivity of $2.8 \times 10^{-10}\ m^2\ s^{-1}$). Laser scanning around the entrance zone of the micromixer identified a bright image only in the half-zone containing Rhodamine. Bright images



Passive Micromixers, Figure 7 Three-dimensional twisting flow in a channel with obliquely oriented ridges on one wall. (**a**) Schematic of channel with ridges. (**b**) Optical micrograph showing a top view of a red stream and a green stream flowing on either side of a clear stream in the channel. (**c**) Fluorescent confocal micrographs of vertical cross-sections of a microchannel such as in (**a**) [11]

were also observed at the no-barrier zone in the first half-cycle, thus confirming the cross-sectional rotating flow effect induced by the slanted grooves. When the streams entered the barrier zone in the next half-cycle, laser scanning showed that the flow was rotated yet further. The experimental results confirmed that the barrier embedded micromixer yielded an excellent species mixing within a short channel length.

Micromixers Based on Slanted Well

Stroock et al. [11] presented chaotic mixers (Fig. 7) designed to mix streams of steady pressure-driven flows in microchannels at low Reynolds numbers. The authors considered two different microchannel designs, namely one channel with straight ridges on one wall and a second channel with a staggered herringbone pattern on one wall. The mixing performances of the two microchannels were compared with that of a smooth microchannel. In the evaluation experiments, cross-sectional images taken at the same distance (3 cm) from the junction were acquired and the mixing efficiency was assessed by computing the standard deviation σ of the fluorescence intensity in the confocal images as a function of the distance along the mixing channel length, Δy. The deviation maintained a constant value of approximately 0.5, indicating a poor mixing performance. The results revealed that the micromixer with straight ridges on one microchannel wall yielded a poor mixing performance. The standard deviation profile for a low Pe number was approximately 0, which signifies an almost complete mixing. Others investigated the effects of the asymmetry index p and depth ratio α of the groove on the mixing performance of a staggered herringbone mixer with patterned grooves. Since the two vortices within the mixing channel are determined by the asymmetry index p, vortices with dissimilar scales were shown to provide a better mixing performance than two equally sized vortices. Furthermore, the results showed that the intensity of the vertical fluid motions at the side edges of the grooves increased with increasing groove depth α, resulting in a significant improvement in the mixing effect.

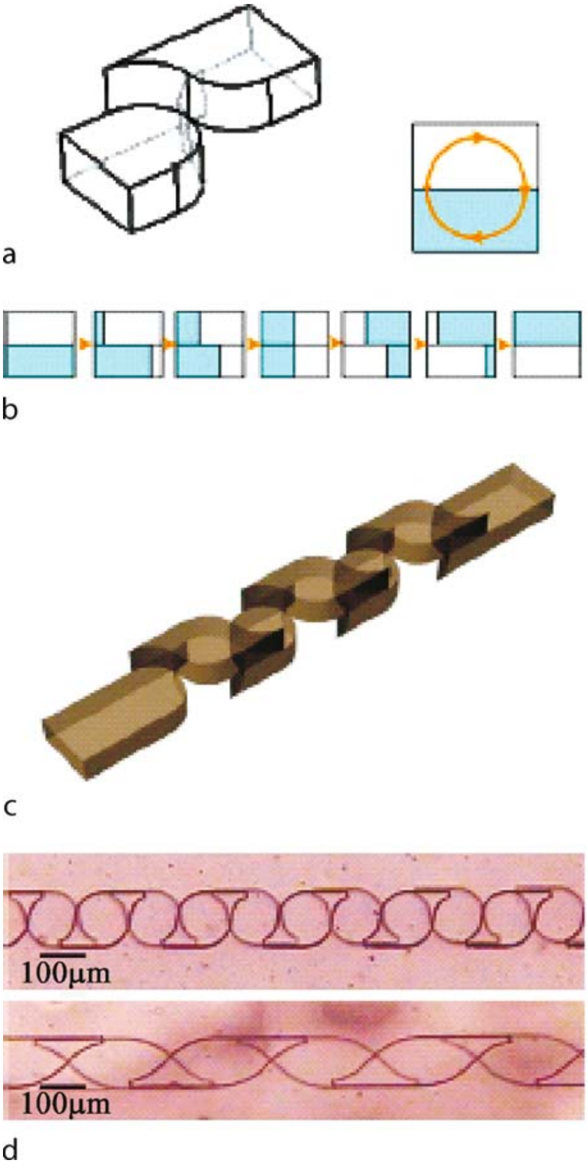
Micromixers Based on Twisted Channels

In twisted microchannel applications, the micromixer featured is a three-dimensional structure of twisted microchannels designed to induce a chaotic mixing effect within the fluid streams. The twisted microchannels were designed such that the angle of the channels' lower surfaces alternated in each longitudinal subsection of the mixing channel. The fluid flow sways from side to side as it travels along the microchannel, resulting in a chaotic advection effect. Park et al. [12] presented a breakup method based on passive rotation for enhancing the mixing efficiency of micromixers. The proposed method not only actively generated interfaces between the mixing species, but also enhanced the diffusion process at the interface. The micromixer actually incorporated two separate mixing regions, namely one region with short segments of length 200 μm and a second region with long segments of length 400 μm (Fig. 8). The results showed that this design caused a rotation of the fluids flowing through the channel. It was found that the fluids were mixed well and their interface was distorted at high Reynolds numbers. Conversely, at low Reynolds numbers, the fluids were hardly mixed and the interface was not distorted, i. e. only the respective positions of the two fluid streams were changed.

Key Research Findings

Grooved Staggered Herringbone Micromixers

Grooved staggered herringbone micromixers are based on the original design proposed by Aubin et al. [13] and have an off-centered herringbone pattern on the lower surface of the microchannel, which creates a transverse velocity component in the flow field. Such mixers have several mixing cycles, where each cycle comprises two sequential regions of grooves, i. e. two half-cycles. The direction of asymmetry of the herringbone pattern switches with respect to the centerline of the microchannel every half cycle. In order to improve the mixing efficiency, the depth of the grooves in staggered herringbone micromixers should be specified



Passive Micromixers, Figure 8 Schematic diagrams of (**a**) one mixer segment and (**b**) flows in the microchannel recirculating along the walls. (**c**) Schematic of mixer 1. as 30% of the channel height. This promotes both spatial homogenization and a reduction of the striation thickness without increasing the pressure drop across the mixer.

Surface Chemistry Technology in Microchannels

In microfluidic systems, very high pressure gradients are generally required to drive and manipulate the fluid flow. Due to the small characteristic scale of the microchannels in typical microfluidic devices, surface forces dominate, and high friction effects are generated. Conventionally, microchannels are fabricated using silicon dioxide. Silicon dioxide surfaces are typically negatively charged due to their deprotonated silanol groups ($\equiv$Si–O^-). When these surfaces come in to contact with a solution containing ions, the positive ions are attracted to the surface, forming an important layer and a diffuse layer on the surface. If an electrical field is then applied, the positive ion diffuse layer moves in the direction of the applied field. The movement of the diffuse layer drags the bulk fluid into motion via momentum coupling, resulting in the so-called electroosmotic flow (EOF) phenomenon [14].

Future Directions for Research

Mixing in electro-osmotic flow is generally diffusion-dominated. However, it has been shown that the introduction of electrically charged surface heterogeneities enhances the mixing efficiency by creating localized flow circulation regions. By selectively patterning positively charged molecules on a negatively charged channel wall, flow vortices can be induced as a result of the differences in electrostatic potential between the homogeneous and heterogeneous surfaces. It has been shown that these localized flow vortices can be exploited to yield a significant improvement in the mixing performance in a variety of microchannel configurations, including in-line, staggered, serpentine, herringbone and diagonal arrays [15]. In their numerical investigations, the authors specified the patch length and spacing parameters in such a way as to maintain a constant ratio of the heterogeneous-to-homogeneous surface areas over a channel length of 1.8 mm. The results revealed that the nonsymmetrical heterogeneous patterns, namely the staggered and diagonal patterns, generated a better mixing performance than either the symmetrical herringbone pattern or the in-line arrangement. With a theoretical mixing efficiency of 96%, the staggered configuration provided the best mixing performance, outperforming the diagonal, herringbone and serpentine configurations by 8%, 31% and 36%, respectively. Furthermore, compared to the homogeneous case, the staggered configuration provided a 61% improvement in the mixing efficiency. The use of heterogeneous surface charge patches to manipulate electrokinetic flows provides a simple, low-cost solution to mixing problems in Lab-on-a-chip systems, and is therefore likely to receive increasing attention in future studies.

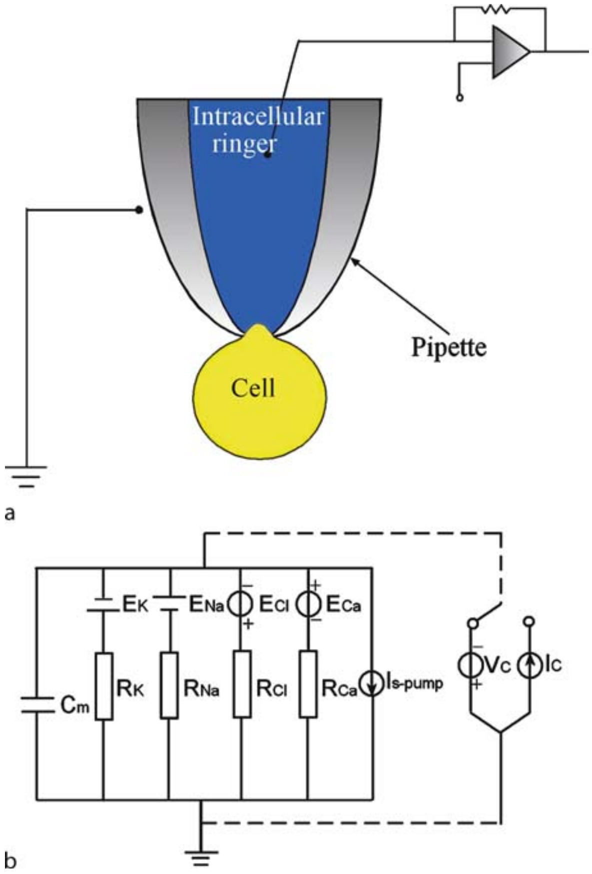
Definition

Ion channels, like molecular pores that open and close in response to stimuli, allow electrically charged atoms – such as sodium, potassium and calcium ions – to pass in and out of a cell through the cell's outer membrane by opening and closing like tiny gates. The *patch clamp technique*, a dominant technique providing valuable information for ion channels, including their electrophysiological properties, molecular structures and the mechanism of drug action in cellular electrophysiology with high resolution, involves the fabrication of a pipette with a micrometer-sized tip which is filled with a conducting solution and the tip gentle suction directed towards the cell membrane with a micromanipulator in order to form a gigaseal between the pipette tip and the cell membrane. A *gigaseal* is a tight seal between the membrane and pipette rim with a resistance in the range of gigaohms (10^9 Ω).

Overview

The patch clamp technique, as a dominant technique, provides valuable information for ion channels, including their electrophysiological properties, molecular structures and the mechanism of drug action in cellular electrophysiology with high resolution. The rationale for using *patch pipettes* and the principles of patch clamp recording, including the information provided, are elaborated in detail first to understand the mechanism of the technique. The advantages and disadvantages of four configurations of this technique, i. e. on-cell patch clamp, whole cell patch clamp, inside-out patch clamp and outside-out patch clamp, are then described in the following. Two different methods for preparation of pipette on-chip and patch clamp device on-chip fabrication and electrophysiology recordings are given to provide reference for the reader. There are some simple but perspicuous figures presented to allow an easier grasp of the patch clamp technique. Finally, the key research findings about this technique are summarized and future directions for research are proposed.

Ion channels provide pores for the passive diffusion of ions across biological membranes. They are often highly selective for a particular ionic species, leading to a classification into sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), chloride (Cl^-) and unspecific cation channels. The direc-



Patch Clamp Measurements On-Chip, Figure 1 Patch clamp technique and an amended equivalent circuit

tion of net ion transport, which is associated with an electric current, depends on the electrochemical gradient (established by interplay of active pumps, co-transporters and ion channels) for the relevant ionic species. Channels occur not only in the external (plasma) membrane, but also in membranes of intracellular organelles. Ion channels are essential for many of the cell's functions, such as impulse conduction in the nervous system or pace-making in the cardiac system, and their dysfunction is pivotal in many diseases. The list of human diseases known to be associated with defects in ion channels has grown considerably during the past few years. Hence, there is a great interest in ion channels not only from academia to understand the biophysics of their function but also from the biotechnology and pharmaceutical industries to develop drugs that modulate ion channels to correct any malfunction.

Several methods are available today to test candidate ion channel active drugs (ICADs): electrophysiology (patch clamp), binding assays, radioactive flux assays, membrane potential-sensitive fluorescent dyes, ion-sensitive dyes and voltage sensing based on fluorescence resonant energy transfer (FRET).

Giving an unsurpassed information content and having high sensitivity, the patch clamp technique, developed by Erwin Neher and Bert Sakmann at the Max Planck Institute, Germany (they were awarded the Nobel Prize in Medicine for this discovery; see Fig. 1), is a powerful tool for studying the electrophysiological properties of biological membranes. It is mainly used to detect currents that pass a patch of cell membrane. This *patch* can be a large one, as large as almost the whole cell membrane; or a small one, so small as to contain only several or even one ion channel. *Clamp* mainly refers to fixing the voltage across the membrane, i. e. membrane potential, at a constant level, or at different levels stepwise, under which conditions transmembrane currents are measured (i. e. voltage clamp mode). Also, the patch clamp technique can sometimes be used to observe the membrane potential when a constant current (usually zero), on which sometimes a squarewave current is superposed, is injected into the cell (i. e. current clamp mode). And furthermore, with this technique cell secretion ions can also be studied by measuring the capacitance of the cell membrane (C_{m}), which, used as an indicator of the area of cell membrane, may change during cell secret ion.

Basic Methodology

Mechanism

Rationale for Using Patch Pipettes

A basic limitation for any current measurement, disregarding instrumentation noise, is the Johnson or thermal noise of the signal source, which for a simple resistor is given by

$$\sigma_n = \sqrt{4kT\Delta f/R}$$

where σ_n is the root-mean-square deviation of the current, k the Boltzmann constant, T the absolute temperature, Δf the measurement bandwidth and R the resistance. From this equation, it is clear that the internal resistance of a signal source (or, more generally, the complex impedance) should be very high for low-noise current recording. Specifically, to record a current of 1 pA at a bandwidth of 1 kHz with 10% accuracy, the internal resistance of the signal source should be about 2 GΩ or higher. We now know that the input resistances of small cells can be as high as that. But in the early 1970s the conventional microelectrode techniques required large cells for reliable current measurements, and these typically had input resistances in the range 100 kΩ to 50 MΩ. Thus, it seemed impossible to reach the required resolution with

standard techniques and standard preparations. What was required was a smaller signal source.

It was clear that they should be good tools for single-channel measurements, if only the *pipette-to-membrane seal* could be made good enough. The impedance of the patch itself should be higher than required, even for a patch as large as 10 μm in diameter. An incomplete seal, however, is "seen" by the measuring amplifier in parallel to the patch, and its noise is superimposed onto the patch signal.

Principles of Patch Clamp Recording

As is known, there is a resting potential (RP) across the membrane of most cells, and based on it action potentials (AP) or local responses can occur. All these electric phenomena involve specific states or activities of different ion channels and pump proteins in the membrane. The commonly cited explanation can be found in any textbook of general physiology, so we only present an amended equivalent circuit (Fig. 1) for a membrane patch, which is useful for understanding various electric phenomena that occur in the cell membrane.

This circuit includes multiple branches but only two nodes. Channels for different ions are equivalent to voltage sources, whose electromotive forces are equal to their respective equilibrium potentials determined by the Nernst formula, and whose internal resistances depend on the permeability of the membrane for, and the diffusion coefficients as well as the concentrations of, respective ions, etc. The ion pumps can be represented by corresponding current sources, all of which can be summed up forming one current source as shown in Fig. 1. If there exist transporters in the membrane, they can be electrically modeled (omitted in Fig. 1) in the same way as pumps. The capacitor represents the effect of the lipid bilayer of the membrane together with the extracellular solution (or the bath solution under artificial conditions) and intracellular solution. All these branches are arranged in parallel.

If no external circuit acts on the membrane, and the membrane potential is constant or changes very slowly, its value can be given by the node voltage formula:

$$V_{\mathrm{m}} = \frac{E_{\mathrm{K}} g_{\mathrm{K}} + E_{\mathrm{Na}} g_{\mathrm{Na}} + E_{\mathrm{Ca}} g_{\mathrm{Ca}} + E_{\mathrm{Cl}} g_{\mathrm{Cl}} - I_{s-\mathrm{pump}}}{g_{\mathrm{K}} + g_{\mathrm{Na}} + g_{\mathrm{Ca}} + g_{\mathrm{Cl}}} = \frac{\sum E_j g_j - I_{s-\mathrm{pump}}}{\sum g_j}$$

Incidentally, if g_{K} is much larger than the conductance for other ions, and the contribution of the net pump current to V_{m} is small enough to be omitted, which is the case for most cells at rest, it can be seen that RP = $V_{\mathrm{m}} \approx E_{\mathrm{K}}$.

If the state of a certain kind of ion channel changes, there generally occurs a change in more than one channel current, accompanied by a change in the membrane potential, i. e. hyper- or hypo-charge of the membrane capacitance.

What interests us most is what ion channels mediate a certain cellular electric activity caused by a certain factor such as alteration in V_{m} or a chemical (ligand) stimulus. Some ion channels are voltage dependent, that is, their permeability changes with the alteration of V_{m}. By holding and changing V_{m} artificially to measure the currents through these channels we can get the details of their voltage-dependent characteristics. On the other hand, many channels such as ligand gated ion channels and G-protein coupled ion channels are chemical dependent, and also respond to V_{m} alteration passively (i. e. voltage independent: the response current is linear with V_{m} alteration with the permeability or conductance of the ion channel remaining constant) or even actively (i. e. voltage dependent as explained above). Under normal circumstances, the activity of these channels caused by a chemical is accompanied by the change in membrane potential. To distinguish between the effect of a chemical and that of V_{m} alteration, it is necessary to fix V_{m} at a constant level to remove the influence of the V_{m} alteration, or at different levels stepwise to observe the amplitude and configuration of the channel current traces for analyzing its ionic mechanisms. The following is a further discussion using some concise and explicit formulae.

V_m is set at a constant level. Once V_{m} is set constant, the capacitive current is zero. This means that the current recorded via the recording pipette equals the transmembrane current (current carried by ions flowing through channels and ions transported by pumps); or briefly speaking, the current recorded is the transmembrane current.

In this case, the current via each kind of ion channel can be expressed as

$$I_j = (V_{\mathrm{m}} - E_j) g_j$$

And the active current caused by the activity of this kind of channel is

$$\Delta I_j = (V_{\mathrm{m}} - E_j) \Delta g_j$$

The whole transmembrane current (including that carried by ion pump s) is

$$I = \sum (V_{\mathrm{m}} - E_i) g_j + \sum I_{s-\mathrm{pump}}$$

and the whole active transmembrane current is

$$\Delta I = \sum (V_{\mathrm{m}} - E_j) \Delta g_j + \sum \Delta I_{s-\mathrm{pump}}$$

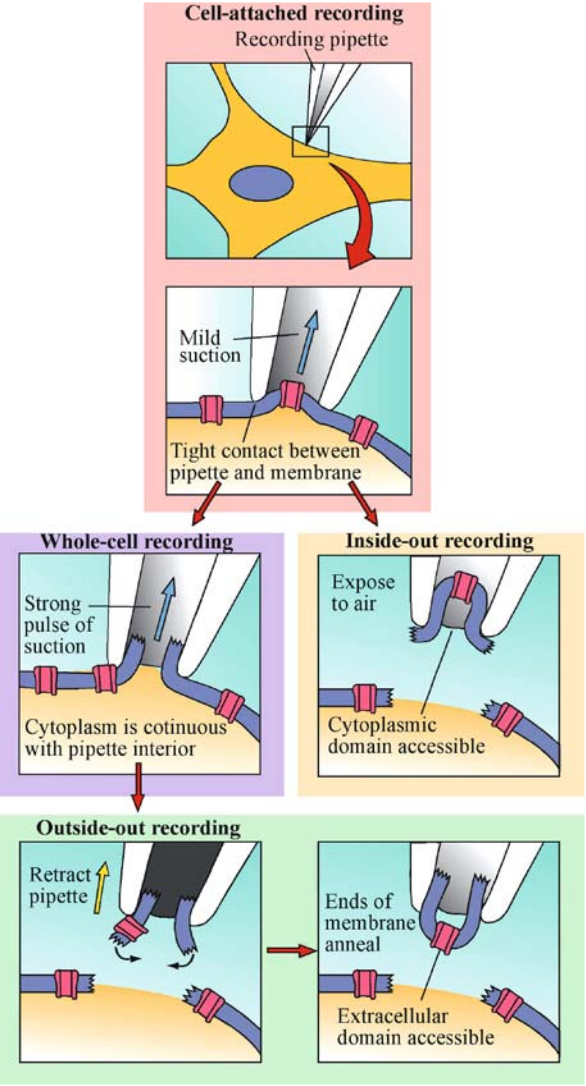
It is clear that the term $\Sigma(V_m - E_j)\Delta g_j$ represents the current response caused by the activity of ion channels, and the term $\Sigma\Delta I_{s-\text{pump}}$, by the activity of ion pumps.

V_m *is set dynamically from one definite level to another.* If V_m clamped jumps from an initial level to a new one, that is, an artificially controlled step voltage $g\Delta V_m$ occurs across the cell membrane, and it causes the activity of some ion channels, the transmembrane current will change from $\Sigma(V_m - E_j)g_j$ to $\Sigma(V_m + \Delta V_m - E_j)(g_j + \Delta g_j)$ (pump currents are omitted here for simplifying the discussion), and the alteration of the transmembrane current will be

$$\Delta I = \sum \Delta V_m g_j + \sum (V_m + \Delta V_m - E_j)(\Delta g_j)$$

The term $\Sigma\Delta V_m g_j$ is the linear transmembrane current change caused by the step voltage, i.e. the passive current response. It can be removed using leak subtraction function for a better observation of the current change caused by the activity of ion channels, i.e. the active current response, which is represented by the term $\Sigma(V_m + \Delta V_m - E_j)(\Delta g_j)$.

Based on the above important concept, the reversal potential V_{rev} is easily accessible. It generally refers to the membrane potential at which the active current response to a kind of stimulus disappears, and beyond which it reappears but flows in the opposite direction. So, let $\Sigma(V_m - E_j)\Delta g_j$ be zero in case (1), or let $\Sigma(V_m + \Delta V_m - E_j)(\Delta g_j)$ be zero in case (2), and we arrive at: $V_{rev} = (\Sigma E_j \Delta g_j)/(\Sigma\Delta g_j)$ (pump currents are omitted, and note that V_{rev} refers to V_m in case (1) and to $V_m + g\Delta V_m$ in case (2)). This is a general formula for discussing reversal potential, and it is helpful in exploring the mechanism underlying a current response that has been observed.



Patch Clamp Measurements On-Chip, Figure 2 Four configurations of patch clamp

Four Configurations

Figure 2 shows the four configurations of patch clamp technique. They are discussed as following.

On-Cell Patch Clamp

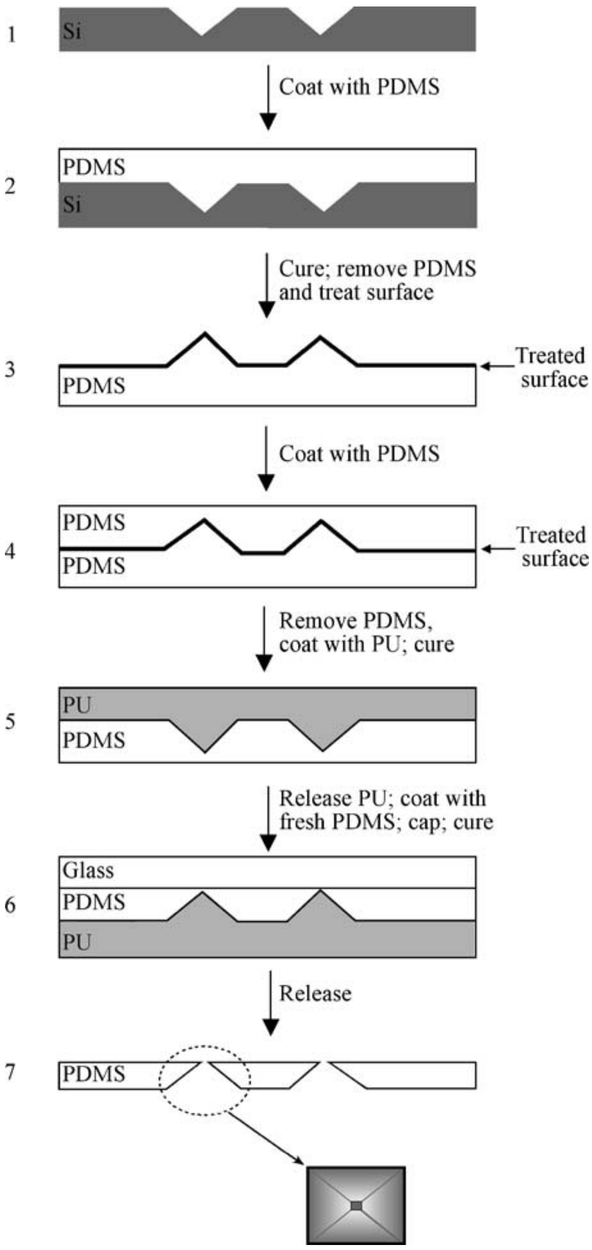
A cell-attached (single-channel) voltage clamp is a form of patch clamp when the voltage of only a small part of the cell is controlled allowing current flowing through individual ion channels to be distinguished.

This technique is based on a very simple idea. A pipette with a very small opening is used to make tight contact with a tiny area, or patch, of neuronal membrane. After the application of a small amount of suction to the back of the pipette, the seal between pipette and membrane becomes so tight that no ions can flow between the pipette and the membrane. Thus, all the ions that flow when a single ion channel opens must flow into the pipette. The resulting electrical current, though small, can be measured with an ultrasensitive electronic amplifier connected to the pipette. Based on the geometry involved, this arrangement usually is called the cell-attached patch clamp recording method.

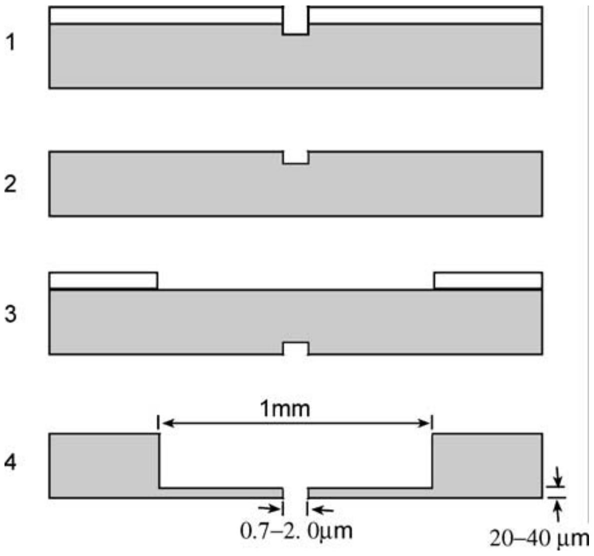
As with the conventional voltage clamp method, the patch clamp method allows experimental control of the membrane potential to characterize the voltage dependence of membrane currents.

Whole Cell Patch Clamp

A whole cell voltage clamp is a form of patch clamp where electrical access is gained to the whole of the cell (usually



Patch Clamp Measurements On-Chip, Figure 3 Multi-pipette tip on-chip fabrication



Patch Clamp Measurements On-Chip, Figure 4 The steps in fabricating a silicon substrate for use as a planar patch clamp. Circles (2 μm diameter) were defined in a photoresist (white layer) using optical lithography and then etched to a depth of 20–40 μm using deep reactive ion etching. The SU-8 resist was then stripped off with an acid bath and the wafer was inverted for back-side processing. A 1 mm diameter well, centered on the 2 μm pore, was defined using optical lithography. Deep reactive ion etching was used to etch the 1 mm well to a depth such that a small pore was formed connecting the base of the well to the other side of the wafer. A 0.5–1 μm thick SiO_2 film was then deposited over the surface of the entire wafer (using PECVD). This film electrically isolates the front side of the wafer from the back and reduced the pore diameter to 1.5–1.8 μm. The deposition conditions could be varied to deposit thicker oxides and thereby reduce pore diameters as small as 0.7 μm

by disrupting the membrane underneath the pipette by suction), allowing the electrical activity of the whole cell to be measured.

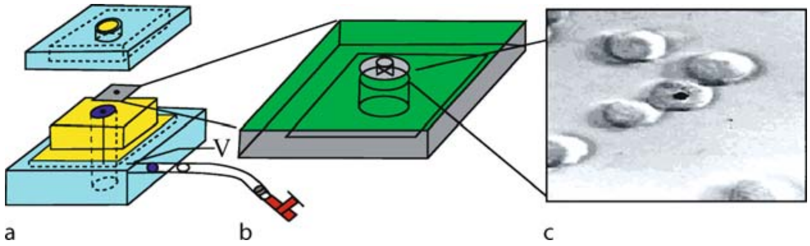
If the membrane patch within the pipette is disrupted by briefly applying strong suction, the interior of the pipette becomes continuous with the cytoplasm of the cell. This arrangement allows measurements of electrical potentials and currents from the entire cell and is therefore called the whole cell recording method. The whole cell configuration also allows diffusional exchange between the pipette and the cytoplasm, producing a convenient way to inject substances into the interior of a *patched* cell.

This is a powerful technique for studying ionic currents at the level of the whole cell membrane.

Inside-Out Patch Clamp

Once a tight seal has formed between the membrane and the pipette, small pieces of membrane can be pulled away from the cell without disrupting the seal; this yields a preparation that is free of the complications imposed by the rest of the cell. Simply retracting a pipette that is in the cell-attached configuration causes a small vesicle of membrane to remain attached to the pipette. By exposing the tip of the pipette to air, the vesicle opens to yield a small patch of membrane with its (former) intracellular surface exposed. This arrangement is called the inside-out patch recording configuration.

This is a true single-channel patch clamp mode allowing the measurement of single-channel currents with the



Patch Clamp Measurements On-Chip, Figure 5 Assembly of the patch clamp device. (**a**) Aligning and sealing the processed silicon chip (grey wafer) between an upper and lower chamber (yellow and blue) electrically isolates one side of the chip from the other (except through the pore in he silicon), and enables independent experimental manipulation of each side. The top and bottom chambers are composed of cured PDMS (yellow) coupled to machined polycarbonate (light blue) supports. The bottom polycarbonate support interfaces the lower PDMS vertical channel to a syringe which is used to apply negative pressure. (**b**) Except for the area immediately surrounding the pore on the topside and the 1 mm well on the underside of the chip, the entire top and bottom surfaces of the silicon wafer were stamped with SU-8 photoresist (green) to enable sealing to the PDMS layers and reduce the chip capacitance to as low as 15 pF. (**c**) A single RIN m5F cell is drawn onto the pore (black spot) following suction. A few seconds after landing on the pore, an individual cell tends to center itself over the pore. This image is of a chip that was recycled after being previously used to patch clamp a cell

added benefit of making it possible to change the medium to which the intracellular surface of the membrane is exposed. Thus, the inside-out configuration is particularly valuable when studying the influence of intracellular molecules on ion channel function, like calcium or ATP.

Outside-Out Patch Clamp

If the pipette is retracted while it is in the whole cell configuration, a membrane patch is produced that has its extracellular surface exposed. This arrangement is called the outside-out recording configuration.

This is a true single-channel recording mode. The patch can be superfused on the extracellular side with solutions containing materials such as neurotransmitters, agonists like GABA or glutamate to activate receptor channels in the patch. This range of possible configurations makes the patch clamp method an unusually versatile technique for studies of ion channel function.

Examples of Patch Clamp On-Chip Design and Fabrication

Multi-Pipette Tip On-Chip Fabrication Based on Polydimethylsiloxane (PDMS)

To scale up fabrication of the planar PDMS, as a typical example, a 4×4 on-chip array described in literature is given here.

The 4×4 array of 400 μm deep, self-terminated pits spaced 1 mm apart was anisotropically etched in a silicon wafer. The strategy was to use the precision of silicon micromachining to create a master structure e with good ordering that would define a shape similar to the tip of a glass micropipette in a thin sheet of molded PDMS. That shape was then transferred through two PDMS molding steps into an array of pyramids in polyurethane (see Fig. 3). An important step in forming the PDMS in step 4 of the figure was the treatment of the first PDMS mold so that the two PDMS layers could be separated. The final PDMS electrode partition was formed by pouring freshly prepared PDMS onto the polyurethane mold and then capping the polyurethane pyramids with a glass slide (step 6). The contact between the tip of the polyurethane pyramid and the glass slide excluded the PDMS to form small apertures. The size and shape of the aperture depended on the amount of contact with the glass slide. The authors chose polyurethane because it deforms sufficiently when contacting the glass slide to make holes 4 – 20 μm in size.

P

For patch clamp measurements the PDMS planar electrode array was plasma-oxidized then mounted in the recording system shown in Fig. 6. To electrically isolate each electrode, the partition was sealed onto the chamber bottom over an array of openings that each contained an Ag–AgCl wire and suction tubing. The Ag–AgCl wire was connected to the multiplexer chip mounted on the circuit board under the chamber. The multiplexer then connected to the input of the amplifier. The tubing connected to a suction manifold that permitted individual or global suction.

The electrode resistance values were measured to confirm that the electrodes were electrically isolated and that the apertures were open. Fig. 6 shows a *macro-patch* recording obtained when a devitellinized oocyte, expressing Shaker potassium channels, was dropped onto an aperture. The ionic currents carried by a population of ~ 80 Shaker channels were measured in response to positive step changes in membrane potential. The overall success rate for forming a gigaseal on a xenopus oocyte using a planar PDMS patch electrode was 13% (10 out of 75). This is lower than the ~ 40 % success rate for the conventional patch electrodes with or without PDMS coating and surface treatment.

In general, a planar electrode has many advantages over the conventional patch pipette electrode. First, the planar electrode can be easily scaled to an array of electrodes to permit multi-cell or multi-site measurements. Second, the planar electrode has the potential for integrating microfluidic lines that would permit exchange of the electrode solution, something rarely achieved with a micropipette. The amplifier electronics can also be integrated into the substrate of the electrode for improved noise performance. Third, a planar electrode can be mounted over a fluorescence microscope to simultaneously record electrical and optical signals.

Also, micromolding a planar electrode from PDMS has advantages over the other microfabricated planar electrodes under development. First, the fabrication is simple and economical so that the electrodes are disposable, therefore eliminating the difficult step of cleaning the device. Second, microfluidic lines can be micromolded in the same structure or added by bonding PDMS layers. Third, PDMS is optically transparent so that alignment to underlying components can be done visually. The transparency of the material may also be advantageous when integrating an optical recording system. Fourth, the PDMS surface can be chemically modified to facilitate seal formation.

However, the probe nature of the conventional patch pipette still has its advantages. Most importantly, it can penetrate the top layers of tissue to permit patch clamp measurement on a cell within a tissue. Second, the electrode can be pulled away from a cell to make an *excised patch* recording, useful for applying modifying agents to the patch of membrane. Third, the pipette can be moved quickly between lines of solution flow for quick changes in modifying agents. Integrated microfluidics may negate the need for these last two points but more complicated micromachining may be required to fabricate planar patch electrodes that can penetrate tissue.

The need to plasma-treat the PDMS surface just before use may be a disadvantage of the planar electrode. This would add a plasma system to the required equipment for patch clamp experiments. However, the planar electrodes do not require use of the high-quality optical microscope and micromanipulators currently required for patch clamp recording. In addition, conventional patch pipettes commonly require several processing steps before use including heat polishing and coating.

Patch Clamp Device On-Chip Fabrication

As another typical example, a method for silicon chip-based patch clamp electrodes integrated with PDMS microfluidics is given in the following.

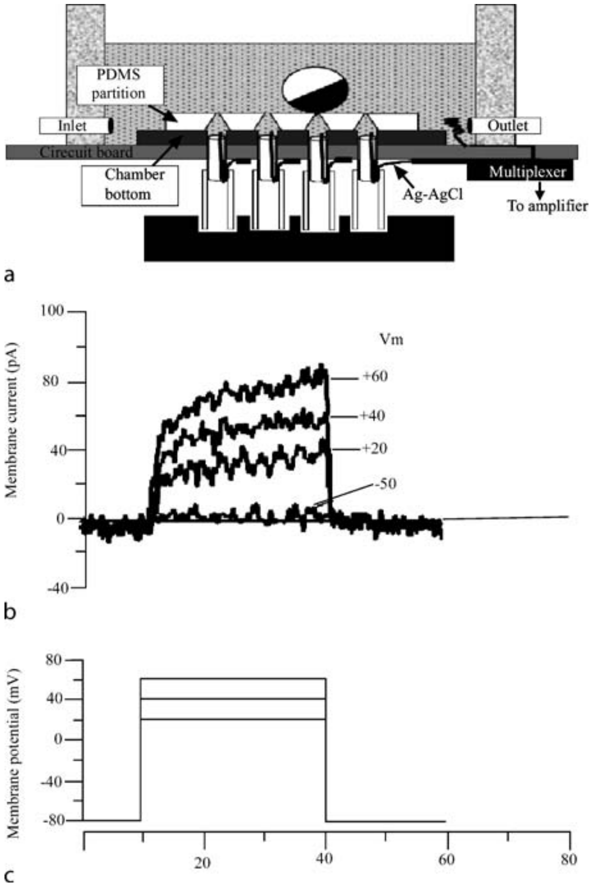
Silicon Chip Microfabrication. Up to 80 silicon chips to be used for patch clamping experiments were parallel fabricated in a single sequence of steps (Fig. 4) using standalone processing tools. Patterns for pores were defined using a photoresist in concert with a custom-designed mask and a mask aligner (operating with 365 and 405 nm radiation lines and in constant power mode). The patterns were developed to etch out the pores using a plasmatherm deep reactive ion-etching system. In the region surrounding the pore, the silicon wafer was thinned to about $20-40\,\mu$m for the micropores ($1.5-2\,\mu$m diameter) and $10-20\,\mu$m for the nanopores ($0.7-1\,\mu$m diameter). Each wafer was fabricated with a small array of usable pores. In the following, only one device was used for any given experiment, and so the chips were diced into 8×8 mm sections, each containing a single pore. The chips were acid cleaned, rinsed using copious amounts of 18 MΩ H_2O and dried under flowing nitrogen. The chips were then coated with a $0.5-1.0\,\mu$m thick insulating film of SiO_2 using plasma-enhanced chemical vapor deposition (PECVD). The top side of the chip was exposed for $20-40$ min and the bottom side was exposed for $10-20$ min. This procedure shrunk the pore diameters by about 0.4 μm. For the nanopores, the oxide was deposited at lower pressure. Deposition at lower pressure was necessary in order to increase the oxide density, deposit a thicker layer of SiO_2, and to conserve the circular symmetry of the nanopores. At this point, the tip fabrication process was essentially complete. *PDMS Microfluidic Fabrication.* Fluidic platforms for both the front and back sides of the wafer were prepared from micromolded PDMS. For most measurements, the chambers simply allowed for separate chemical access to the front and back sides of the micropore. The minimum microfluidic channel widths were 100 μm and the typical channel heights were 100 μm. A mold master was photolithographically patterned into a spin-coated film of photoresist on silicon as described in the literature. The microfluidic channels that were used for cell focusing consisted of two layers of micromolded PDMS that formed one final microchannel network component. The bottom layer of the PDMS microchannel network defined the focusing channels which interfaced the silicon substrate, and the top layer interfaced the focusing channel to larger channels that had inlet and outlet ports. Modified syringe needles were pierced through the top layer to connect the input and output ports with Teflon tubing for the introduction and extraction of cells and solutions. The focusing channel was designed to allow for optical access to the micropore region when the syringes were in place.

Device Assembly. The molded PDMS fluidic chambers were pressure bonded to the silicon chips (Figs. 5a,b). This chemically isolated one side of the pore from the other,

thereby creating a device that enabled independent experimental control of each side of the pore (or membrane sealed over the pore). To prevent electrical leak around the silicon chip, SU-8-5 photoresist was applied around the edges of the surface of the chip with a cotton swab (Fig. 5b) or by transferring the SU-8-5 with a PDMS stamp, and then cured. This coating not only permitted a quick, greaseless method for sealing the chip surface to the PDMS surfaces of the experimental cell-chip chamber (Fig. 5a), but it also reduced the chip capacitance. Chip capacitance values as small as 15 pF were achieved when the stamping technique was utilized. However, for the devices that were integrated with PDMS microchannels, little or no SU-8 resist was applied, since the PDMS channels themselves prevented solution leak around the silicon chip and minimized stray capacitance. In order to recycle the same batch of chips several times, the SU-8 resist and oxide layers were sequentially stripped away using standard oxidizing solutions. First, an oxidizing clean (2:1 concentrated H_2SO_4:H_2O_2 (30 %)) was used to remove the SU-8-5 resist. Next, the oxide was stripped using a buffered oxide etching (BOE) solution. The oxide layer was then re-deposited using PECVD.

Electrophysiology recordings. To record currents from sealed cells, the silicon chip assembly was used as a chamber for a voltage clamp setup (Fig. 6). Each half of the chamber (top and bottom) was connected to the electrodes of a headstage. The top chamber was connected to the input of the patch clamp amplifier and the bottom chamber was connected either to either the ground or the command voltage depending on the amplifier used.

The silicon chip device, coupled to a voltage clamp setup was prepared for cells by adding external and internal solution to the top and bottom chamber, respectively. An amount of 50 μl of cell solution (about 5×10^4 cells) was introduced into the top chamber with a syringe that had a 2 cm piece of Teflon tubing on its tip. The cells were tracked by viewing the top surface of the chip with a microscope and by monitoring the electrical resistance across the pore. Once the cells covered 20 – 30 % of the chip surface, gentle suction was applied from the bottom chamber side. The progress and quality of the seal of a cell over the pore was monitored visually through the microscope and by measuring the capacitance and resistance across the pore. Once the seal reached maximum resistance, the suction was released and electrophysiological recordings from the cell were made.



Patch Clamp Measurements On-Chip, Figure 6 Planar PDMS patch electrode array recording of Shaker potassium channel currents. (**a**) Schematic of planar patch electrode array recording system. The 400 mm thick, oxidized PDMS partition is sealed onto the chamber bottom with vacuum grease. The chamber bottom contains an array of openings, each containing tubing and an Ag–AgCl wire. The tubing connects to a suction manifold and the Ag–AgCl wire connects to a multiplexer chip on the circuit board under the chamber bottom. The multiplexer connects each contact to the amplifier electronics. Another Ag–AgCl wire in the bath solution connects to the ground of the amplifier. Bath solution is exchanged through solution lines into and out of the bath chamber. A devitellinized oocyte is dropped onto the aperture to make a patch clamp recording. (**b**) Current traces recorded from a xenopus oocyte expressing inactivation-removed Shaker potassium channels. Each trace represents a step change in membrane potential from rest, 80 mV. Voltage steps are to 50, 20, 40 and 60 mV, as noted, before returning to 80 mV. Leakage currents were subtracted from the raw data by a P/4 protocol (Penner, 1995).

Key Research Findings

The inherent complexity of the technique limits its uses in high-throughput screening for drug discovery and drug safety. To meet high-throughput screening requirements, many efforts have been made to improve the patch clamp system. Planar patch clamp electrodes, scalable and easy to use, have been fabricated using silicon oxide-coated nitride membranes, deep reactive ion etched silicon holes coated with PECVD oxide, polyimide films, track-etched quartz, silicon oxide nozzles, glass substrates and oxygen

P

plasma-treated PDMS. Microfluidics have also been integrated with patch clamp systems using PDMS or glass. Those devices have made possible fast fluid exchange for single electrodes.

Some patch clamp setups with more advantages have been developed to be used more easily. For example, a lateral-based patch clamp setup is compatible with high-resolution microscopy (with a working distance in the $100-300\,\mu$m range). The idea is to trap a cell onto a lateral microchannel in a manner which makes it easier in terms of fabrication and fluidic integration. Niels Fertig has made use of state-of-the-art microstructuring techniques to define three-dimensional micro-openings in planar substrates, with the geometry of an inverted patch clamp pipette tip.

Future Directions for Research

The on-chip-based patch clamp technique broadens the possibilities of ion channel analysis by transferring the classic patch clamp principle onto a microstructured chip format. The planar patch clamp technique enables the automation and parallelization of ion channel measurements. This is an example of the beneficial integration of microtechnological processes in the field of cellular electrophysiology. The chip-based patch clamp technique not only improves ease of use as well as throughput capability compared to conventional patch clamping, but also opens new experimental possibilities for the biophysical characterization of ion channels such as intracellular perfusion or optical accessibility of the chips for combined optical and electrical recordings from ion channels. The automated and parallel patch clamp methods should be further developed in the near future for academia and industry.

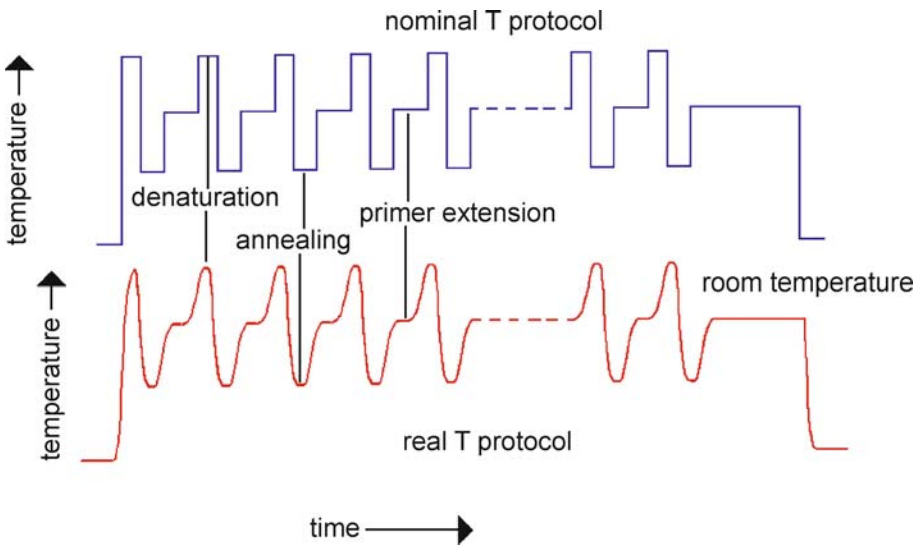
Definition

PCR Lab-on-Chip devices are microfluidic instruments for the biochemical amplification of DNA by thermocycling using the polymerase chain reaction at the microscale.

Overview

PCR Lab-on-Chip devices are miniaturized fluidic systems for fast DNA amplification. The polymerase chain reaction (PCR) is a molecular biological technique for addressing and exponentially amplifying a DNA fragment. The PCR process is based on temperature cycles with an enzymatic amplification step. It works without the use of a living cell. For PCR, a liquid mixture of an analyte



PCR Lab-on-Chip Devices, Figure 1 Temperature protocol for PCR with repeated thermal addressing of process steps; nominal and real temperature tracks (double-strand separation, primer annealing, primer extension)

containing DNA with an amplification buffer solution containing nucleoside triphosphates (building units for DNA synthesis), primers (starter molecules), catalyst (the enzyme polymerase) and some additives is applied. The exponential increase of concentration of the sequence of interest is due to the doubling during each temperature cycle. The synthesis of a daughter strand of DNA on a mother single strand (template) occurs by template-directed condensation of nucleotides. The primers are applied for addressing a selected sequence part of DNA template molecules from the analyte sample carrying the genetic information of interest. Very small amounts of interesting DNA are required. Under optimized conditions, a single template DNA molecule is sufficient for starting the process. DNA fragments up to about 10,000 base pairs can be amplified by PCR.

The addressed sequence is identically replicated to a large extent during the thermocycling process. The miniaturization by transferring the technology from classic block thermocyclers into Lab-on-Chip devices is associated with a miniaturization of sample and with a large reduction of process time. In addition, Lab-on-Chip PCR allows the integration of sample preparation and post-amplification treatments including labelling and/or separation in order to realize a completely automated process chain in a miniaturized system. DNA microanalysis systems can be built, in which the micro PCR is the key operation for getting the molecular information carrier in a concentration suited for convenient signal readout.

Amplification of DNA by Lab-on-Chip PCR is mainly used for genotyping. In connection with a reverse transcription process using RNA-dependent DNA polymerase, this technique can also be applied for the characterization of RNA, in particular for the identification and measurement of messenger RNA. As a result, the Lab-on-Chip PCR devices can be also applied for gene expression studies.

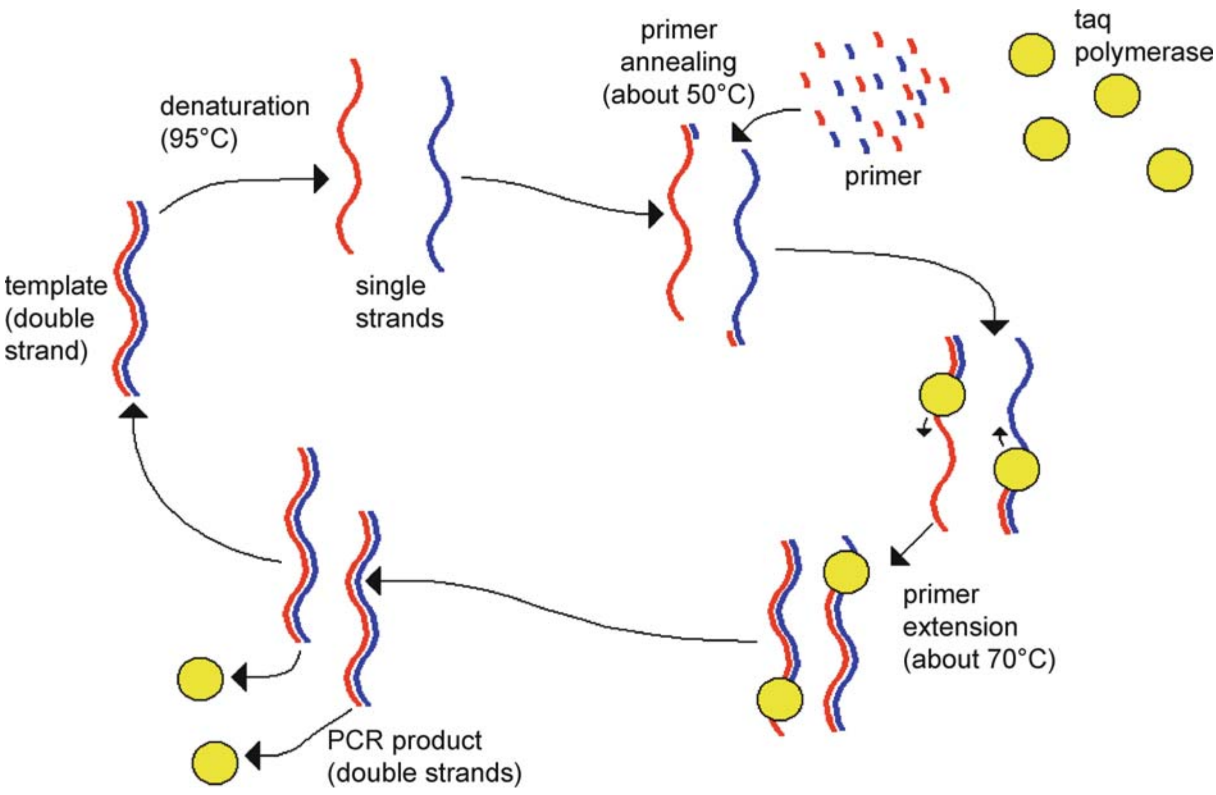
The application of PCR chip devices is connected with several important advantages with respect to conventional systems:

- low sample volumes
- very fast process steps
- low power consumption, suited for point-of-care diagnostics
- well reproducible temperature protocols
- processing of larger sample series under the same conditions
- low space requirements of devices
- integration of functions like reverse transcription process (for gene expression studies), on-line measurement of double-strand DNA concentration or real-time measurement by multi-sensor arrangements.

Hence, miniaturized PCR devices are very interesting for a broader application of PCR in laboratories as well as for point-of-care diagnostics, screenings or investigations for food safety and environmental protection.

Basic Methodology

The basic technique is the PCR invented by K. Mullis in 1983. This technique allows one to replicate DNA identically without any living cell. The PCR has developed



PCR Lab-on-Chip Devices, Figure 2 Principal molecular processes of PCR during thermocycling

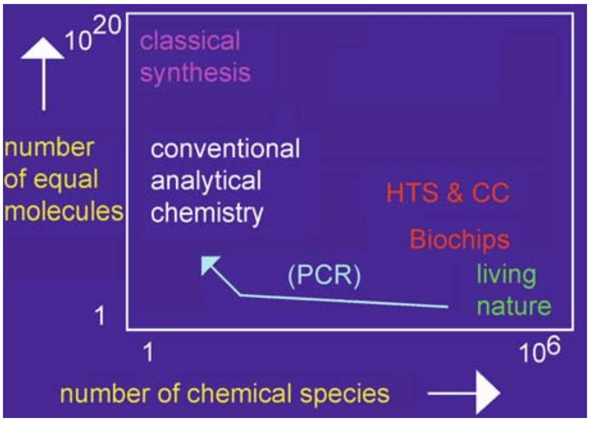
into a common technique used in medical and biological research and diagnostics as well as in forensic, archaeological and other investigations. It is the key method for sequencing of genes, for the diagnosis of hereditary diseases, for paternity testing and for molecular identification of infectious microorganisms.

The PCR technique succeeds by the use of the DNA-dependent DNA polymerase from bacteria living in hot sources (taq-polymerase). This enzyme is able to elongate primers (oligonucleotide starter molecules) in a complementary pattern to a template DNA single strand at a temperature of about 70 °C. This high temperature is necessary in order to create a temperature-controlled three-step process. The whole process includes the following steps:

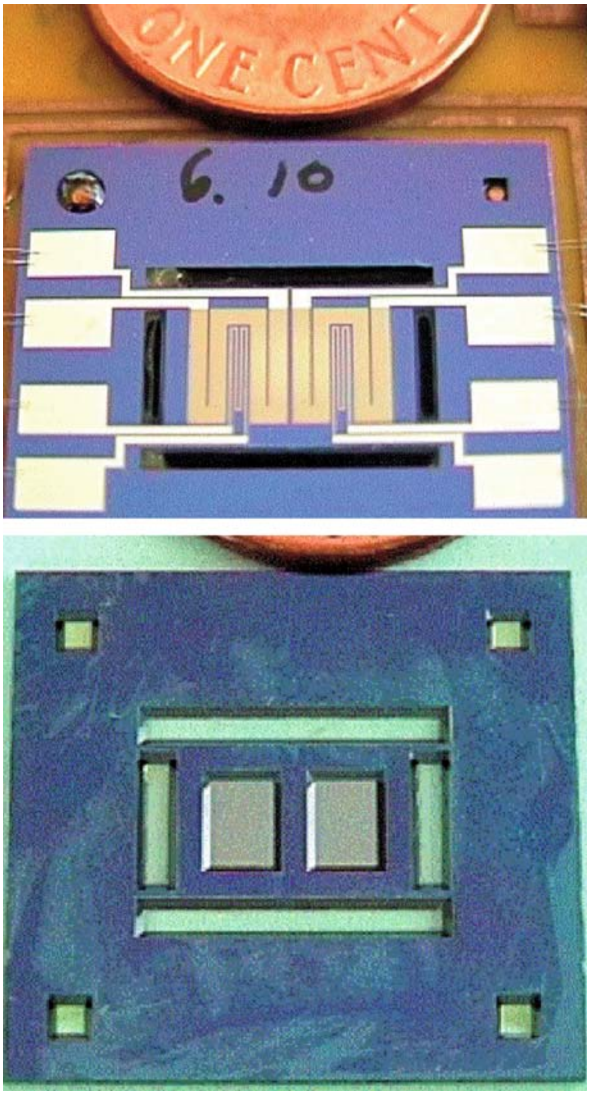
1. the initialization step for denaturation of DNA double strand into two single strands at about 95 °C by thermal disruption of the hydrogen bonds between the complementary bases in the double strand;
2. the addressing of a short well-known sequence pattern by base-pairing of primers (*primer annealing*) at suitable temperatures in the range between about 45 and 65 °C depending on primer length, AT/CG ratio and desired selectivity; and
3. the elongation of the primers with the complementary order of nucleotides by the synthesis of the new DNA strand by the enzymatic activity of the taq-polymerase (*primer extension*).

Two suitable primers are applied in order to generate both new complementary single strands of a selected DNA sequence in the replication during one temperature cycle. The repeated application of temperature (Fig. 1) cycles leads to a fast increase of the concentration of the selected DNA sequence by doubling the DNA in each cycle (Fig. 2). As a result, the selected sequence can be amplified by a factor of about 1000 in 10 temperature cycles, by a factor of about 1 million in about 20 temperature cycles and about 1 billion in 30 temperature cycles. This amplification is high enough for all characterization techniques like fluorescence detection, electrophoretic characterization, sequencing or chip hybridization. PCR bridges the gap between the molecular diversity in living nature using small numbers of key molecules and the analytical tools of chemistry and sensorics (Fig. 3).

Classic PCR is performed in Eppendorf tubes, microtiterplates or similar repositories by conventional thermocyclers with thermostatted blocks. The typical time required



PCR Lab-on-Chip Devices, Figure 3 Schematic of PCR as gap bridging technology between the biomolecular and chemical worlds: number of molecular species (types) and number of molecules of the same type in chemical and biological systems



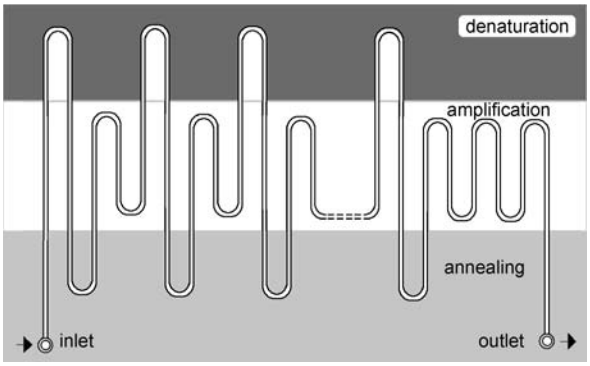
PCR Lab-on-Chip Devices, Figure 4 Example of a silicon chip thermocycler (IPHT Jena, Germany): microlithographically patterned thin-film transducers at the back side (above), liquid chambers and air chambers for heat transfer control at the front side (below)

is in the range of about 90 min up to about 3 h. Faster working thermocyclers need powerful heaters as well as coolers in order to realize high heating and cooling rates.

The temperature control can be realized by alternating mechanical contact to heating/cooling plates, by fluidic switching between heating and cooling liquids or by Joule heating using thick-film or thin-film microheaters. The latter method is frequently combined with passive cooling by heat conduction or convective cooling. In several chip devices, microheaters and thermal microsensors are prepared in close proximity in order to realize efficient feedback loops in electrical heating.

Despite the high amplification factor, the volumes can be small that have to be operated in thermocycling for PCR. So, DNA amplification can be done with volumes in the lower μl or in the nl range. The reduction of sample volume gives the possibility to apply chip devices or other miniaturized systems for the PCR. The reduction of size allows a crucial enhancement of heating and cooling rate and at the same time a reduction of power consumption. Power reduction and process rate enhancement become possible due to the lowering of parasitic heat capacitances and by efficient transfer of heat inside the system. So, miniaturized PCR devices can work at high process speed with low power requirement. Therefore, they are particularly applicable for hand-held devices, mobile analytical systems and microautomated systems.

Microtechnology offers two different strategies for Lab-on-a-Chip PCR. The first is the stationary concept. This concept corresponds to the classic thermocycler. The core element is a miniaturized chamber for PCR liquid equipped with heaters and temperature sensors (Fig. 4). Fast PCR is realized by fast heating and cooling the whole system. The maximum process rate is mainly determined by the ratio of heating and cooling power to the heat capacity of chamber and sample. The second strategy is based on a microflow-through concept. The device contains a long microchannel, which is conducted in meanders through three temperature zones (Fig. 5). Thus, the three regions of the device remain at constant temperature, and the temperature cycling is realized by changing contact of the liquid with the three different temperature zones. The maximum process rate is mainly determined by the heat capacity of the streaming liquid itself and by the heat conduc-



PCR Lab-on-Chip Devices, Figure 5 Principle of construction of a flow-through chip thermocycler

tivity between sample and walls. In principle, the time for single temperature cycles can be reduced down to a few seconds. The whole PCR process with 20 – 40 cycles can be done in time scales between a few minutes and about half an hour.

The acceleration of the PCR process is a very important advantage of PCR Lab-on-a-Chip systems. A second advantage is in the possibility to integrate further functions into the microdevice. Thus, steps of sample preparation as well as separation and detection supporting process steps can be integrated. In this way, miniaturized DNA analysis systems are constructed, in which the Lab-on-Chip amplification by PCR is the central process.

Key Research Findings

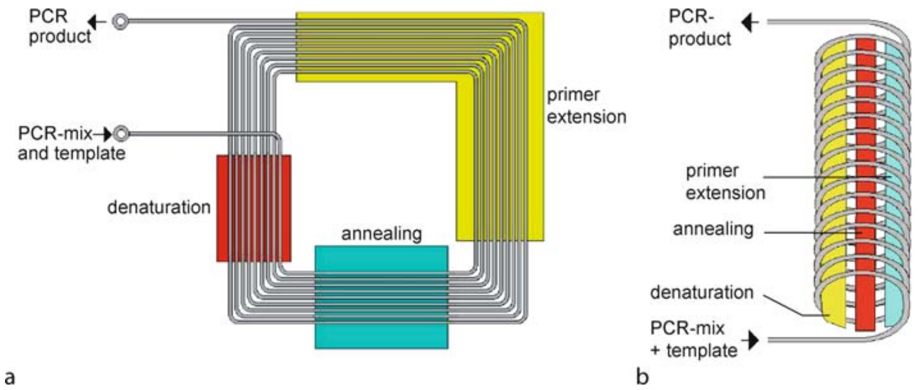
The motivation for miniaturization of PCR was driven by several factors. First, PCR should be made faster in order to get results more quickly. Second, larger sets of samples should be processed. Third, DNA-based diagnostics should be evolved from a laboratory technique requiring experienced specialists to an automated on-site diagnostic method operated after brief instructions by anybody. Finally, the amplification by PCR should be integrated in a diagnostic chain (μ-TAS concept) and implemented in a miniaturized transportable system. The power consumption of the thermocycling process should be as low as possible.

The simplest way for meeting the requirements mentioned above and realizing micro-PCR on-a-Chip consists in a transfer of the conventional PCR technique into a microchamber chip. Therefore, microchambers for liquid volumes between a few μl and several hundred nl were etched anisotropically in silicon wafers. A lithographically micropatterned metallic thin-film system at the backside of the wafer was applied in order to control temperature by Joules heating and thermoresistive temperature measurement. Metal film thicknesses of about 1 μm or several hundred nm were sufficient for achieving all temperatures necessary for PCR. The bottom membrane of the chamber carrying the metal transducers was built by the residual silicon thickness after time-controlled chamber etching. The high heat conductivity of the material guaranteed a fast heat transfer between the thin-film transducers and the liquid.

The cooling steps of PCR could be realized by direct contact of the bottom membrane with a cooling element (e.g. a Peltier cooler) or by indirect cooling using the passive heat transfer from the silicon chamber to ambient. For the second method, the fine tuning between temperature homogeneity in the core region of the PCR chamber and temperature gradients between core region (with PCR chamber) and the outer frame region of the microsystems were of particular importance. The problem was solved by the definition of spatially restricted areas *(heat conduction beams)* for passive heat transfer between core and frame by etching holes into the silicon. Optimized chips supplied high temperature homogeneity in the core region of PCR chips and heating and cooling rates of 40 – 80 K/s. Cycle times could be downscaled to a few seconds. The time required for the whole PCR process could be reduced down to 30 – 10min.

An important advantage of microchamber chips, beside the good dynamics, is the flexibility. Temperature/time protocols can easily be adapted and varied. Thus, this technique is useful for the development and optimization of protocols.

Microtiterplates (MTPs) are the most commonly used chamber arrays for PCR. The open chambers have to be covered by oil or sealed by membranes in order to suppress evaporation of water during the process. A fast working PCR in arrays can be realized, if small chamber volumes are applied and the wall thickness of the plate material is thin enough for fast heat transfer. Such chamber arrays can be prepared by in situ forming of array plates by means of a thermostatted block suitable as metal master. A further miniaturization of chamber volumes is possible by using nanotiterplates (NTPs). Microlithography allows the preparation of chambers in the lower μl range as well as over the whole nl and pl range. There are technologies for preparation in silicon as well as in glass. Polymer carriers are made in many cases by replication from microstructured silicon or glass master chips. A wide spectrum of materials is available for NTPs. The thermostatting can be realized by the conventional incorporation of the sealed NTPs in metal block devices or by integration of thermal transducers in the carrier systems. The application of micropatterned thin-film heaters



PCR Lab-on-Chip Devices, Figure 6 Micro-flow-through PCR in tube arrangements: (**a**) spiral-like arrangement (two-dimensional), (**b**) helical arrangement (three-dimensional)

and thin-film sensors for direct thermostatting of NTPs is compatible with well-established microsystem technologies using glass and silicon substrates. It is more difficult in the case of polymer materials. The high conductivity of silicon is responsible for the attractiveness of using these materials for all processes connected with fast temperature changes. Silicon carriers are of particular interest for NTPs used in PCR. The comparatively high affinity of silicon against proteins is a disadvantage and demands special surface covering or chemical surface modifications (see below).

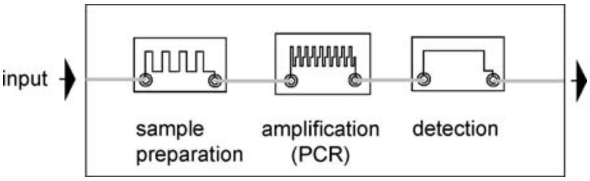
The power consumption for heating and cooling of samples can be reduced if the temperatures in the device are kept constant in three different regions and the sample is moved between these three regions. This movement can be operated at the surface of a thermostatting chip, for example by electrostatic manipulation or by surface acoustic waves (SAWs). Therefore fluidic transport paths (hydrophilic areas) are defined lithographically in a hydrophobic environment on a piezoactive substrate like lithium niobate. The excitation of SAWs is realized by microlithographically prepared thin-film electrodes. SAW systems are of particular interest due to the fast manipulation and the very efficient mixing processes, which can be applied also for sample preparation. The small volumes of droplets make the evaporation of water a serious problem. This can be overcome to a certain extent by oil covering.

The evaporation of solvent can be avoided completely if closed microchannels are used for a micro-PCR with moving of samples between different temperature zones. The simplest variant consists of a flow-through PCR realized in a tube, which is conducted repeatedly through the three temperature zones. There are two principal geometries for the arrangement of tubes. In one variant the tube is coiled in one plane like a spiral (Fig. 6a). This geometry can be easily realized. But, this arrangement suffers from increasing or decreasing residence times in all three temperature zones due to the changing diameter of the tube loops. The alternative is a three-dimensional, helical arrangement of the tube. In this geometry, the conditions at all temperature cycles can be kept equal (Fig. 6b).

A certain disadvantage of using tubes is the low heat conductivity of polymer tube materials and the comparatively high thicknesses of tube walls. This leads to low temperature gradients. As a result, the outside temperature must be adapted to the flow rate-dependent heat required inside the tube and the heat transfer conditions in the tube wall.

The principle of flow-through PCR can further be miniaturized and optimized with respect to heat transfer conditions by realizing flow-through chip thermocyclers. These are devices for flow-through PCR on silicon, glass or polymer chips. The use of silicon (high thermal conductivity) and glass (low heat conductivity) in one device allows convenient control of temperatures in the three process zones by choosing a suitable local heat capacity and heat exchange conditions. In analogy to chip chamber cyclers, etched holes in silicon support the thermal separation of temperature zones, and thin-film resistors are applied for heating and electroresistive temperature measurements.

DNA amplification can occur either in a continuous flow mode or in a serial flow mode. In the continuous flow mode, a template is mixed continuously with the PCR mix and transported through the flow thermocycler. This mode is well suited for preparing amplificates of a certain DNA sequence in constant quality. In contrast to continuous amplification, most PCR applications are found in analytics. Therefore, the enhancement of throughput of samples in one analytical system is the deciding parameter. In principle, series of template-containing samples can be applied in a certain clock pulse in a flow-through system. But, the subsequent injection of different samples in



PCR Lab-on-Chip Devices, Figure 7 Schematic of integration of PCR in a μ-TAS arrangement with sample pre-treatment and separation/detection unit

continuous flow leads to strong cross-talk effects due to the fluidic dispersion which is caused by the laminar flow behaviour in the microtubes and microchannels. This fluidic cross-talk is particularly critical due to the exponential character of the amplification process during PCR.

A crucial improvement of sample separation in serial processing can be achieved by the application of a segmented flow in the micro-PCR. The separation of aqueous fluid segments containing the PCR mix and the different templates by immiscible organic liquids converts the laminar flow to a plug flow. If the inner surface of the wall is hydrophobic, the chemical cross-talk between fluid segments can be suppressed completely. Thus, the segmentation of flow improves the transport behaviour as well as inhibiting effects of the wall. In addition, the plug flow guarantees constant residence times for all samples and all volume parts of one sample in all temperature regions and in all cycles. The segmented flow principle can be applied for both microtube PCR and on-chip PCR.

Serial PCR using flow segments allows comparatively high sample frequencies. The generation of segments can occur up to frequencies of some tens per second. Reconsidering a certain redundancy (several segments of the same sample), it is possible to process in the order of 10^4 samples per hour. This high throughput power of serial flow micro-PCR makes this technique interesting for screening procedures with well-standardized protocols. The fixed definition of temperature protocols is necessary because the length of capillaries or tubes in the different temperature zones is fixed. Changing of flow rate leads only to a proportional change in all temperature zones. The ratio of residence times is fixed by the design of the flow-through device. So, flow-through thermocyclers are much more efficient than chamber thermocyclers, but less flexible. Flow-through PCR is therefore preferably applied for well-defined analytical problems with high numbers of analogue samples.

A big additional advantage of flow-through processes in comparison with stationary processes consists in the possibility of implementation of process chains (Fig. 7). In this way, complete microanalytical systems can be designed. They can include sample pre-treatment like cell separation, cell lysis or chemical separation. Reverse transcription processes can be directly connected on-chip with the DNA amplification by thermocycling (RT-PCR). The analytical chain can also include post-amplification steps like fluorescence labelling, separation by capillary electrophoresis or hybridization on DNA chips.

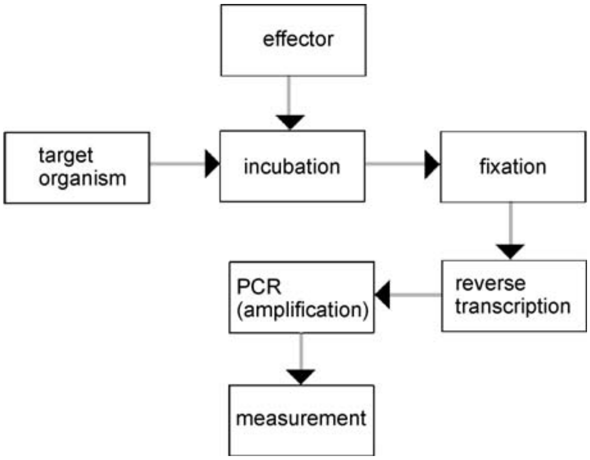
Chemical compatibility is a particularly important problem for Lab-on-Chip PCR devices. The taq-polymerase possesses a certain surface affinity due to their amphiphilic character. In addition, the low start concentrations of DNA for amplification are critical if the molecules are adsorbed at wall surfaces. The molecule–surface interactions are particularly critical due to the high surface-to-volume ratios in chip devices. The suppression of undesired adsorption demands inert materials. Polymers like polypropylene or polytetrafluoroethylene are much better suited than glass or silicon. The OH groups at the surface of native glass, silicon or silicon dioxide surfaces are mainly responsible for disturbing adsorption. The affinity of surfaces against the biomolecules can be suppressed by surface treatments. Therefore, alkylsilanization (by alkyltrichlorsilanes or alkyltrimethoxysilanes for example) is particularly suited. The surface properties change during the exposure of walls against cell suspensions and PCR solutions. Certain rinsing, cleaning and resilanization protocols are applied in order to achieve a high reproducibility in the case of reused Lab-on-Chip PCR systems.

Micro-flow-through PCR has been investigated in the last few years for several biological and medical applications. They relate to the identification of DNA in different research experiments, for genotyping of microorganisms, in particular the identification of pathogens, as well as for genotyping of tissue material, gene expression studies using a preceding reverse transcription step for conversion of messenger-RNA into DNA and for adaptation and development studies of insect embryos.

Future Directions of Research

Further research for Lab-on-Chip PCR devices is focused on four main topics: the improvement of the performance of the amplification process, the integration of new functions in PCR-based analytical chip devices, the integration of PCR in microautomated diagnostic systems and the extension of PCR-based nucleic acid microdiagnostics to new applications.

The improvement of heat transfer by optimized channel and wall geometries and the choice of best-suited materials contribute to the enhancement of process speed and to a better control of selectivity. Adapted selectivity can be achieved by realizing well-defined temperature proto-



PCR Lab-on-Chip Devices, Figure 8 Process scheme for use of Lab-on-Chip PCR for expression diagnostics in drug screening

cols for the primer annealing step. Therefore, steep cooling and heating ramps are of interest. Special material combinations and the adaptation of manufacturing technologies are under investigation for the improvement of speed and surface compatibility.

Sample throughput is particularly important for screening processes with large numbers of samples. Low-cost DNA diagnostic tools are necessary for biomedical screenings in order to identify genotype-determined health risks in the human population. They are also of interest for screenings for dangerous microbial genotypes. Despite biomedical, environmental and agricultural screenings, high sample throughput is also required for pharma screenings. Here, expression studies depending on drug concentrations and drug combinations demand low-cost solutions including fast RT-PCR (Fig. 8). Highly parallelized systems and in particular fast working serial PCR systems are of interest for such pharma screenings.

The specific fields of recent and future applications of rapid flow-through chip PCR demand the development of PCR-based chip devices with additional integrated functions for sample pre-treatment, on-line sensing, process control and real-time measurement, for referencing and reproducibility tests. Therefore, further efforts for integration of transducers as well as additional fluid manipulation functions are required.

Process speed, sample throughput as well as selectivity could be improved by ultra-miniaturization of Lab-on-Chip PCR. In nature, DNA amplification takes place in reaction volumes (cells) down to the sub-micrometre level. This corresponds to volumes in the sub-femtolitre range. In principle, the PCR process could be down-scaled to this region. Recently, most PCR Lab-on-hip devices are working with sample volumes in the sub-μl and in the nl range. By ultra-miniaturization, these volumes could be reduced by factors of between 10^{-3} and 10^{-7}. Therefore, special strategies of liquid handling and, in particular, microencapsulation techniques, vesicle techniques or ultra-miniaturized segmented flow techniques are necessary.

The very different possibilities of using information from nucleic acids for health care, drug development, environmental control, product and process safety, food control, control of trade and transport and so on demand cost-efficient special solutions with microsystems for DNA or RNA analysis. So, further research will address a wide spectrum of different special diagnostic solutions integrating Lab-on-Chip PCR. The questions of universality, reusability, safety and recyclability will become important, in future, like the questions of costs, operability, robustness and reliability.

Peristalsis

Definition

Peristalsis is transport in a flexible duct via traveling contraction waves. Peristalsis is the process by which material is moved through anatomical passages, for example of the digestive tract, by the contraction of smooth muscle in rhythmic waves. In biological systems, peristalsis moves liquids or solids. Micropumps based on the principle of peristalsis have been designed to move liquids and gases.

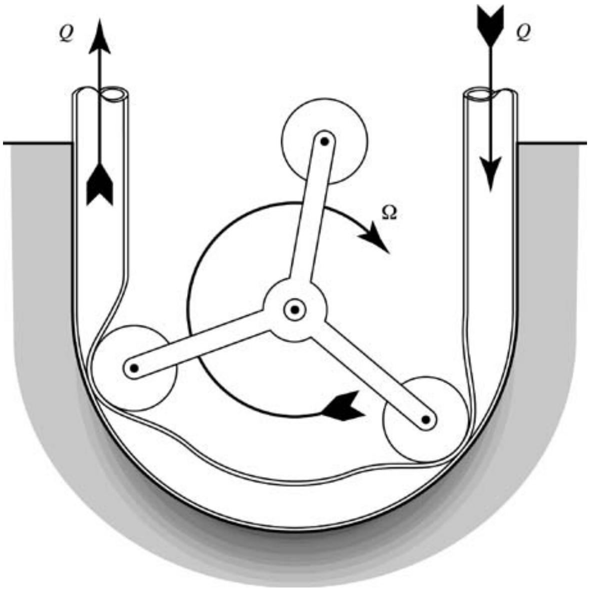
Definition

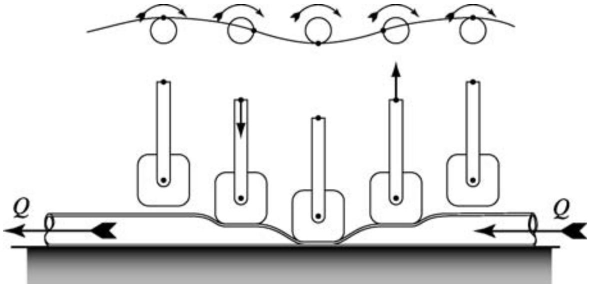
Peristaltic pumps are mechanical displacement pumps that induce flow in a fluid-filled, flexible-walled conduit through ►peristalsis – transport due to traveling contraction waves. While macroscale peristaltic pumps appear in a variety of configurations, micropumps based on this principle almost exclusively use the sequenced contraction and expansion of a small number of discrete actuators – typically three – placed along the fluid channel.

Overview

Peristaltic pumps emulate the biological process of peristalsis, in which material is moved through the esophagus or other anatomical passage by the contraction of smooth muscle in rhythmic waves. Figure 1 is a schematic of a typical ►rotary peristaltic pump, as implemented at the macroscale, in which a set of revolving contact elements creates a traveling compression wave in a section of a flexible tube. Figure 2 is a schematic of a macroscale implementation of a ►linear peristaltic pump, in which a number of translating piston actuators cyclically compress a flexible tube. In either case, a moving boundary displaces fluid and induces a flow, placing peristaltic pumps in the class of positive-displacement pumps. Increasing the tube diameter or the pumping cycle frequency increases the flow rate. A major attraction of macroscale peristaltic pumps is cleanliness. The fluid is completely isolated from the pump components since it never leaves the tube. Furthermore, it is a simple matter to change the tubing to avoid cross-contamination between fluids, and the tubing material may be tailored to ensure compatibility with a particular application. The pumping action is relatively gentle, making peristaltic pumps suitable for reactive liquids or cell suspensions. Also, the pumps may be self-



Peristaltic Pumps, Figure 1 A typical macroscale rotary peristaltic pump design. A set of rotating contact elements cyclically compresses a flexible tube. The elements may roll or slide along the tube; the number of contact elements may also vary. The fluid never leaves the tube, protecting the fluid from contamination by the pump elements, and the pump elements from corrosion or abrasion by aggressive fluids. The tube itself is easily replaced. Tube size and composition may be adjusted to accommodate different fluids, or to change the flow rate. Changing the rotation rate Ω changes the flow rate; changing the sign of Ω reverses the flow direction



Peristaltic Pumps, Figure 2 A typical macroscale linear peristaltic pump design. A set of translating actuators cyclically compresses a flexible tube. The number of actuators may vary. Features of macroscale rotating peristaltic pumps also apply to microscale linear peristaltic pumps. Linear peristaltic pumps are used in applications such as drug delivery, when accurate flow rate control is needed

priming due to the low-pressure region created behind the moving constriction, and the flow direction can be easily reversed. At the macroscale, use of rotary peristaltic pumps is widespread, while linear peristaltic pumps are found mainly in niche applications, such as intravenous drug delivery.

Cleanliness considerations do not translate to the microscale, nor does the notion of interchangeable components. Therefore, use of peristaltic micropumps must be justified for other reasons. Self-priming and bidirectionality remain appealing features, but perhaps the main benefit is simplicity of design. Any mechanism providing volume change in a chamber or channel is a candidate actuator for a peristaltic pump. For example, a typical active microvalve involves a membrane that can be forced against a seal to close, or pulled away from the seal to open [1, 12]. Two or more active microvalves can be arranged in sequence and actuated with the appropriate phasing to create a linear peristaltic micropump. The principles of peristaltic pumping apply to liquid or gas, and micropumps for both have been demonstrated. The ease with which an actuator can be transformed into a pump accounts for the wide variety of linear peristaltic micropumps that have been reported, including an early micromachined silicon and glass version by Smits (as reviewed in [3, 12], or see the original paper referenced therein).

In this article we refer to an actuator as *closed* when the associated chamber or channel volume is minimized, and as *open* when that volume is maximized. The volume in the closed position is called the ► dead volume, and the difference between the volume in the open position and the dead volume is the ► stroke volume. The ► stroke volume divided by the dead volume is the ► compression ratio. Compression ratio is particularly important when pumping gases, since the amount of gas ejected from the actuator is reduced by the compressibility of the fluid. In pure liquids this effect is much less, but compression ratio plays an important role in determining how severely bubbles impact a particular pump. In classifying micropumps, a distinction is sometimes made between ► integrated actuators – fabricated along with the other components of the microfluidic system – and ► external actuators – fabricated separately and attached later. It is common to see peristaltic micropumps of either kind.

While a linear pump can easily be built up from two or more basic actuation units, microscale rotary mechanisms face significant fabrication challenges. Accordingly, rotary peristaltic micropumps have seen very limited implementation. While several rotary mechanical micropumps are described in the literature (see the summaries in [1], [3] and [12], for example), to our knowledge there is only one example in the literature of a true rotary peristaltic micropump; Kim et al. (Sensors and Actuators A 128:43–51, 2006) use a silicone membrane for the deformable channel surface, and a rotating ferrofluid plug driven by an external magnet for actuation. Also notable is a miniature rotary peristaltic pump by Bar-Cohen and Chang (*Smart Structures and Materials 2000: Active Materials:*

P

Behaviors and Mechanics, *Proceedings of SPIE 3992, 2000*) that employs a traveling flexural wave in a piezoelectric ring. Reflecting their dominance in the literature, the subsequent discussion will consider only linear peristaltic micropumps, which for brevity are henceforth referred to simply as peristaltic micropumps. Most reported microscale implementations approximate continuous peristaltic action using two or more (most commonly three) discrete collapsible chambers. A notable exception, and one which does not fit well into the analysis scheme presented here, is the colloidal peristaltic pump presented in [15]. There a large number (approximately twelve) of 3 μm colloidal silica particles are oscillated sinusoidally in a 6 μm deep polydimethylsiloxane (PDMS) channel using external actuation by optical trapping with a scanned 532 nm laser. Flow rate on the order of 1 nl/h are induced in an aqueous solution by the resulting traveling wave. Peristaltic actuation through movable suspended particles is, to our knowledge, unique to [15]. The remainder of this paper focuses on the much more common case of discrete collapsible chambers.

Peristaltic pumps have found wide application in microfluidic systems based on PDMS, due to their ease of fabrication and versatility in operation. PDMS is a popular material for microfluidics for several reasons. Compared to traditional semiconductor industry fabrication schemes, both the materials and processing tools are inexpensive. PDMS is biocompatible, resistant to many chemicals, and transparent to wavelengths of light useful in chemical and biochemical analysis. Figure 3 shows a typical actuator design, similar to that first reported in [4], with the fluid channels formed between a thin PDMS layer and a glass, silicon, or PDMS substrate, and actuator channels formed at right angles to the fluid channels in a thicker PDMS layer, bonded to the planar side of the fluid layer. We refer to the area of the fluid channel under an actuator channel as a pump chamber, even though it is geometrically identical to the rest of the channel. The actuator channels are inflated from an external pressure source to close the pump chamber; when the pressure is removed the natural elasticity of the PDMS restores the channel to its original shape. As suggested by the figure, due to the low modulus of elasticity of PDMS, the pump chambers may be designed to collapse completely when closed, allowing them to act either in concert for pumping, or in isolation as pure valves.

In a peristaltic pump, the volume of fluid displaced by the individual actuators is rectified, that is, directed in the desired direction of flow, solely by the phasing of multiple actuators. Other types of displacement pumps rectify flow differently. A passive check-valve pump uses two passive, one-way check valves incorporating moving flaps or other components. One such valve at the pump inlet permits fluid to enter the chamber as the pump chamber expands, but prevents it from leaving as the chamber contracts. Likewise, a passive check valve at the outlet prevents backflow on the expansion stroke, but permits fluid to exit the chamber on the contraction stroke. Valveless rectification pumps are similar, but use flow diodes instead of mechanical check valves. Flow diodes are diffuser/nozzle structures or so-called Tesla valves that have no moving parts, but exhibit a preferential flow direction due to their geometry. More detail on passive check-valve or valveless rectifier pumps may be found in [1], [3] or [12]. Since these require only a single actuator, versus two or more for peristaltic pumps, they are natural design alternatives. Reasons to prefer a peristaltic design include ease of integration onto the microchip, with no special fabrication steps or external connections. For example, [13] presents an electrostatically-actuated peristaltic micropump suitable for incorporation into a micro-total analytical system (μTAS) with no additional special considerations. Peristaltic pumps avoid the more complex microfabrication typically required for passive check valves, and the susceptibility of such valves to fouling by particles or bubbles. Valveless rectifiers are simple to fabricate, and not prone to fouling, but may have a larger footprint than peristaltic designs. Finally, peristaltic pumps may be used to generate forward or reverse flow by modifying the actuator phasing, while bidirectional versions of the other two options are difficult to realize. Some guides to peristaltic pump design advise adding series passive check valves to aid in rectification if the application allows [1], though this reduces to some extent the operational and fabrication benefits that peristaltic designs offer over check-valve designs.

In many peristaltic micropump implementations identical actuators provide both stroke displacement and flow valving. However, these functions may also be divided between actuators of different design. One analysis reported in the literature treats a large stroke displacement actuator with a low flow resistance, flanked by active valves with small stroke displacement [5]. While similar in concept to a passive check-valve diaphragm pump, the valving actuators in this case are actively opened and closed by external commands, and flow direction is determined by the phasing of these commands with regard to actuation of the central diaphragm. Hence, this design may properly be classified as a peristaltic pump.

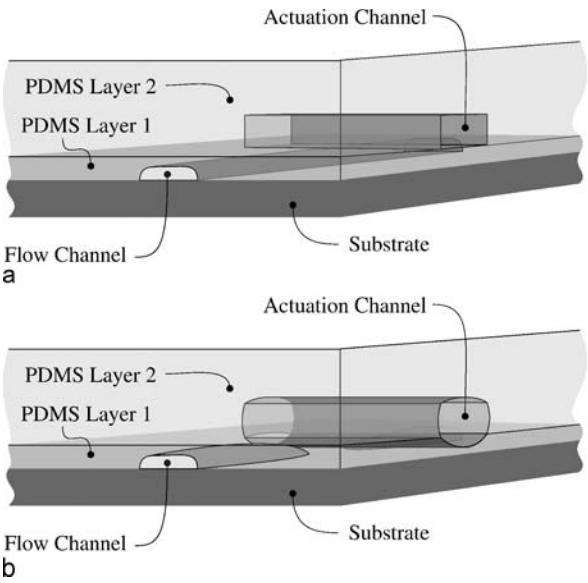
Due to a combination of surface tension and viscosity effects, the pressure drop per unit length along a channel with characteristic length l (radius or hydraulic diameter) scales unfavorably (as $1/l^3$ or $1/l^2$, depending on the analysis). Thus mechanical pumps must generate extremely high pressures to maintain flow rates as channel diameters

shrink. For this reason, it is widely accepted that mechanical pumping mechanisms, including peristaltic pumps, are not suitable for very small channels. Nguyen and Wereley survey the literature, and, using water as a working fluid, give 10 µl/min as the flow rate below which nonmechanical pumping principles are preferred [1]. However, that boundary is somewhat arbitrary, as demonstrated by flow rate of 0.14 µl/min reported in [4] for pneumatically-actuated peristaltic pumping of water in PDMS channels, the flow rate of 1.7 nl/min for electrostatically-actuated peristaltic pumping of ethanol in parylene channels [13], and the flow rate of 1 nl/h reported in [15] for optically-actuated peristaltic pumping by colloidal particles suspended in an aqueous solution.

Basic Methodology

A linear peristaltic micropump consists of two or more actuators arranged along a channel, and driven in a particular sequence. Important parameters that quantify pump performance are the maximum flow rate, denoted here by Q^*, the maximum pressure that can be generated between the pump inlet and outlet (called the ►pump head), denoted here by p^*, and the efficiency with which the pump converts external power into flow power, denoted here by η. Given a particular actuator, or set of available actuators, pump design consists of selecting the number of actuators, the actuation sequence, and the frequency of actuation. Important information about the individual actuators includes the stroke volume, V, the dead volume, V_0, the flow resistance in open and closed configurations, R_o and R_c, respectively, the maximum pressure the actuator can generate, p^*_{act}, called the ►closing pressure, the minimum time required for the actuator to either open or close completely, T_{min} (the minimum time to open and the minimum time to close are typically different; here T_{min} would be the larger of the two) and the energy or power required to operate an actuator. Almost any mechanical transducer can be used as an actuator in a peristaltic micropump, making generalizations about pump performance difficult. For example, the response time of a thermopneumatic actuator may be dominated by heat transfer out of the actuator, while that of a piezoelectric actuator is primarily determined by material stiffness and membrane geometry. As another example, a thermal actuator may require continual power to remain in the closed position, while – once closed – an electrostatic or pneumatic actuator may be held closed with little or no additional power consumption.

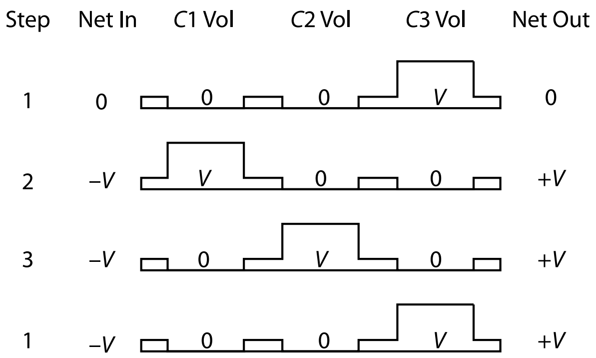
In this article we focus on those considerations that are common to all peristaltic pump designs. This rules out detailed physical analysis. However, some broad assumptions about actuator and system characteristics allow rough comparisons for pump design purposes. We begin by assuming ideal actuators, with infinite flow resistance in the closed position and zero dead volume. The first property allows easier accounting of the movement of fluid, the second allows issues related to fluid compressibility to be ignored.



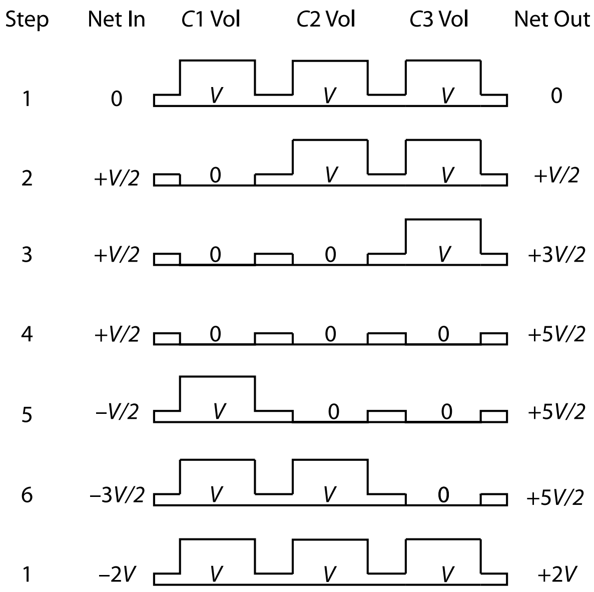
Peristaltic Pumps, Figure 3 A typical pump chamber in a multilayer PDMS implementation (similar to those of [4]). The chamber is open by default, as shown in (**a**). Inflating the actuation channel with compressed air closes the chamber, as shown in (**b**). PDMS layer 1 defines the fluid channels (sometimes called the working channel), while PDMS layer 2 defines the actuation channels. In both cases casting or spinning PDMS on a negative mold creates the channel structures. The molds are defined photolithographically, with standard positive resists used for thin channels (on the order of a micrometer) and negative resists such as SU8 used for thicker channels (up to one millimeter). The patterned side of the fluid layer is bonded to a glass, silicon, or PDMS substrate, and the patterned side of the actuation layer is bonded in turn to the planar side of the fluid layer. For convenience, we refer to the area of the fluid channel under the actuation channel as the pump chamber, even though it is otherwise indistinguishable from the rest of the channel. Baking the fluid layer mold at high temperature after the pattern is developed causes the photoresist to *reflow*, yielding rounded corners in the fluid channels. These rounded corners reduce leakage when the chamber is closed

The first step in this simplified analysis is estimating the volume of fluid transported in a complete pumping cycle. To do this, we apply the following rules:

1. When an actuator closes, the fluid within is completely expelled.
2. When an actuator opens, it completely fills with fluid.
3. If an actuator remains closed during a step in the sequence, no fluid may pass across it.
4. If, in a single step, some actuators open while others close, and there is a path for fluid to flow between them, then fluid is transferred from the latter to the former.



Peristaltic Pumps, Figure 4 A three-step, three-actuator pumping sequences, used in numerous pumps, including thermopneumatic pumps by Grosjean and Tai (see the reference in [1]) and Jeong, et al. [9]. The stroke volume is designated V. Chambers 1, 2, and 3 are abbreviated $C1$, $C2$, and $C3$. At every step two chambers are closed, reducing leakage. Note that Grosjean and Tai use a similar looking figure to define the pump sequence, but in their paper the raised level indicates actuation, which corresponds to *closing* the chamber



Peristaltic Pumps, Figure 5 A six-step, three-actuator pumping sequences proposed in the literature [6]. At step 1 all chambers are open, allowing backflow which will reduce the net flow rate

5. If an actuator opens or closes with no closed actuators between it and either the inlet or the outlet, the transfer of fluid is made equally from or to both sides. Once the fluid volume is computed, the flow rate flows from the actuation frequency. Maximum head is taken to be the maximum pressure exerted by an actuator (though this is not often known), and efficiency is estimated from the actuation sequence. Often, an estimate of flow rate is all that is desired. It must be noted that these estimates are very coarse, with for examples, errors of a factor of two reported, and attributed to unmodeled valve leakage [6].

Simplified Sequence Analysis

As an illustration of the simplified analysis, consider the three-step cycle shown in Fig. 4 for a pump consisting of three identical ideal actuators with stroke volume V. At the start of the cycle, no fluid has yet been transferred. In step 2, chamber $C1$ opens while chamber $C3$ closes. By rules 1 and 2, $C1$ must fill with volume V while $C2$ expels volume V. Since the intervening chamber $C2$ is closed, by rule 3 $C1$ must take volume V from the inlet, while $C3$ must expel volume V to the outlet. In step 3 $C1$ closes while $C2$ opens. By rule 4, since there is an open path between them, this transfers volume V from $C1$ to $C2$. Likewise the return to step 1, which completes the cycle, transfers volume V from $C2$ to $C3$. We conclude that, ideally, volume V is pumped per complete three-step cycle. At the final step the net fluid volume increase at the outlet must equal the net decrease at the input. This is a useful check that the analysis was done correctly.

Maximum Flow Rate

If each step requires time T, the pumping rate is $V/3T$. The maximum flow rate Q^* then corresponds to the minimum cycle time, $T_{\min}$: $Q^* = V/3T_{\min}$.

Maximum Head

In step 2, $C3$ is emptied to the outlet. If the outlet pressure is greater than p^*_{act}, the maximum pressure the actuator can provide, the chamber will be unable to close. Thus, the maximum head can be approximated as the closing pressure, $p^* = p^*_{\text{act}}$.

Efficiency

Fluid power is the product of flow rate by head. In an ideal ►positive displacement pump, flow rate is independent of head. Therefore, the maximum fluid power is approximately $P^* = p^*Q = p^*_{\text{act}}V/3T$. One actuator closes at each step, and two actuators must be held closed at each step. If energy E_{act} is required to close an actuator, and power P_{act} is required to hold it closed, we see that each cycle requires total energy $3E_{\text{act}} + 6P_{\text{act}}T$ (we assume no energy is required to open an actuator). The total power consumed per cycle is $(E_{\text{act}}/T) + 2P_{\text{act}}$, and the maximum efficiency is $\eta = p^*_{\text{act}}V/(3E_{\text{act}} + 6P_{\text{act}}T)$.
Experiments suggest that a linear relation between flow rate and pump head may be a more appropriate model [5]. In that case, the maximum fluid power is given by $P^* = p^*Q^*/4$.

Design Comparison

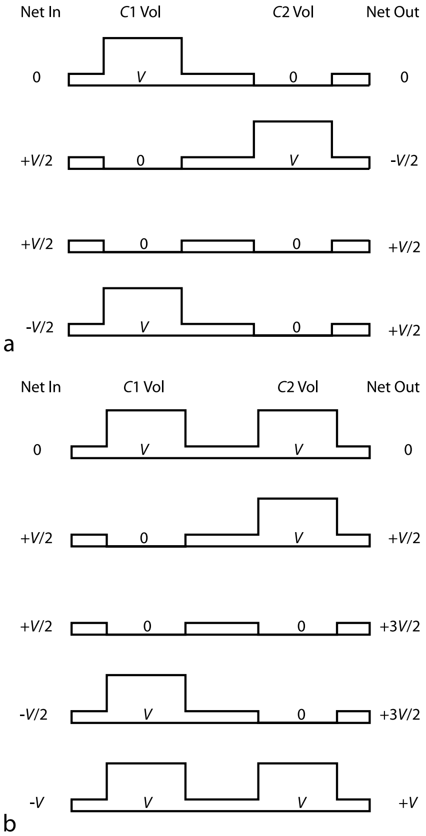
To illustrate the use of the simplified analysis in design, we compare the actuation sequence analyzed above to a six-step three-chamber sequence also reported in the literature [6], and shown in Fig. 5. The analysis is similar to the three-step sequence, except for steps 1 and 6, where an actuator closes with no closed actuators between it and either the inlet or the outlet. By rule 5, the expelled fluid is divided evenly between the inlet and the outlet. Two considerations make application of the simplified model more problematic in this case. The first is the all-actuators-open configuration in step 1. If there is significant head across the pump, this may produce an unmodeled backflow. The second is the assumption mentioned above, that the flow splits evenly in step 1 and 6. If the external system flow resistances as seen from the input and output are different, or if there is significant head, the split will *not* be even. These issues aside, we find that a volume $2V$ is pumped in each six-step cycle.

If each step requires time T, the pumping rate is $2V/6T$, or $V/3T$. The maximum flow rate is $Q^* = V/3T_{\text{min}}$. This is the same as for the three-step sequence.

In steps 2, 3, and 4 chambers are emptied to the outlet. The maximum head can again be approximated as the closing pressure.

The maximum fluid power is approximately $P^* = p^*Q = p^*_{\text{act}}V/3T$. In each cycle, energy $3E_{\text{act}}$ is required for actuator closings, and energy $9P_{\text{act}}T$ is needed to hold actuators closed, for a total cycle power requirement $(E_{\text{act}}/2T) + (2P_{\text{act}}/3)$. The maximum efficiency is $\eta = 2p^*_{\text{act}}V/(3E_{\text{act}} + 9P_{\text{act}}T)$.

To the level of modeling accuracy applied, the two designs have the same maximum flow rate and maximum head. The six-step sequence is more power efficient, but there are unanswered questions about how well this design will perform, particularly if there is significant backpressure. If power usage is more important than maximum head, the six-step design may be preferable, but further investigation will be required. If efficiency is not important, the three-step sequence should be chosen for its higher resistance to backflow. An advantage of the six-step sequence is that only one chamber is actuated per step. This makes the sequence insensitive to asymmetries in opening versus closing actuators. For example, if the actuators close ten times faster than they open, fluid may not transfer smoothly between chambers in the sequence of Fig. 4, but instead may leak out of the chamber. Avoiding this risk by adding intermediate steps, as for example, in the five-step sequence used by Smits [2] will reduce the maximum flow rate, and make the sequence of Fig. 5 more attractive.



Peristaltic Pumps, Figure 6 Pumping sequences for two-actuator peristaltic pumps [7]. Sequence A has at least one actuator closed at all times. Sequence B has a higher maximum flow rate, but may have problems with backflow under high head conditions

Most reported peristaltic micropump designs use three actuators. A few use more, but typically not more than five. Since the actuators take up potentially valuable space, and require connections for power and switching, it is desirable in many applications to use the minimal possible number. Some authors have stated that three chambers are the fewest possible for peristaltic pumping. However, the sequences shown in Fig. 6 have been shown to provide peristaltic pumping using only two chambers [7].

Diagrams like Figs. 4–6 are easy to grasp visually, but a more compact description of pumping sequences is also useful. One method used in the literature (for example, in [8]) is to indicate an actuated (closed) chamber by a 1 and an un-actuated (open) chamber by a 0. Thus the sequence in Fig. 4 is written $\{110, 011, 101\}$, that of Fig. 5 becomes $\{000, 100, 110, 111, 011, 001\}$, and those of Fig. 6 A and B are $\{01, 10, 00\}$ and $\{00, 10, 11, 01\}$, respectively. The five-step sequence used by Smits [2] is, following the convention of 1 for closed, 0 for open, $\{011, 001, 101, 100, 110\}$. (This sequence does involve an

actuator closing simultaneously with another opening, but they are separated by a closed chamber.) Some care is required in using this notation, since some mechanisms close when actuated (e. g. thermopneumatic), while others open (e. g. piezoelectric).

Dynamic Modeling

Leaks, backpressure, and actuator dynamics all influence the performance of peristaltic pumps. Leaks and backpressure effects will alter the distribution of fluid as actuators open and close. The dynamics of the actuators determines the maximum actuation rate, which in turn limits the maximum flow rate. These effects can be incorporated into lumped-parameter models for analysis and simulation. We do not pursue this further in this article, but refer the reader to the literature. One general approach is presented in [5]. Also relevant for further study are [6], [13] and [14], which present dynamic models for pneumatic and electrostatic pumps, respectively. All of these works are applied to liquid pumps. For gas pumps, or robustness to bubbles, compressibility becomes a factor. Some considerations of micropumps for compressible fluids may be found in [1]. Finite-element analysis of individual chambers can also be used to obtain detailed predictions of pump dynamic performance.

Key Research Findings

Fabrication Materials and Actuator Types

Peristaltic pumps have been demonstrated in all materials common for microfluidic applications, using a variety of physical principles. Space constraints prevent a comprehensive listing, but [1], [3], and [12] provide good overviews. Summarizing here just the main fabrication materials, the operating principle, and the working fluid, these include for silicon and/or glass devices, piezoelectric, thermopneumatic, and electrostatic actuators pumping water. For PDMS devices only pneumatic pumping of water is reported. For plastic or mixed-type devices, electrostatic, thermopneumatic, and pneumatic actuators are reported, pumping water and air. A novel traveling wave pump implemented using optically-actuated colloidal silica spheres is reported in [15]. Recently, Husband et al. (Microelectronic Engineering 73–74:858–863, 2004) report a piezoelectric silicon-glass device pumping water and air, Pan et al. (Proceedings of the 26th Annual International IEEE EMBS Conference, 2004) report a magnetically driven PDMS pump for water, and Jeong et al. report a thermopneumatic PDMS pump for water [9]. Electrostatic pumps implemented in parylene for integration with μTAS devices are reported in [13].

Reducing Device Complexity

Peristaltic pumps already offer simpler fabrication than passive check-valve pumps. Even the simplest actuators, however, require at least two patterned layers, as, for example, in the PDMS device of Fig. 3. However peristaltic pumping was recently demonstrated in a device with a single patterned layer of PDMS on an un-patterned glass or PDMS substrate [10]. The single patterned layer incorporates both pneumatic actuation lines and the water-filled working channels. Rather than press on the fluid channel from above, the actuation lines in this device squeeze the working channel from the sides. While these actuators provide enough stroke and increased resistance for pumping, cell sorting, and mixing, in their closed configuration they are still quite leaky, and do not completely seal the channel. However, the elimination of the second layer, along with the associated alignment and bonding tasks, should yield a significant reduction in device cost.

Reducing Number of Off-Chip Connections

Each actuator in a peristaltic pump is an active element, requiring switching and power. In applications such as Lab-on-a-Chip, the number of required off-chip connections can become very large. As mentioned above, one means for doing this is by using two actuators instead of three [7]. The proliferation of pumps and valves is a particular problem in pneumatically actuated pumps that require external valving. An innovative approach to ameliorating this problem is described in [11] for pneumatically actuated pumps fabricated in PDMS. Here, a single pneumatic actuation channel has a serpentine shape, crossing over the straight channel containing the working fluid at multiple intersections. The phasing of the actuation is provided by the natural delay associated with the propagating inflation zone in the serpentine channel. In this way the equivalent of a three-, five-, or seven-actuator peristaltic pump is realized using a single actuator line.

Multifunction Components

The individual actuators in a peristaltic pump can also serve as individual valves. Additional flexibility in integrating peristaltic pumps into large microfluidic systems can be gained from providing components with multiple functions. An example of this is the rotary mixer described in [8], which can serve as an effective dynamic micromixer, or as a peristaltic pump, depending on the actuation pattern of the individual valves.

Future Directions for Research

Progress in peristaltic pump design has paralleled the advancement of microfluidics as a field. As new materials and applications have been developed, peristaltic pump designs have soon followed. This trend seems likely to continue.

Peristaltic pumps are commonly used in PDMS-based systems. As those systems have attracted increasing amounts of research effort, due to their biocompatibility and demonstrated success in manipulation of cells, genetic material, and proteins, new innovations in PDMS-based pumps have followed. Progress has been made in reducing the need for external connections, but improvement would be welcome in the area of fully integrated pumps of reasonable cost and low complexity.

Phosphorescence

Definition

Phosphorescence is the emission of light from triplet-excited states, whereby one set of electron spins is unpaired. This means that electrons in the excited orbital have the same spin as the ground state electrons. Therefore, transition to ground state is not possible and emission rates are slow (in the region of $10^3 - 10^1\ s^{-1}$. Phosphorescent life-times have durations in the millisecond range. Following exposure to light, phosphorescent substances glow for several minutes as the excited phosphors return to the ground state very slowly.

Definition

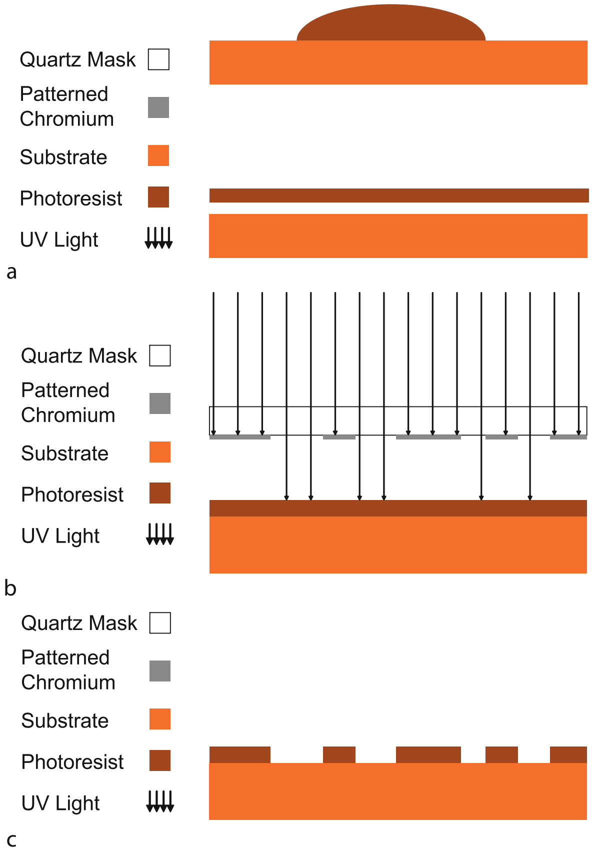
Photolithography is a process mainly used but not limited to manufacturing integrated circuits, and involves the photographic transfer of a desired pattern to a surface for further processing (e. g. etching).

Overview

Photolithography is the most popular method among various forms of lithography when transferring patterns from a mask (reticle) onto a surface of a substrate. Photolithography is widely used in the integrated circuit (IC) industry. However, it has other potential important applications such as developing methods for controlling the position of cells on a substrate or micropatterning of cells that has many bioengineering applications including the design of biosensors that can be used for drug and toxicity sensing devices and environmental monitoring devices, tissue engineering applications, and basic biology studies.
Photolithography is widely used in the semiconductor industry to perform a series of successive patterning on a given substrate to achieve an electronically functioning product. Although, this pattering method is limited to planar surfaces, it can provide accurate patterning feature sizes at the submicrometer level.

Basic Methodology

Photolithography is comprised of sequential process steps that are schematically summarized in Fig. 1. The process begins by choosing or preparing a substrate for the photolithography process. The ideal substrate should be dehydrated before any application of photoresist. This dehydration is usually done by a baking step called *dehydration bake* to remove adsorbed water from the substrate, usually a silicon wafer. Thereafter, the dehydrated substrate is spin coated with a photoresist adhesion promoter using a spinner. Usually, hexamethyldisilazane (HMDS) is used for this step, which is called priming. Then, the primed substrate is spin coated placing excess amount



Photolithography, Figure 1 (**a**) The top image shows the deposition of photoresist on a dehydrated and then primed wafer. The image below shows the coated wafer with uniform layer of photoresist. (**b**) The photoresist-coated wafer is exposed to UV light with an intact mask. (**c**) The pattern is developed by rinsing the substrate in a developing solution or using a spray developer. This process will remove the unwanted photoresist and leaves the pattern on the surface of the substrate.

of a photoresist, a photosensitive material. The photoresist will be spread uniformly on the surface of the substrate by centrifugal force. This process is one of the most important parts of the process, as the quality of the pattern transfer depends on effective spin coating of photoresist material. The most important requirements of spin coating are having a known uniform thickness of the photoresist material throughout the substrate, and this should be optimized for different substrate–photoresist combinations to determine the appropriate amount of photoresist and spinning velocity to use during the spin coating step. The thickness of photoresist may be varied according to the spinning speed and the viscosity of the photoresist-containing fluid. Usually, photoresist vendors provide information on how thickness may vary according to the spinning velocity of a given photoresist. The photoresist-coated substrates are subjected to a prebaking

step or soft baking step before being exposed to UV light with an intact stencil called a *photomask*. This prebaking step is usually done at 80 – 110 °C for 5 to 10 min depending on the thickness of the photoresist layer. This step will enhance the adhesion of the photoresist to the substrate by removal of the solvent in the photoresist and any built in stresses.

The exposure can then be conducted using an aligner. An aligner is comprised of a light source including any reflecting and/or refracting optics needed for collecting, collimating, filtering, and focusing the light onto the mask with the desired image. The most common aligners are contact printers and projection printers. In the contact printer approach the mask is held against the photoresist; in the projection printing method a set of lenses (projector/objective) is placed between the mask and the wafer to refocus light onto the photoresist. After exposure, the pattern is developed by rinsing the substrate in a developing solution or using a spray developer. This process will remove the unwanted photoresist and leaves the pattern on the surface of the substrate. This is also a very important step as it is very temperature sensitive, and will affect control and maintenance of line widths of the pattern, resist contrast, and resist profiles. There are two types of pattern transfer: positive and negative. In the positive form, the photoresist pattern on the substrate is the positive image of the mask pattern; in the negative form, the image of the photoresist pattern is the inverse image of the photomask pattern.

After developing, the substrate is subjected to a hard baking process to harden the photoresist. The hardening of the photoresist is done as the patterned substrates may be used for further processing such as plasma etching or ion implantation. Once all the processing is complete, any remaining/developed photoresist can be removed using a commercially available organic photoresist stripping solvent. This substrate can be used for further patterning by starting another photolithography step.

Future Directions for Research

The future directions for research in photolithography will be in improving minimum feature size. The variables that involve improving minimum feature size include photoresist, mask, and exposing wavelength. Thus, one can think that the future improvement in photolithography will depend on improving resist types, and designing better mask-refining technology and better laser technology.

Definition

The instrument used to measure illuminance or irradiance of light. It is the general term covering instruments for detecting scattered light intensity, absorption, fluorescence applied in the field of photometry. Spectroscopic techniques using photometer can probe the change of energy, frequency, wavelength and intensity of light caused by the interaction with matter. Most photometers are based on a photoresistor, photodiode, or photomultiplier tubes for photon observation. Either exhibits a change in electrical properties when exposed to light, which can be detected with a suitable electronic circuit.

Photometer, Table 1 Symbols, SI units and abbreviations used in photometer

Quantity	Symbol	SI unit	Abbreviation
Luminous energy	Q_V	lumen second	lms
Luminous flux	F	lumen (= cdsr)	lm
Luminous intensity	I_V	candela (= lm/sr)	cd
Luminance	L_V	candela per square metre	cd/m^2

Photometer, Table 2 Comparison of two photodetectors: photodiodes and photomultipliers

Advantages of photodiodes	Advantages of photomultipliers
• Excellent linearity of output current as a function of incident light • Spectral response from 190 nm to 1100 nm (silicon), longer wavelengths with other semiconductor materials • Low noise • Ruggedized to mechanical stress • Low cost • Compact and light weight • Long lifetime • High quantum efficiency • No high voltage required	• Large area • Flexible internal gain • Higher overall sensitivity • Photon counting is possible

P

Overview

The interaction of electromagnetic radiation with matter is essentially a quantum phenomenon and is dependent on the properties of the radiation and on the appropriate structural parts of the material involved. As the origin of the radiation is due to energy changes within the matter itself, an understanding of the properties of electromagnetic radiation and its interaction with matter leads to a recognition of the variety of types of spectrum, and consequently spectroscopic techniques, and their application to the solution of biological problems. Photometry is the science of measurement of light, historically, in terms of its perceived brightness to the human eye. It is distinct from radiometry, which is the science of measurement of light in terms of absolute power; rather, in photometry, the radiant power at each wavelength is weighted by the luminosity function that models human brightness sensitivity. Thus many different units of measure are used for photometric measurements and sometimes that can't be converted from radiometry. For example, in photometric quantities, every wavelength is weighted according to how visible it is, while radiometric quantities use unweighted absolute power. Because the eye responds much more strongly

to green light than to red, a green source will have higher luminous flux than a red source with the same radiant flux would. Light outside the visible spectrum does not contribute to photometric quantities at all, so for example a 1000 W space heater may put out a great deal of radiant flux (1000 W, in fact), but as a light source it puts out very few lumens (because most of the energy is in the infrared, leaving only a dim red glow in the visible). Watts (radiant flux) and lumens (luminous flux) illustrates the distinction between radiometric and photometric units. The watt is a unit of power. As power is not a measure of the amount of light output, power is only a rough guide to light output. In contrast, the lumen is the photometric unit of light output. The lumen is defined as amount of light given into one steradian by a point source of one candela strength; while the candela, a base SI unit, is defined as the luminous intensity of a source of monochromatic radiation, of frequency 540 THz, and a radiant intensity of $1/683\ \mathrm{Wsr}^{-1}$. (540 THz corresponds to about 555 nm, the wavelength, in the green, to which the human eye is most sensitive. The number 1/683 was chosen to make the candela about equal to the standard candle, the unit which it superseded). Combining these definitions, we see that 1/683 W of 555 nm green light provides one lumen. The definition tells us that 1 W of pure green 555 nm light is equal to 683 lm. It should be noted that it does not say anything about other wavelengths. Because lumens are photometric units, their relationship to watts depends on the wavelength according to how visible the wavelength is. Infrared and ultraviolet radiation, for example, are invisible and do not count. That means one watt of infrared radiation is worth zero lumens.

In photometry, illuminance is the total luminous flux incident on a surface, per unit area. It is a measure of the intensity of the incident light, wavelength-weighted by the luminosity function to correlate with human brightness perception. Similarly, luminous emittance is the luminous flux per unit area emitted from a surface. Luminous emittance is also known as luminous exitance. In SI derived units, these are both measured in lux (lx) or lumens per square metre (cdsrm^{-2}). In the CGS system, the unit of illuminance is the phot. One phot is equal to 10,000 lx. Illuminance was formerly often called brightness, but this leads to confusion with other uses of the word.

Irradiance is a radiometry term for the power of electromagnetic radiation at a surface, per unit area, which is used when the electromagnetic radiation is incident on the surface. The SI unit for this quantity is watts per square meter ($\mathrm{W/m}^2$), which is sometimes called intensity. This quantity characterizes the total amount of radiation present, at all frequencies. It is also common to consider each frequency in the spectrum separately. When this is done for radiation incident on a surface, it is called spectral irradiance, and has SI units $\mathrm{W/m}^3$, or commonly $\mathrm{Wm}^{-2}\mathrm{nm}^{-1}$.

Basic Methodology

Photometric Measurements

Photometric measurement is based on photodetectors, devices that produce an electric signal when exposed to light. Simple applications of this technology include switching luminaries on and off based on ambient light conditions, and light meters, used to measure the total amount of light incident on a point. More complex forms of photometric measurement are used for detecting scattered light intensity, absorption, fluorescence.

Light Scattering

Light scattering is one of the two major physical processes that contribute to the visible appearance of most objects, the other being absorption. Major forms of elastic light scattering (involving negligible energy transfer) are Rayleigh scattering and Mie scattering. Inelastic light scattering effects include Brillouin scattering, Raman scattering. Light scattering can also give color to some objects, usually shades of blue, but resonant light scattering in nanoparticles can produce different highly saturated and vibrant hues, especially when surface plasmon resonance is involved. At values of the ratio of particle diameter to wavelength more than about 10, the laws of geometric optics are mostly sufficient to describe the interaction of light with the particle, and at this point the interaction is not usually described as scattering. For modeling of scattering in cases where the Rayleigh and Mie models do not apply such as irregularly shaped particles, there are many numerical methods that can be used. The most common are finite-element methods which solve Maxwell's equations to find the distribution of the scattered electromagnetic field.

Rayleigh Scattering

Rayleigh scattering is a process in which light is scattered by a small spherical volume of variant refractive index, such as a particle, bubble, droplet, or even a density fluctuation. This effect was first modeled successfully by Lord Rayleigh, from whom it gets its name. In order for Rayleigh's model to apply, the sphere must be much smaller in diameter than the wavelength (λ) of the scattered wave; typically the upper limit is taken to be about 1/10 the wavelength. In this size regime, the exact shape of the scattering center is usually not very significant and can often be treated as a sphere of equivalent volume. The inherent scattering that radiation undergoes

passing through matter is due to microscopic density fluctuations as the molecules in matter move around, which are normally small enough in scale for Rayleigh's model to apply. This scattering mechanism is the primary cause of the blue color of the Earth's sky on a clear day, as the shorter blue wavelengths of sunlight passing overhead are more strongly scattered than the longer red wavelengths according to Rayleigh's famous $1/\lambda^4$ relation. Along with absorption, such scattering is a major cause of the attenuation of radiation by the atmosphere. The degree of scattering varies as a function of the ratio of the particle diameter to the wavelength of the radiation, along with many other factors including polarization, angle, and coherence.

Mie Scattering

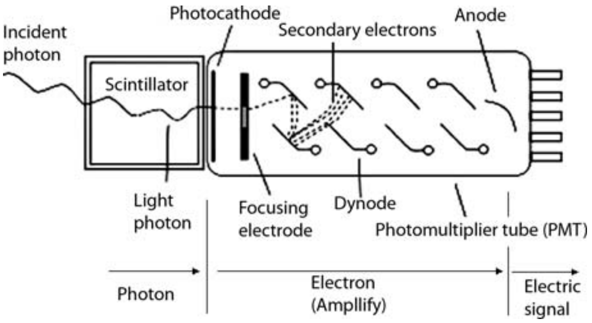
For larger diameters, the problem of electromagnetic scattering by spheres was first solved by Gustav Mie, and scattering by spheres larger than the Rayleigh range is therefore usually known as Mie scattering. In the Mie regime, the shape of the scattering center becomes much more significant and the theory only applies well to spheres and, with some modification, spheroids and ellipsoids. Closed-form solutions for scattering by certain other simple shapes exist, but no general closed-form solution is known for arbitrary shapes.

Raman Scattering

Raman scattering is the inelastic scattering of a photon. When light is scattered from an atom or molecule, most photons are elastically scattered (Rayleigh scattering). The scattered photons have the same energy (frequency) and, therefore, wavelength, as the incident photons. However, a small fraction of scattered light (approximately 1 in 1000 photons) is scattered from excitations with optical frequencies different from, and usually lower than, the frequency of the incident photons. Raman scattering can occur with a change in vibrational, rotational or electronic energy of a molecule. Raman spectroscopy employs the Raman effect for material analysis. The frequency of light scattered from a molecule is changed based on the structural characteristics of the molecular bonds. A monochromatic light source (laser) is required for sufficient illumination, and a spectrogram of the scattered light then shows the deviations caused by state changes in the molecule.

Doppler Shift

Electromagnetic radiation scattered by moving scattering centers does undergo a Doppler shift, which can be detected and used to measure the velocity of the scattering center/s in forms of techniques such as radar. Both Mie



Photometer, Figure 1 Photomultipliers are constructed from a glass vacuum tube which houses a photocathode, several dynodes, and an anode. Incident photons strike the photocathode material which is present as a thin deposit on the entry window of the device, with electrons being produced as a consequence of the photoelectric effect. These electrons are directed by the focusing electrode towards the electron multiplier, where electrons are multiplied by the process of secondary emission

and Rayleigh scattering are considered elastic scattering processes, in which the energy (and thus wavelength and frequency) of the light is not substantially changed. However, this shift involves a slight change in energy.

Absorption (Electromagnetic Radiation)

Absorption is the process by which the energy of a photon is taken up by another entity, for example, by an atom whose valence electrons make transition between two electronic energy levels. The photon is destroyed in the process. The absorbed energy may be re-emitted as radiant energy or transformed into heat energy. The absorption of light during wave propagation is often called attenuation. The absorbance of an object quantifies how much light is absorbed by it. This may be related to other properties of the object through the Beer-Lambert law. For most substances, the amount of absorption varies with the wavelength of the light, leading to the appearance of color in pigments that absorb some wavelengths but not others. For example, an object that absorbs blue, green and yellow light will appear red when viewed under white light. More precise measurements at many wavelengths allow the identification of a substance via absorption spectroscopy.

Fluorescent Measurement

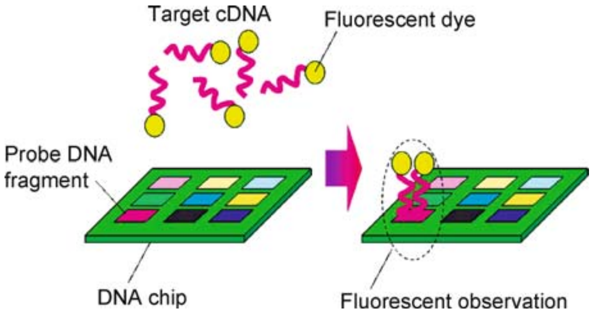
Fluorescent measurement uses the luminescence of fluorescence that is mostly found as an optical phenomenon in cold bodies, in which the molecular absorption of a photon triggers the emission of another photon with a longer wavelength. The energy difference between the absorbed and emitted photons ends up as molecular vibrations or

heat. Usually the absorbed photon is in the ultraviolet range, and the emitted light is in the visible range, but this depends on the absorbance curve and Stokes shift of the particular fluorophore. The fluorescence quantum yield gives the efficiency of the fluorescence process. It is defined as the ratio of the number of photons emitted to the number of photons absorbed. The maximum fluorescence quantum yield is 1.0 (100%); every photon absorbed results in a photon emitted. Compounds with quantum yields of 0.10 are still considered quite fluorescent. The fluorescence lifetime is an instance of exponential decay. Thus, it is similar to a first-order chemical reaction in which the first-order rate constant is the sum of all of the rates (a parallel kinetic model). Thus, the lifetime is related to the facility of the relaxation pathway. If the rate of spontaneous emission, or any of the other rates are fast the lifetime is short (for commonly used fluorescent compounds typical excited state decay times for fluorescent compounds that emit photons with energies from the UV to near infrared are within the range of 0.5 to 20 ns). The fluorescence lifetime is an important parameter for practical applications of fluorescence such as fluorescence resonance energy transfer. There are several rules that deal with fluorescence.

Photodetectors

Photoresistor

A photoresistor is an electronic component whose resistance decreases with increasing incident light intensity. It can also be referred to as a light-dependent resistor (LDR), photoconductor, or photocell. A photoresistor is made of a high-resistance semiconductor. If light falling on the device is of high enough frequency, photons absorbed by the semiconductor give bound electrons enough energy to jump into the conduction band. The resulting free electron (and its hole partner) conduct electricity, thereby lowering resistance. A photoelectric device can be either intrinsic or extrinsic. An intrinsic semiconductor has its own charge carriers and is not an efficient semiconductor, e. g. silicon. In intrinsic devices, the only available electrons are in the valence band, and hence the photon must have enough energy to excite the electron across the entire bandgap. Extrinsic devices have impurities added, which have a ground state energy closer to the conduction band – since the electrons don't have as far to jump, lower energy photons (i. e. longer wavelengths and lower frequencies) are sufficient to trigger the device. If a sample of silicon has some of its atoms replaced by phosphorus atoms(impurities), there will be extra electrons available for conduction. This is an example of an extrinsic semiconductor.



Photometer, Figure 2 DNA microarrays. The probes are complementary fragment oligonucleotides, of target DNA or mRNA are spotted onto the microarray surface. This type of array is typically hybridized with target cDNAs that are labeled with fluorophores. The samples are amplified by PCR and hybridized to the microarray, and then scanned in a microarray scanner to visualize fluorescence of the fluorophores on the chip. Absolute levels of gene expression cannot be determined, but relative differences in expression among different spots can be estimated when we used the two-color array, each color represents two different samples

Photodiode

A photodiode is a semiconductor diode that functions as a photodetector. Photodiodes are packaged with either a window or optical fibre connection, in order to let in the light to the sensitive part of the device. They may also be used without a window to detect vacuum UV or X-rays. A phototransistor is in essence nothing more than a bipolar transistor that is encased in a transparent case so that light can reach the *base-collector junction*. The phototransistor works like a photodiode, but with a much higher responsivity for light, because the electrons that are generated by photons in the base-collector junction are injected into the base, and this current is then amplified by the transistor operation. However, a phototransistor has a slower response time than a photodiode. A photodiode is usually a p-n junction structure. When a photon of sufficient energy strikes the diode, it excites an electron thereby creating a mobile electron and a positively charged electron hole. If the absorption occurs in the junction's depletion region, or one diffusion length away from it, these carriers are swept from the junction by the built-in field of the depletion region, producing a photocurrent. Photodiodes can be used under either zero bias (*photovoltaic mode*) or reverse bias (*photoconductive mode*). In zero bias, light falling on the diode causes a current across the device, leading to forward bias which in turn induces *dark current* in the opposite direction to the photocurrent. This is called the photovoltaic effect, and is the basis for solar cells – in fact, a solar cell is just a large number of big photodiodes. Reverse bias induces only little current (known as saturation or back current) along its direction. But a more important effect of reverse bias is widening of the depletion layer

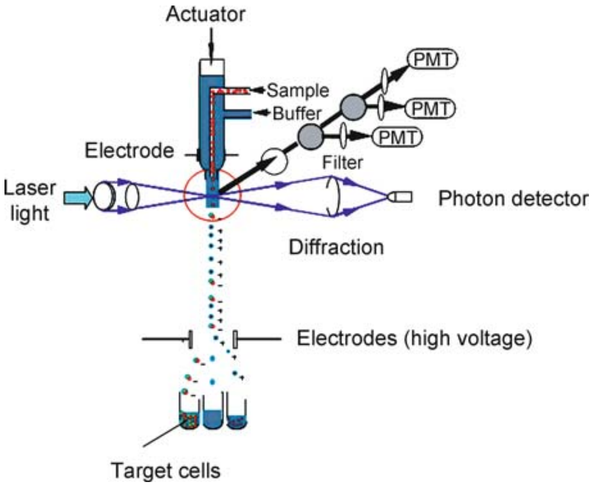
(therefore expanding the reaction volume) and strengthening the photocurrent. Circuits based on this effect are more sensitive to light than ones based on the photovoltaic effect and also tend to have lower capacitance, which improves the speed of their time response. On the other hand, the photovoltaic mode tends to exhibit less electronic noise.

Photomultiplier Tubes (Photomultipliers, PMT)

Photomultiplier tubes are extremely sensitive detectors of light in the ultraviolet, visible and near infrared. These detectors multiply the signal produced by incident light by as much as 10^8, from which single photons can be resolved. Avalanche photodiodes have replaced photomultipliers in some applications, but photomultipliers are still used in most cases. The electron multiplier consists of a number of electrodes, called dynodes. Each dynode is held at a more positive voltage than the previous one. The electrons leave the photocathode, having the energy of the incoming photon (minus the work function of the photocathode). As they move towards the first dynode they are accelerated by the electric field and arrive with much greater energy. On striking the first dynode, more low energy electrons are emitted and these, in turn, are accelerated toward the second dynode. The geometry of the dynode chain is such that a cascade occurs with an ever-increasing number of electrons being produced at each stage. Finally the anode is reached where the accumulation of charge results in a sharp current pulse indicating the arrival of a photon at the photocathode.

Avalanche Photodiodes (APDs)

Avalanche photodiodes (APDs) are photodetectors that can be regarded as the semiconductor analog to photomultipliers. By applying a high reverse bias voltage (typically 100-200 V in silicon), APDs show an internal current gain effect (around 100) due to impact ionization (avalanche effect). However, some silicon APDs employ alternative doping and beveling techniques compared to traditional APDs that allow greater voltage to be applied (> 1500 V) before breakdown is reached and hence a greater operating gain (> 1000). In general, the higher the reverse voltage the higher the gain. Since APD gain varies strongly with the applied reverse bias and temperature, it is necessary to control the reverse voltage in order to keep a stable gain. Avalanche photodiodes therefore are more sensitive compared to other semiconductor photodiodes. If very high gain is needed (10^5 to 10^6), certain APDs can be operated with a reverse voltage above the APD's breakdown voltage. In this case, the APD needs to have its signal current limited and quickly diminished. Active and passive current quenching techniques have been used for this purpose. APDs that operate in this high-gain regime are in Geiger mode. This mode is particularly useful for single photon detection provided that the dark count event rate is sufficiently low.



Photometer, Figure 3 Fluorescence-activated cell-sorting (FACS). The cell suspension is entrained in the center of a narrow, rapidly flowing stream of buffer liquid. The flow is arranged so that there is a large separation between cells relative to their diameter. A vibrating mechanism of actuator causes the stream of cells to break into individual droplets. The system is adjusted so that there is a low probability of more than one cell being in a microdroplet. Just before the stream breaks into microdroplets the flow passes through a fluorescence measuring station where the fluorescent character of interest of each cell is measured. An electrical charging ring is placed just at the point where the stream breaks into droplets. A charge is placed on the ring based on the immediately prior fluorescence intensity measurement and the opposite charge is trapped on the droplet as it breaks from the stream. The charged droplets then fall through an electrostatic deflection system that diverts droplets into containers based upon their charge. In some systems the charge is applied directly to the stream and the droplet breaking off retains charge of the same sign as the stream. The stream is then returned to neutral after the droplet breaks off

Key Research Findings

Biochemical and Medical Measurements

There is a wide range of applications for photometer in biochemistry and medicine. Especially, in micro/nano fluidics field, fluorescent chemical groups can be attached with small amount of biological molecules by a chemical reaction, and the fluorescence of the attached tag enables very sensitive detection of the molecule by fluorescent photodetector.

DNA Microarray

A DNA microarray (*gene* chip, DNA chip, or gene array) is a collection of microscopic DNA spots, commonly repre-

senting single genes, arrayed on a solid surface by covalent attachment to chemically suitable matrices. DNA arrays are different from other types of microarray only in that they either measure DNA or use DNA as part of its detection system. Qualitative or quantitative measurements with DNA microarrays utilize the selective nature of DNA-DNA or DNA-RNA hybridization under high-stringency conditions and fluorophore-based photodetection. DNA arrays are commonly used for expression profiling, i. e., monitoring expression levels of thousands of genes simultaneously, or for comparative genomic hybridization. Applications of these arrays include mRNA or gene expression profiling, comparative genomic hybridization (Array CGH), SNP detection arrays, and Chromatin immunoprecipitation (chIP) studies.

Fluorescent-Activated Cell Sorting (FACS)

Fluorescence-activated cell-sorting (FACS) is a specialised type of flow cytometry. It provides a method for sorting a heterogenous mixture of biological cells into two or more containers, one cell at a time, based upon the specific light scattering and fluorescent characteristics of each cell within microdroplet. It is a useful scientific instrument as it provides fast, objective and quantitative recording of fluorescent signals from individual cells as well as physical separation of cells of particular interest. The acronym FACS is trademarked and owned by Becton Dickinson although it is used within the scientific community as a general term.

Future Directions for Research

Photometer is important for identifying the materials in micro- and nano-scale flow, especially when the channel size is small and the flow speed is high. Although photometer itself does not have spatial resolution, the development of nanofluidics for single molecule detection should be desirable to develop new experimental methods and applications for single molecule based applications.

Photo Patterned

Synonyms

Lithography; Optical lithography

Definition

Photo patterned is a process used in IC and microfabrication to selectively remove parts of a thin film (photoresist). It uses light to transfer a geometric pattern from a photomask to a light-sensitive chemical on the substrate. A series of chemical treatments then engraves the exposure pattern into the material underneath the photoresist.

Photoresist Reflow

Definition

Photoresist reflow refers to a unique method to generate the photoresist patterns with hemispheric cross-section using heating effect of photoresist for 3-D microstructure fabrications. The 3-D structures are formed by heating up the photoresist to a certain high temperature after the photoresist is patterned by the conventional lithography. When the temperature is higher than the glass transition temperature of the photoresist, the photoresist begins to melt

and reflow. Due to the surface tension of the liquid resist and the surface property of the substrate, the resist always tends to form a convex shape on top of the substrate. This is an effective way to form convex lens, cylinder type channels or round tops of the structures as the replica molds for MEMS applications.

Photoresist SU-8

Definition

The photoresist SU-8 is an epoxy-based photosensitive polymer that losses its resistance to chemical etching when exposed to ultra-violet radiation. It is used especially in the transference of a structure pattern to a substrate. It offers properties such as high mechanical strength, good adhesion on many different substrate materials and biocompatibility. The fabrication of SU-8 structures is a low-cost process and ultra-violet lithography semiconductor compatible.

Photoresponsive hydrogels; Photoswitchable hydrogels

Definition

A hydrogel is defined as a network of hydrophilic polymer chains that is able to swell and retain large amounts of water. The crosslinks can be produced by chemical reactions to form covalent bonds, or physical interactions, such as hydrogen bonding, van der Waals force and polymer entanglement. Hydrogels can absorb over 99% water in their three-dimensional swollen network. Hydrogels possess a degree of flexibility very similar to natural tissue, due to their significant water content. Responsive hydrogels can reversibly change volume in response to a slight change of external stimulus, including pH, temperature, electric field, ionic strength, salt type, solvent, external stress or light. Photoresponsive is defined as a light-induced reversible change of chemical structures and physical properties.

Chemical and Physical Principles

Definition of Photochromism

Photochromism is the process of light-induced reversible color changes in a medium or more generally of their absorption spectra [1]. Photochromic compounds can exist in two different states, A and B, whose relative concentration depends on the wavelength of the incident light. The thermodynamically stable form A is transformed by irradiation into form B. The back reaction can occur either photochemically or thermally:

$$A \underset{h\nu_2 \text{ or } \Delta}{\overset{h\nu_1}{\rightleftharpoons}} B \tag{1}$$

Photochromic molecules, or light-sensitive chromophores, are chemical species having photochromic properties. Examples of photochromic molecules and photochromic processes are summerized in Table 1.

Chemical Processes Involved In Photochromism

Pericyclic reactions Cycloadditions are found in spiropyrans, spirooxazines, chromenes, hexa-1, 3, 5-triene, diheteroarylethenes, cyclohexa-1, 3-diene and spirodihydroindolizines systems.

Cis–trans isomerizations *Cis–trans* isomerizations occur in stilbenes, azobenzene, azines, thioindigoids, as well as some biological receptors.

Intramolecular hydrogen transfer Intramolecular hydrogen transfer is found in anils, benzylpyridines, tri-

azoles, oxazoles, metal dithizonates and perimidine-spirohexadienones.

Intramolecular group transfers Intramolecular group transfers are found in polycyclic quinones (periaryloxyparaquinones).

Dissociation processes Heterolytic bond cleavages occur in triarylmethanes and related systems.

When incorporating a small amount of photochromic molecules into a hydrogel matrix, either through chemical coupling or physical impregnation, a molecular level conformational change often leads to a macromolecular structural change and then macroscopic change of shape due to swelling and contraction in the hydrogel. Such a photoresponse has many advantages over other stimulation methods because:

- light is readily available;
- the amount of energy conversion can be carefully controlled by the wavelength, intensity of the exciting light, choice of chromophores and choromphore–polymer interactions;
- use of lasers offers high spatial resolution (up to nanometers), large areas and volumes, and fast speed; and
- it produces no waste during the photochemical process.

Key Research Findings

Hydrogels, which are crosslinked polymer networks surrounded with aqueous solution, are *intelligent* soft materials. In response to external stimuli, such as pH, temperature, light, electric potential, chemical agents and biological agents, polymer chains and water molecules will associate or dissociate, resulting in swelling and shrinking respectively, with a change of volume up to several hundred percent and a change of shape of the polymer.

In 1986, Irie and Kungwatchakun reported a synthesis of photosensitive gels by incorporating photosensitive molecules (1 – 4 mol%), such as leucocyanide and leucohydroxide, into the gel network [2]. These gels underwent volume changes upon irradiation; however, no phase transition was observed. In 1990, a photoinduced phase transition was first reported in thermoresponsive *N*-isopropylacrylamide (PNIPAAm) gels, by copolymerizing light-sensitive bis(4-(dimethylamino)phenyl)(4-vinylphenyl)methyl leucocyanide into the gel network [3]. In the absence of light the gels are neutral and undergo a sharp, yet continuous volume change. Upon irradiation by ultraviolet light, the neutral triphenylmethane leuco derivatives are dissociated into triphenylmethyl cations, creating internal osmotic pressure that induces swelling of the gels, showing a discontinuous volume phase transition. This transition process is slow since it depends on the photochemical ionization and subsequent recombination of ions.

Later, a much faster process (response time of the order of milliseconds) was reported. This was achieved by impregnating light-absorbing chromophores, trisodium salt of copper chlorophyllin, into PNIPAAm gels and illuminating with visible light [4, 5]. In this case, the phase transition was induced by local heating of polymer networks. According to the Flory–Huggins mean field theory, at equilibrium with zero osmotic pressure, the gel temperature, T, increases monotonically with the network density, ϕ:

$$T = T_{\mathrm{gel}}(\phi) \tag{2}$$

When illuminated by light, the chromophore absorbs the light and subsequently dissipates heat locally, inducing an increase in the local temperature. The temperature increment is proportional to the incident light intensity and the concentration of chromophore, and therefore also to the network density ϕ. Thus

$$T = T_0 + \alpha I_0 \phi \tag{3}$$

where T_0 is the ambient temperature, I_0 is the illuminating light intensity and α is a constant related to the heat capacity of the gel. Therefore

$$T_0 = T_{\mathrm{gel}}(\phi) - \alpha I_0 \phi \tag{4}$$

The term $\alpha I_0 \phi$ describes the ability of the system to undergo a local volume phase transition upon illumination of light. When the gel is in thermal equilibrium at a fixed gel temperature T, ϕ increase discontinuously with the increase of light intensity, I_0, beyond a threshold value. When I_0 is decreased, ϕ decreases discontinuously and the gel does not exhibit hysteresis as a function of I_0.

Because the increase of local temperature is the result of a balance between absorption of light and heat dissipation, the swelling and shrinking process of the gel in response to light is much faster compared to the response to ionization and ion migration, which requires collective diffusion of the gel network.

When introducing a small amount of ionic charge either through addition of salt or copolymerization of charged monomers in the light-sensitive gels mentioned above, the phase transition temperature was found also to be a function of pH. In ionic gels, the phase transitions are governed by the extent of hydrophobic interactions or the degree of hydrogen bonding induced between the polymer chains. The temperature and/or visible light intensity determine the extent of hydrophobic interactions, whereas pH affects the degree of hydrogen bonding. In the absence of external

stimulus, the ionic gel exhibits a large hysteresis between the collapsed and swollen states, which is indicative of the existence of two free energy minima. It would, therefore, be possible to control the phase behavior by manipulation of other external factors in addition to visible light.

According to the principle of kinetics of gels, the time needed for swelling and shrinking of a gel is dependent on the diffusion of water in and out of the hydrogel, which is proportional to the square of the characteristic linear dimension of a gel, l^2. It is expected that response time will be decreased to microseconds and nanoseconds if we can shrink the gel size to the submicrometer scale. This also means we need to perturb the environment extremely fast. Using a laser T-jump, a switching time of the order of $\sim$100 ns was observed in individual PNIPAAm nanogels [6].

Another common approach to prepare light-sensitive hydrogels is to covalently couple chromophores either in the polymer side chains or in the main chains [7, 8]. The chromophores undergo crosslinking through photodimerization or *trans–cis* isomerization, which brings about a change of the dipole moment or structure, the dissociation of the chromophore into ions, or change of hydrophilicity of the polymer, thus varying the shape and volume phase transition of the hydrogel network.

Photocrosslinking linear PNIPAAm with photodimerizable chromophores, such as stilbene, stilbazolium and acridizinium cations, has been studied [8]. The reversible photodimerization reactions allow for dynamic tuning of the crosslinking density of the gel network, which in turn influences the phase transition temperature and swelling ratio. The introduction of the chromophores could affect the hydrophobic nature of the polymer. Compared to stilbene and stilbazolium, the positive charge in acridizinium cations compensates the hydrophobicity of aromatic groups, resulting in a smaller decrease of the critical transition temperature of PNIPAAm, $-2.7\,°C$ vs. $-11.0\,°C$ in the stilbazolium photopolymer, and a higher photoreversibility. A complete reversion to monomer will be impossible if the monomer absorption is higher than that of dimers at the irradiation wavelength.

A conformational change of a hydrogel can be induced by photoisomerization of a chromophore group, such as azobenzene and spiropyran. For azobenzene and derivates, the thermodynamically more stable *trans* form is converted into the metastable *cis* isomer by UV light irradiation, and the *cis* isomer can return to the *trans* form by visible light irradiation or thermally in the dark. A spiropyran group is known to undergo photoisomerization from its neutral, *closed* spiro form (colorless and nonpolar) to the *open* merocyanine form (highly polar and zwitterionic) under UV light irradiation, which isomerizes back to the spiro form under visible light irradiation or thermally in the dark [8]. The formation of zwitterionic merocyanines can be further exploited to bind with charged molecules to manipulate the phase transition of hydrogels. Kinetics study suggests that photoisomerization is dependent on solvent, polymer composition and the free volume distribution around the chromophore. A bulky substituent in the polymer chains seems to slow down the *trans–cis* isomerization but increases the thermal recovery rate (the *cis–trans* isomerization). Typically, it requires hundreds of seconds up to minutes of photoirradiation to induce reversible swelling and shrinkage of hydrogels using this approach.

Examples of Application

Because of their interesting properties, such as swellability in water, hydrophilicity, biocompatibility and lack of toxicity, hydrogels have been widely used in biological and biomedical applications. In response to an environmental stimulus, responsive hydrogels undergo various types of volume phase transition, which converts chemical potential energy into mechanical force. Thus, responsive hydrogels have been used in microfluidic devices such as actuators, pumps and valves, artificial muscles, controlled delivery, sensors and separation. Responsiveness to light and the potentially fast response time provide an additional opportunity to design microfluidic devices that can be triggered without disturbing the system. One could design a submicrometer optical switch on a gel surface, and control an on/off nature by focusing the light in a local area of the gel, generating features analogous to *memory* or *display*. When photoresponsive polymers are grafted onto a porous membrane, reversible UV or visible light irradiation induces a change of the polymer solubility in water, leading to photoregulating permeability and mass transport through the membrane [8].

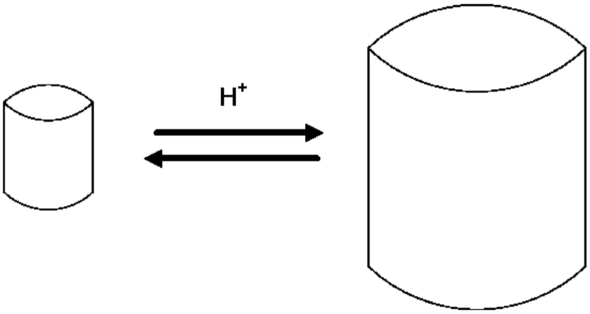
Definition

A pH-sensitive hydrogel is a gel structure that is sensitive to changes in pH. Most commonly, the hydrogel will swell or contract in response to a change in the local chemical environment. Hydrogels can be made using in situ polymerization techniques, which makes it very useful in incorporating them into microfluidic systems. These pH-sensitive hydrogels have applications in forming valves that are sensitive to a change in pH or in systems that can release a compound when the pH is changed, and in pH sensors.



pH-Sensitive Hydrogel, Figure 1 Schematic representation of the reproducible swelling that occurs in a pH-sensitive hydrogel

Overview

A pH-sensitive hydrogel consists of a gel structure which varies with a change in the pH of the system. The basis of a pH-sensitive hydrogel is a structure that swells or contracts depending on the pH of the solution (Fig. 1). The use of a hydrogel structure allows these devices to be easily fabricated within a microfluidic system. Placing these devices in a microfluidic device enables flow control to be accomplished by changing the pH of the solution that is being pumped through the system. Alternatively, a series of these hydrogels make it possible to sort solutions according to pH by placing two different hydrogels sensitive to either basic or acidic solutions into a microfluidic system, or by using a hydrogel to regulate the pH of solutions flowing out of a mixing hydrogel.

Basic Methodology

Hydrogels are polymer structures that contain a high water content. Because they contain a large amount of water, their physical configuration can change in response to the local chemical environment [1]. In particular, hydrogels undergo a change in volume in response to chemical or physical stimuli. Hydrogels that change their structure in response to temperature have been widely studied [2]. Hydrogels can also change in response to chemical conditions. The chemical environment that is often able to induce this type of volume change in a hydrogel is the pH of the system. In this type of a system the swelling of the hydrogel is produced from an ion-driven effect. How fast the gel expands is therefore dependent on the diffusion of ions into and out of the gel. Furthermore, swelling of the gel is an equilibration effect, and will be limited by how fast a steady state can be reached within the gel.
The ability to change in response to pH has been applied to two general applications. The first is as a valve. Because the volume of the hydrogel changes, a valve can be fabricated in which a hydrogel expands to plug a channel under

one set of conditions and contracts to allow flow under another set of conditions. The other application that hydrogels have been applied to is as pH detectors. This approach involves allowing a hydrogel to swell with a change in pH and to detect and measure the swelling of the hydrogel.

One of the great challenges in microfluidics is in preparing functional devices within a microfluidic system. Often, it is necessary to fabricate a functional device within a microfluidic system. Hydrogels are very useful in microfluidic systems because they can be either fabricated in bulk or they can be fabricated in situ. The in situ fabrication approach is particularly important in microfluidics because it greatly simplifies the fabrication of complex devices compared to more traditional methods of fabrication, which are usually based on semiconductor fabrication technology. The in situ synthesis of a hydrogel is usually performed using monomers that are somewhat hydrophilic, such a acrylic acid (AA), or 2-hydroxyethyl methacrylate (HEMA). A hydrophilic monomer allows water to penetrate the hydrogel, and therefore enables the polymer to swell and contract. The crosslinking monomer (such as ethylene glycol dimethacrylate, DGDMA) allows the polymer to retain its cohesiveness with swelling. The amount of crosslinker used affects many parameters in the resulting hydrogel such as how much it can swell, how much water can permeate the gel and the pore structure of the polymer. The actual polymerization step requires an initiator. The use of a photoinitiated monomer enables the hydrogel to be patterned into a specific portion of the microfluidic channel. The fabrication methods for placing a hydrogel into a microfluidic channel are critical in enabling their use in these applications.

Key Research Findings

There are two major areas that pH-sensitive hydrogels are used for in microfluidics. The first of these applications is as a valve. A hydrogel has the ability to change volume. When they expand, the hydrogel has the effect of closing off a channel. When the hydrogel contracts, the channel is opened. An early example of this approach involved introducing a pH-sensitive hydrogel into a microfluidic system in order to regulate the pH in the system [3]. This study utilized a circular chamber with a pH-sensitive hydrogel and included inlet channels that had solutions at a pH of 2 and 12. The outlet of the system was regulated at a pH of 7 by the action of the hydrogel. This study found that the geometry of the hydrogel has a strong effect on the regulation of the outlet pH. When a circular hydrogel is used the outlet pH was observed to oscillate; however, the use of a star-shaped hydrogel greatly reduced the oscillation. Another study fabricated two pH-sensitive hydrogels in a "V" shape in order to mimic a biomimetic valve such as those found in the veins [4]. This valve arrangement has the effect that flow through the valve is enabled in the forward direction, but is restricted in the reverse direction, effectively acting as a check valve. Furthermore, flow regulation is enhanced because the pressure drop across the valve is constant across a wide range of flow rates (0.4 – 1.8 ml/min). This ability to have the same pressure drop across the valve is due to the elasticity of the hydrogel; it enables the hydrogel to act as a pressure regulator in the microfluidic system, while the pH sensitivity enables the valve to be activated and deactivated depending on the solution being used. In another study a pH-sensitive hydrogel sphere was used as the actuating element in a microfluidic valve [5]. This approach involved placing the pH-sensitive hydrogel microsphere in a chamber. The swelling microsphere contacts a thick-centered membrane. This contact causes the membrane to close the valve. This approach allows the valve to be activated without the hydrogel being present in the main microfluidic channel, and the activation of the valve can be performed independently of the solvent in the microfluidic channel. This is because the hydrogel microsphere is in a channel separate from the main channel, and the two channels are isolated from one another via the membrane. The primary drawback is that this approach requires a more complex fabrication process to incorporate the valve into the microfluidic system.

In addition to pH-sensitive hydrogels being used as valves in microfluidic devices, they have also been used as a method to determine the pH of a solution in a microfluidic device. The pH of the solution in a microfluidic system can be very important in performing functions on a solution, such a protein digestion or a synthetic step. However, detection of the pH in a microfluidic channel can be very difficult due to the small volumes involved in these channels. One approach involved incorporating a pH-sensitive dye within a hydrogel [6]. The synthesis of the hydrogel with the pH-sensitive dye is relatively simple because the hydrogel is simply synthesized with the dye incorporated within the polymer gel structure. The pH of the system can then be determined by the color of the dye. Using UV-visible spectroscopy enables very specific determination of the dye state. The primary limitation on the time required to determine the pH is the diffusion of within the hydrogel. Another approach that has been demonstrated to measure the pH in a microfluidic channel involves a hydrogel actuating a piezoresistive device [7]. This approach involves fabrication of a pH-sensitive hydrogel in contact with a bending plate. This plate then actuates a piezoresistor, the electrical signal of which is then read to give an indication of the pH in the microfluidic device. While

the piezoresistor makes fabrication of these systems more complex, it has the advantage of enabling rapid and precise electronic indication of the pH of the system.

A key parameter that has been studied for pH-sensitive hydrogels is their mechanical properties [8]. This is very important because the macromolecular properties will determine how the gel performs in the system. For instance, the mechanical properties in a valve will determine how well it can seal a channel, and can also affect how fast the valve can close. A wide variety of experimental techniques have been developed to characterize the mechanical properties of microgels, particularly the tensile strength [9]. In these studies it was found that the mechanical properties are dependent on the extent of equilibrium swelling as well as the polymerization conditions used to produce the gel. The mechanical properties can be controlled by adjusting the amount of crosslinker that is used in the hydrogel composition. The ability to control the mechanical properties of a pH-sensitive hydrogel will be critical in applying these components into specific microfluidic applications.

Future Directions for Research

While there have been a number of devices demonstrated for pH-sensitive hydrogels, there is a great deal of development work that can still be done. In particular pH-sensitive hydrogels need to be demonstrated in more robust environments, and their reliability and longevity need to be explored. The use of these systems in more robust situations will enable them to be explored in more complex microfluidic systems. In particular, devices will need to be made that can incorporate multiple valves in order to enable complex flow paths to be constructed. While this may be accomplished utilizing pH-sensitive hydrogels, it may be advantageous to incorporate valves in the system that are actuated via different approaches. This may further enable complex systems to be fabricated. The synthesis of pH-sensitive hydrogels will also need to become more refined to enable them to be placed into these more complex systems. Part of this development will include refining the synthetic methods to produce hydrogels with the desired mechanical, physical and chemical properties. In developing hydrogels with specific chemical properties there are two possible approaches. The first is to incorporate specific chemical functionalities into the polymerization mixture of which the hydrogel is made. The other approach is to coat or react a specific chemical functionality on the surface [10]. The ability to control the chemistry will enable these devices to be used with a wide variety of solutions and may improve their versatility.

Picoliter Flow Calibration

ZHANHUA SILBER-LI
LNM, Institute of Mechanics, Chinese Academy of Sciences, Beijing, China

Synonyms

pL; Flow rate

Definition

Flow rate is defined as the volumes or masses of fluids flowing through a special area in unit time. The standard unit of flow rate is m^3/s. Picoliter (pL) is a unit of volume, $1\,pL = 10^{-15}\,m^3$ and transfers to other units as: $1\,pL = 10^{-3}\,nL = 10^{-6}\,\mu L = 10^{-9}\,mL = 10^{-12}\,L$. An example describes the volume of a picoliter: a droplet with a diameter of 20 μm has a volume of about 4.2 pL.

Overview

Classic flow rate measurement tools are mass flowmeter, electromagnetic flowmeter, rotameter and turbine flowmeter, their measurement ranges being normally larger than $10^{-7}\,m^3/s$ (0.1 mL/s). But in microscale flows, the range of flow rate is usually $10^{-7} - 10^{-12}\,m^3/s$, in other words, $10^2\,\mu L/s$–1 nL/s. In nanoscale flows, the flow rate is from 10^{-15} to $10^{-18}\,m^3/s$ (1 pL/s–1 fL/s). So the measurement and calibration methods will be different for micro- or nanoscale flows, compared to classic macroscale flows.

Colin [1] has reviewed some measurement methods in microscale flow, including the weighing method, thermal method, wave reflection method, acoustic vibration method, and so on. Here two common methods, the weighing and displacement methods, are introduced. In the weighing method [2], the total mass M of fluids flowing out within a time Δt are measured, and the flow rate is calculated as:

$$Q_g = \frac{M}{\Delta t} \tag{1}$$

The uncertainty of this method is directly proportion to the accuracies of balance and stopwatch. If a balance with an accuracy of within ±0.001 g is used to measure a kind of flow whose range is larger than 1 μL/s, the measurement accuracy is about ±1%.

The displacement method [1, 3] is another kind of indirect method, which calculates flow rate by measuring the displacement L of a fluid in a capillary tube with a diameter D and interval Δt:

$$Q_m = \frac{\pi D^2 L}{4\Delta t} \tag{2}$$

Because flow rate Q_m is proportion to the second power of diameter D, the uncertainty of flow rate is mainly related to the accuracy of D. The measuring precision of the diameter of capillary tubes using a toolmaker's microscope is ±0.01 mm, so the uncertainty can reach ±2%, for a flow rate range of 1 – 100 nL/s.

For saving samples, reducing cross-contamination and operating fluids with smaller volume in microfluidic devices, designers hope that the dimensions of channels or tubes are as small as possible. When the characteristic dimension of channels decreases to the nanoscale, picoliter-scale flow will occur. De Heij et al. [4] designed a nozzle array of 50 μm diameter, which can produce

100 – 700 pL discrete droplets. Ahmed and Jones [5] controlled dielectrophoretic (DEP) force, capillary force and inertial force by an electrophoresis method, and produced discrete droplets on the substrate of a channel, whose volumes were smaller than 10 pL. He et al. [6] drove water flow through a nozzle of diameter 1.7 µm by electric pulse, and formed 8 – 14 pL water droplets in an oil environment making use of Rayleigh instability. Ellson [7] used focused acoustic energy to spray droplets from the surface of fluids, whose volumes are about 0.1 pL–1 µL. Karnik et al. [8] controlled protein to transmit in nano- and microchannels under the effect of an electrostatic field, the dimension of the channel being 1 – 100 nm, equivalent to the Debye length. The height of the channel cross-section was just 30 nm, so this device can be used to control picoliter-scale flow of protein solution.

From these literature reports we can see that pL flows have been achieved and applied in sampling devices of biology chips, in micro- or nanochannels and two-phase flows, so the measurement and calibration of pL volume fluid flow have great importance attached to them.

Basic Methodology

The methods that are usually used to calibrate ultra small-volume fluids are the static weighing method, comparing method, flow velocity measurement method, and so on. The study of picoliter flows has just begun, so the perfect calibration methods have not been formed yet. This section will review partial methods to produce pL flow, their measurement accuracy and the relevant calibration methods. A fuller coverage is not possible because of space limitations.

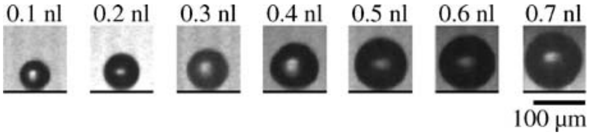
Visual Inspection Measurement

As shown in the literatures, pL flows always present as droplet form. So it is important to pay attention to measuring the volume of droplets in pL flow measurement. The common methods are calculating volume by the size of the microvial or microchannel in which droplets are formed, or measuring droplet diameters from their images and calculating volume by the ball volume formula:

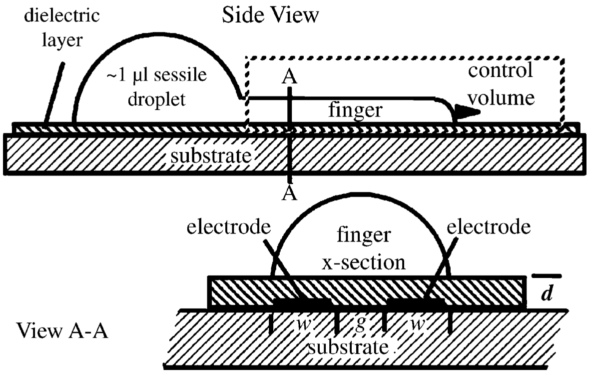
$$V_\mathrm{d} = \frac{4}{3}\pi R^3 = \frac{1}{6}\pi D^3 \tag{3}$$

Here, the radius R or diameter D are measured from images captured by a microscope, with a calibrated microruler.

De Heij et al. [4] designed a nozzle array to produce continuous droplets. The diameter of the nozzle is 50 µm.



Picoliter Flow Calibration, Figure 1 The droplet volume measured with stroboscope camera [4]

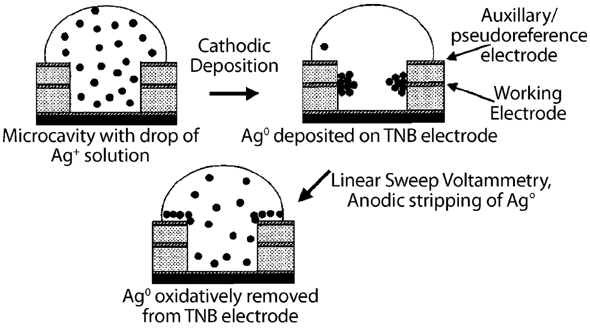


Picoliter Flow Calibration, Figure 2 Side view of a DEP-driven finger emerging from a sessile droplet using parallel co-planar electrode (top) and the cross-sectional (view A–A) [5]

A digital stroboscope (Visit Video Stroboskop MOCRON-RT) was used to record the spraying process of droplets, and then the image processing software was used to calculate the diameter (Fig. 1). The accuracy of image measurement is ±5%. They have measured droplets from 0.1 to 0.7 nL, and the measurement accuracy is ±0.1 pL.

Ellson et al. [7] used the method of focused acoustic energy to eject a pL droplet from a nanoliter-scale well, the droplet diameter being also measured by a digital stroboscope. In their experiment, 20 pL droplets were ejected from 20 nL liquids. The accuracy of liquid volume measurement is determined by the accuracy of image measurement. They used a precisely calibrated micrometer to measure the image size, the accuracy being estimated as about ±5 µm based on the image resolution. The minimum volume of experimental droplets is 20 pL, and the measurement accuracy is ±0.1 pL. Thousands of droplets were produced continuously, and the whole fluid volume divided by the number of droplets calibrated the average volume.

Ahmed et al. [5] proposed a method to produce discrete pL droplets on substrate by an electrophoresis method. A finger will be formed when water is driven by electrophoresis force above an electrode (Fig. 2). The key parameter dominating capillary instability is the Bond number, which is expressed by $\mathrm{Bo} = \rho g R^2 \gamma$, which presents the relation between hydrostatic pressure $\rho g R$ and Laplace pressure



Picoliter Flow Calibration, Figure 3 Schematic diagram of the electrode and the procedure for small volume measurement using anodic stripping voltammetry [9]

γ/R. If the electrical potential is taken out for $\mathrm{Bo} < 10^{-3}$, the capillary force will dominate, and the finger will be broken to form droplets. The front part of the finger is assumed to form a hemispherical shape droplet, whose diameter is about $D = 2w + g$, where w is the width of the electrode and g is the interspace between the electrodes. The volume of the hemispherical droplet can be calculated by reference to formula (3).

Ahmed et al. used a camera to record the droplet forming process at 500 frames/s, 6 continuous frames being used to calculate the extending length of the finger, and compared to the estimated value of droplet diameter. In the experiment, the average volume of 30 droplets is 40 pL. If the size of the microelectrodes decreases further, 10 pL volume droplets would be obtained. The minimum measurable volume is of the order of 10 pL, and the accuracy is about ±5 pL, but the volume measured by this method has not been calibrated.

In the methods discussed above, fluid volumes were measured by visual inspection, so other methods are needed for fluids which cannot be inspected directly or which flow in opaque channels.

Electrical Measurement

Coulometric Method

Vandaveer et al. [9] proposed anodic stripping voltammetry to measure fluids with ultra-small volume. The advantages of this method are avoiding optical detecting devices, fast and easy and suitable for irregular shapes of fluid flows.

A microvial with electrodes in the wall is used in this method. The volume of fluids can be calculated by exhaustive reduction of current under the effect of continuous changed voltage (Fig. 3). Recessed microdisk (RMD) electrode, tubular nanoband (TNB) electrode and reference electrodes were installed on the bottom, sidewall and top of the microvial, respectively. Soluble metal species were added into the sample fluids, and then they were deposited on the electrodes on the sidewall driven by voltage. After that, the deposited metal species were removed under a voltage of -0.6 to 1 V. Droplets volumes can be measured indirectly by the quantity of electricity integrated from the relation between removed current and voltage of reference electrodes, the formula being expressed as [9]:

$$V_s = \frac{Q}{nFC^*} \tag{4}$$

where Q is the total Coulomb value integrated from the anodic removed curve, n is the moles of electrons transferred per mole of metal ions, F is the Faraday constant ($F = 96{,}485$ C/mol) and C^* is the initial concentration of metallic ions in solution.

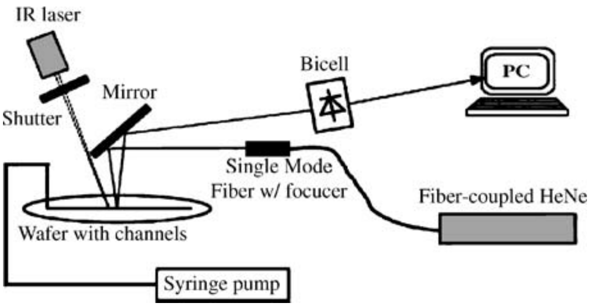
Electrodes are installed on the wall of the microvial, and as a result the minimum size of the microvial is 8 μm in height and 13 μm in diameter; in other words, 1 pL measurable volume. The accuracy of this method is 1.49 nL ± 20 pL. It is easier for smaller volume fluids to dissipate and deposit, so this method is better for measuring fluid volumes below 1 nL. Also, because the method is coulometric, calibration curves are not required [9].

Impedance Method

Hjelt et al. [10] proposed an integrated, noninvasive method to measure sub-nanoliter volume droplets. Microelectrodes were integrated on the bottom of a reactor and covered with a layer of SiN. According to the impedance characteristic between electrodes, the size of droplet can be obtained. The volumes of the reactor fabricated in the experiment are 60–40 pL. The relation between liquid volumes and electrodes voltages was calibrated, and the accuracy of voltage measurement was ±5%, and the resolution of volume measurement could be up to 1 pL. To calibrate the measurement results of the impedance method, the authors used a fluorescence microscope to inspect the liquid volume inside the reactor, and they concluded an accuracy could be achieved of ±5%. The minimum measuring volume in the experiment is 30 pL, and the measurement accuracy is ±1.5 pL.

Optical Measurement

Markov et al. [11] measured the velocity of the flow in an electrophoresis chip by backscatter interferometry (Fig. 4). An infrared laser with a shutter was used to heat the fluid periodically in an upstream position, and a bicell was used as a position-sensitive device in the detecting section. The



Picoliter Flow Calibration, Figure 4 Diagram of backscatter interferometry for fluid flow measurement [11]

changes of refractive index of fluids as a function of temperature were converted to electrical signals, and these signals had the same frequency as that of the heating laser, but with different phase. The phase difference between the shutter signal and the bicell signal was used to calculate the time interval Δt during which fluids flowed from the heating section to detecting section. Then the velocity can be calculated. The authors also calibrated the relations between the flow rate and the phase difference.

Experiments were carried out in a $200\,\mu$m channel, with a measurement accuracy of $0.833 - 1.66\,\text{nL/s} \pm 0.127\,\text{nL/s}$, but the velocity measurement results were not calibrated.

Key Research Findings

Several methods to obtain and measure pL fluid volumes have been reviewed: visual inspection measurement, electrical measurement and optical measurement. Visual inspection measurement captures a droplet image by microscope or stroboscope, and measures the size of the droplet in the image to calculate its volume. The minimum volume of droplets can reach 10 pL, with a measurement accuracy of ± 0.1 pL. Coulometric and impedance methods were introduced as electrical measurements, which measure the quantity of electricity or impedance of fluids to calculate the droplet volume. The minimum volume of droplets measurable with these methods is 30 pL, with ± 1 pL accuracy. Finally, optical measurement, especially the backscatter interferometric method, was introduced. This method measures the difference of light phase to calculate the velocity of a fluid, and then calculates the volume. Flow rates from 0.833 to 1.66 nL/s were measured in experiments and the accuracy was ± 0.127 nL/s.

Obviously, visual inspection measurement is the easiest method with the highest accuracy to date. The impedance method also uses it for calibration [10].

For calibration, if the cumulative volume of liquid is larger than $1\,\mu$L, the volume weighing method is suggested. But for calibration of single droplet volume, the visual inspection method is simpler.

Future Directions for Research

In principle, calibration methods of ultra small-volume droplets include static weighing method, comparing to standard volume and calibration by high-accuracy velocity measurement. Traditional optical devices, microscopes, stroboscopes, etc., are still the main measurement method for pL fluid volume calibration, and the accuracy is about 0.1 pL. Novel measurement techniques are needed for calibration of sub-picoliter fluid volume.

Definition

Piezoelectricity means *squeeze* or *pressure* electricity, from the Greek *pieze* which means to press or squeeze. The casual definition of piezoelectric materials is that they develop an electric charge differential along an axis of ► piezoelectric polarization if placed under appropriate mechanical strain, called the ► direct piezoelectric effect, and deform if an electric field is applied along the same axis of polarization, the converse piezoelectric effect. The electric field to mechanical strain coupling occurs when the positive and negative charge of the individual ions within the material do not displace symmetrically upon the application of an external strain. Strictly speaking, piezoelectric materials exhibit electric polarization upon the application of a stress and vice versa. Often the casual and strict definitions are the same, though confusion may arise with the casual definition. All piezoelectric materials are ► anisotropic, and there are useful examples of piezoelectric materials that are single crystals, polycrystalline ceramics, and polymers. Many of the known piezoelectric materials have at one time or another been used as sensors or actuators in microfluidics, for which their rapid response and large force transmission have been beneficial, though researchers have had to learn to overcome small strains, thermal losses, aging, and difficulties in fabrication, especially in process compatibility.

Overview

Piezoelectric materials offer the ability to directly transform (transduct) from electrical to mechanical energy and vice versa, convenient for microtechnology in sensing and actuation; a material is said to be piezoelectric if an applied stress generates an electric field within, and vice versa. They may be used to provide static and dynamic deformation at frequencies up to several gigahertz, depending on the motion to be induced, the scale of the device, and the material used. Compared to other methods of power transduction, including electrostatic, electrostrictive, magnetostrictive, and electromagnetic means, piezoelectric transduction typically provides large forces at small strain rates ($< 1\%$ strain typically) for actuation, and relatively large voltages and small currents for sensing. Piezoelectricity is usually treated as a linear interaction between mechanical and electrical phenomena, though this assumption is generally invalid for high-power applications or in materials with either large losses or large deformations (polymers). The ► hysteresis in such conditions is the deviation from linear transduction. This is different than the typically weak ► electrostrictive [2] behaviour of many insulating materials which exhibit a strain proportional to the square of the applied field, though some materials, like ► relaxor ferroelectrics are exceptions. Single crystal materials are usually naturally polarized, implying they may be used without additional treatment, while polycrystalline and polymeric materials must be polarized with either an applied electric field or an applied strain prior to use.

Recognition of the piezoelectric effect has been known since ancient times [6]. Theophrastus noted in 314 BC the attraction of small pieces of straw and wood to tourmaline after heating, but recognition of the presence of an electrostatic field causing the attraction had to wait for the nineteenth century, along with a name provided by Brewster in 1824: ► pyroelectricity. All pyroelectric materials are piezoelectric; Jacques and Pierre Curie studied piezoelectric materials in the 1880's and were able to describe many of the characteristics of the phenomena used in applications today. Once synthetic quartz and high-performance

materials like barium titanate, lead zirconate titanate and subsequent variations became available in the 1950's and 60's, a wide variety of applications beyond sonar became feasible.

Many of the piezoelectric materials used for applications are single crystals or polycrystalline matrices of single-crystal grains. Overall, crystalline media may be organized into thirty-two crystal classes or point groups based on their symmetry; the names of some of these groups are commonly known; triclinic, orthorhombic, cubic, and isotropic are especially well-known. ► Hermann–Mauguin notation [1] is often used to precisely describe the properties of these materials. For example, triclinic materials are represented with either a 1 or –1, depending on whether or not the material has ► inversion symmetry, respectively. Of these thirty-two crystal classes, twenty-one possess no centre of symmetry; they are said to be ► non-centrosymmetric or to lack inversion symmetry, and all but one of these classes are piezoelectric. The exception is class 432, which has other symmetries which negate the non-centrosymmetric nature of the crystal structure. The remaining crystal classes which are piezoelectric are 1, 2, m, 222, mm2, 23, 3, 3m, 32, 4, –4, 422, 4mm, –42m, –43m, 6, –6, 622, 6mm, and –62m.

Out of these twenty piezoelectric classes, ten also lack symmetric characteristics along a particular axis, and are therefore able to retain a natural ionic charge separation in the crystalline structure along that axis—a ► spontaneous polarization—that forms an electric dipole which remains even without an externally applied electric field. This is in contrast to all insulating or dielectric materials which polarize to form such dipoles only with an externally applied field. These crystal groups are *pyroelectric*, including 1, 2, m, mm2, 3, 3m, 4, 4mm, 6, and 6mm. A crystal belonging to one of these crystal groups that has a polarization that may be reversed through the application of an external electric field is said to be ► ferroelectric. A distinct characteristic of ferroelectric materials, in the strictest definition, is the presence of hysteresis. All ferroelectric materials are both piezoelectric and pyroelectric. Lead zirconium titanate (PZT or $Pb_xZr_{(1-x)}O_3$) is one of the most important ferroelectric materials, class 6mm, though PZT is only found in polycrystalline form as a ► perovskite ABO_3.

Most piezoelectric materials tend to be quite capacitive. The pyroelectric nature of all polarized piezoelectric materials can cause the development of significant charging across the material due to thermal expansion coupled to the direct piezoelectric effect causing a charge displacement from the thermal strain; voltages of 1 kV are not unheard of in PZT after a temperature change of 50 °C, and caution is warranted in any application. However, a piezoelectric material will lose its spontaneous polarization if its temperature is raised above the ► Curie temperature, near the temperature of maximum dielectric constant, the ► Curie–Weiss temperature. Since the mechanical and electrical behavior are coupled, a change in boundary conditions in one domain will change the behavior of the material in the other domain. By leaving a polarized piezoelectric element open-circuited, the mechanical stiffness of the material will be higher, called stress stiffening. Similarly, mechanically clamping a piezoelectric element will tend to increase the impedance.

With polycrystalline and amorphous *piezoelectric* materials, a spontaneous polarization can rarely be obtained as a consequence of the natural ordering within the material during fabrication. Some form of applied strain or electric field is necessary to polarize the material before use. A common sensor material, polydivinylfluoride (PVDF), is stretched to polarize it, while standard PZT must have a large ($> 10\,\text{kV/cm}$) electric field applied to it to order the electric Weiss domains, or groups of dipoles, in the general direction of the applied field. It is a common misconception that polarization of these materials implies the dipole polarization is rotated to be aligned with the electric field or that the atomic structure itself is realigned within the material. In reality, the atomic structure is essentially fixed, preventing such rotation or realignment. Once polarized, the material can be said to be a member of the pseudocrystal group ∞ mm, and is often represented as a 6 mm material. Generally, the domains are randomly oriented beforehand.

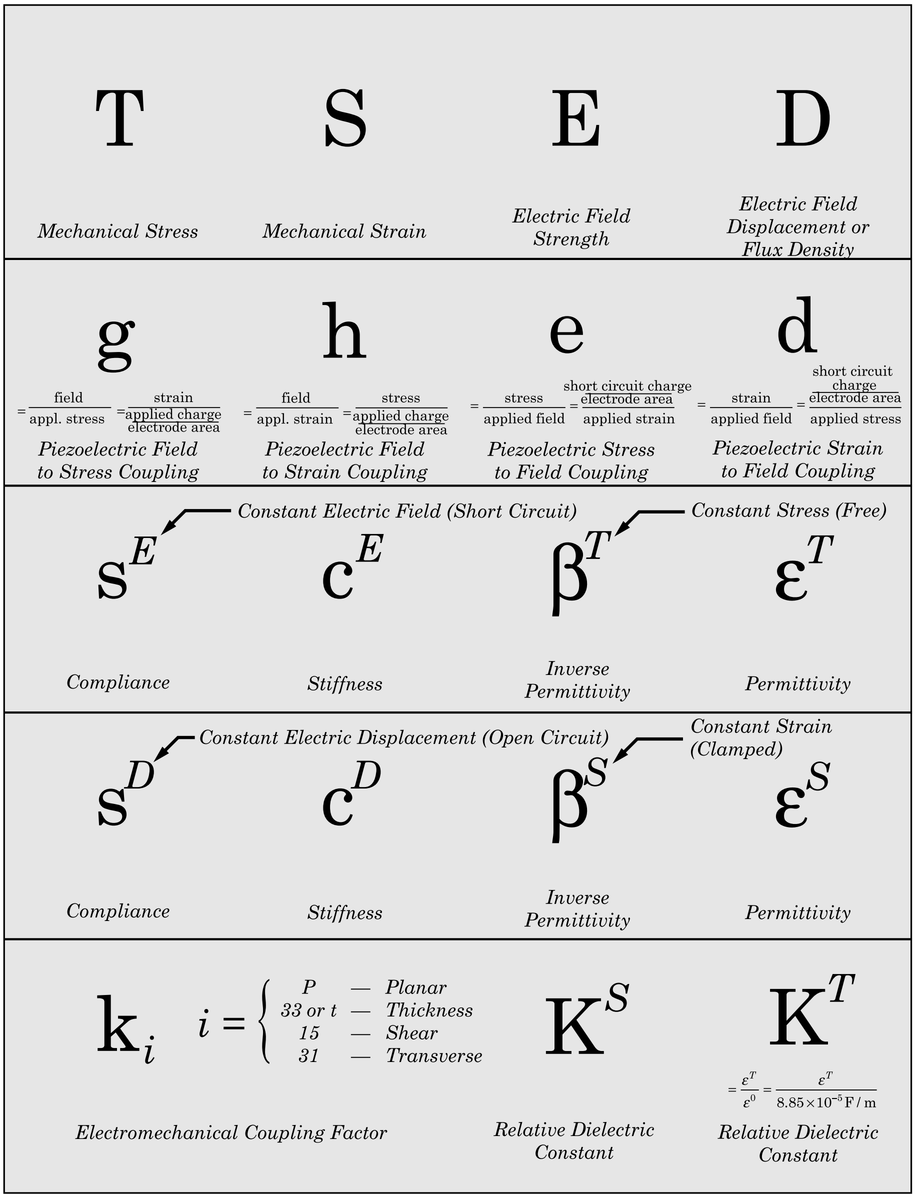
At times, particularly with amorphous materials, the term *electret* is used instead of *piezoelectric* to describe a material; the term was introduced as an electric counterpart to the magnet, defined as all materials that are able to retain at least a quasi-permanent electric polarization within, and perhaps trap charge on the surface (or within in a porous material). Polytetrafluorethylene (PTFE) is a powerful electret material. The critical difference among the terms is that electrets retain polarization in thermodynamic *non*equilibrium, pyroelectric materials retain polarization in equilibrium, ferroelectrics permit the equilibrium polarization to be reversed along the polarization axis, and piezoelectric materials may or may not have any polarization at all.

Basic Methodology

Modeling Linear Piezoelectricity

Equations for structural dynamics within the solid material, along with the standard equations for electrostatics, are sufficient to model most piezoelectric materials and their applications. The full electromagnetic equations are

P



Piezoelectric Materials for Microfluidics, Figure 1 Variables used in linear piezoelectric material analysis

unnecessary since the mechanical motion propagates at $\sim 10^3$ m/s, several orders of magnitude less than the electric field, permitting the so-called *quasistatic* assumption. For the same reason, magnetic fields are typically weak and may be safely ignored. Still, equations to describe the electrical and mechanical behaviour are needed in addition to the constitutive equations for the material.

Using Auld's notation [1], the full tensor form of the linear constitutive equations with the strain and charge displacement as dependent on the stress and applied field may be written as

$$\mathbf{T} = \mathbf{c}^E : \mathbf{S} - \tilde{\mathbf{e}} \cdot \mathbf{E}$$
$$\mathbf{D} = \mathbf{e} : \mathbf{S} + \tilde{\boldsymbol{\varepsilon}}^S \cdot \mathbf{E} \quad (1)$$

where the terms are defined with units in Figs. 1 and 2 (using contracted notation to be described later). The tilde ($\sim$) is a transpose while the single and double dots represent an inner product across one and two dimensions

Piezoelectric Materials for Microfluidics, Figure 2 Description of subscripts used in piezoelectric analysis

of the adjacent tensors, respectively. In piezoelectric materials analysis, the contravariant basis vectors are typically Cartesian, therefore orthonormal and so the covariant basis is not needed. Upon choosing a coordinate system, an indicial notation may be adopted [14],

$$T_{ij} = c^E_{ijkl} S_{kl} + e_{mij} E_m$$

$$D_i = e_{ijk} S_{jk} + \varepsilon^S_{ik} E_k \,, \tag{2}$$

where summation is assumed across repeated subscripts in products of terms, i. e., k and l in $c^E_{ijkl} S_{kl}$; all of the subscripts range from 1 to 3. The strain S_{ij} is given by astrain-displacement relationship $S_{ij} = \frac{1}{2}\left(u_{i,j} + u_{j,i}\right)$ where the comma in the subscript represents a spatial derivative ($u_{i,j} = \partial u_i/\partial x_j$). The momentum equation is $T_{ij,i} + f_i = \rho \ddot{u}_j$ where $\ddot{u} = \partial^2 u_j/\partial t^2$ and f_i represents a body force. The time-dependent electric field, E_i, and charge displacement, D_i, may be related through the polarization and permeability equation $D_i = \varepsilon_0 E_i + P_i$ where P_i is the polarization. A scalar potential φ may be defined to represent the electric field, $E_i = \varphi_{,i}$, while the charge displacement is *spatially* constant along a particular direction, $D_{i,i} = 0$.

A piezoelectric Poynting energy flux akin to those defined for nonpiezoelectric acoustic waves and electromagnetic waves is given by $-\left(T_{ij}\dot{u}_j - \varphi \dot{D}_j\right)$.

In attempting to use these equations to solve problems, a complete and consistent set of electromechanical boundary conditions are needed. Tiersten [13] provides such a derivation, though solution of anything beyond simple problems requires computation. Fortunately, the mechanical and electrical boundary conditions are usually separable; $u_i = u_i^*$ or $n_i T_{ij} = n_i T_{ij}^*$, and $n_i D_i = n_i D_i^*$ or $\varphi = \varphi^*$. The starred terms represent constants, time-varying values, or values defined within another media adjacent to the piezoelectric material. The outward vector normal to the boundary surface is given by n_i.

Even in the most anisotropic of materials substantial symmetry exists in Eq. (2), permitting contraction of the subscripts [4] and giving a simpler form for the constitutive equation;

$$\begin{aligned} T_p &= c_{pq}^E S_q + e_{mp} E_m \\ D_n &= e_{nr} S_r + \varepsilon_{nm}^S E_m \,, \end{aligned} \tag{3}$$

where p, q, and r range from 1 to 6, while m and n range from 1 to 3. There is *not* a one-to-one correspondence between the two representations in Eqs. (2) and (3). For example, the strain S_{ij} is $S_p = 2^{|\mathrm{sgn}(i-j)|}$. For this reason and the confusion that can arise in defining the momentum and strain-displacement equations, one must use care in solving problems with the contracted notation. The value of p in terms of i, j varies notoriously between authors, but the IEEE standard [4] is the most commonly accepted version; here $p = \frac{1}{2}(i+j)(1 - |\mathrm{sgn}(i-j)|) + |\mathrm{sgn}(i-j)|(9-i-j)$ for i, j = 1,2,3; here the vertical bars $|\cdot|$ represent an absolute value while sgn($\cdot$) is the *signum*, zero when x is zero and the sign of x otherwise.

Most solutions found by solving the complete set of piezoelectric material equations are very simple approximations. Computation, typically using finite element analysis software, is often necessary for practical cases. The ability to handle piezoelectric materials in commercially available finite element analysis software varies, though ANSYS (ANSYS Inc., Canonsburg, PA, USA) and COMSOL (COMSOL Inc., Burlington, MA, USA) are two well-known packages with decent implementations. However, a one-dimensional model of the piezoelectric material behavior offers many of the salient features without the complexity.

Piezoelectricity in One Dimension: Transducer Equations

If we assume a longitudinal plane wave propagates along the z-axis—assumed to be a principal axis of the material—the only non-zero displacement will also be along the z- or 3-axis, $u = u(z, t)$ and the strain will be $S_{33} = \partial u / \partial z$. Further, assuming the applied electric field is only along the 3-axis, $E_3 = E$ while $E_1 = E_2 = 0$, we may find the resulting constitutive equations from substitution into Eq. (2), closely following the approach used by Dieulesaint and Royer [3]:

$$\begin{aligned} T_{ij} &= c_{ij33}^E S_{33} + e_{3ij} E_3 \\ D_i &= e_{i33} S_{33} + \varepsilon_{i3}^S E_3 \end{aligned} \,, \tag{4}$$

where i must be equal to j. If we set $i = j = 1$, the motion would be transverse to the applied field (setting i and j to 2 would give the same result), while if $i = j = 3$, the motion is parallel. Taking the latter option with Eq. (4),

$$\begin{aligned} T_{33} &= c_{3333}^E S_{33} + e_{333} E_3 \\ D_3 &= e_{i33} S_{33} + \varepsilon_{33}^S E_3 \end{aligned} \rightarrow \begin{aligned} T &= c^E S + eE \\ D &= eS + \varepsilon^S E \end{aligned} \,, \tag{5}$$

where we discard the subscripts here and subsequently. The electric field, E, may be eliminated from Eq. (5):

$$T = \left(c^E + \frac{e^2}{\varepsilon^S}\right) \frac{\partial u}{\partial z} - \frac{e}{\varepsilon^S} D, \tag{6}$$

giving

$$\frac{\partial T}{\partial t} = \left(c^E + \frac{e^2}{\varepsilon^S}\right) \frac{\partial^2 u}{\partial z \partial t} - \frac{e}{\varepsilon^S} \frac{\partial D}{\partial t} \tag{7}$$

if we take a time derivative. The quantity $\left(c^E + \frac{e^2}{\varepsilon^S}\right) \equiv c^D$; this relation is also true for the tensor form, and indicates the relationship between the constant-field stiffness c^E and the constant field displacment c^D. There are relations between all of the coefficients as described later. The current passing through the piezoelectric element is given by $I = \int \frac{\partial D}{\partial t} dA$ where A is the cross-sectional area perpendicular to the z-axis. Since the wave is planar, $\frac{\partial D}{\partial t}$ is a constant across the cross-sectional area A, so $\frac{\partial D}{\partial t} = I/A$, and Eq. (7) simplifies to

$$\frac{\partial T}{\partial t} = c^D \frac{\partial^2 u}{\partial z \partial t} - \frac{eI}{\varepsilon^S A} \,. \tag{8}$$

Differentiating Eq. (8) with respect to z,

$$\frac{\partial^2 T}{\partial t \partial z} = c^D \frac{\partial^3 u}{\partial z^2 \partial t} = c^D \frac{\partial^2 v}{\partial z^2} \,, \tag{9}$$

noting $I = I(t)$ alone, and $v = \partial u/\partial t$. From the momentum equation, if the body force $f = 0$,

$$\frac{\partial T}{\partial z} = \rho \frac{\partial^2 u}{\partial t^2} \implies \frac{\partial^2 T}{\partial z \partial t} = c^D \frac{\partial^2 v}{\partial z^2} = \rho \frac{\partial^2 v}{\partial t^2}, \tag{10}$$

The latter part of Eq. (10), $c^D \partial^2 v/\partial z^2 = \rho\, \partial^2 v/\partial t^2$, may be solved as a wave equation:

$$v(x,t) = e^{\jmath\omega t}\left(V_1 e^{-\jmath kz} + V_2 e^{\jmath kz}\right). \tag{11}$$

where the circular frequency-wavenumber ratio is related to the material properties by $\omega/k = \sqrt{c^D/\rho}$ and $\jmath = \sqrt{-1}$; the first and second parts of the solution in Eq. (11) are waves traveling in the positive and negative z-directions, respectively.

An acoustic impedance may be defined as $Z = T/v = \sqrt{c^D \rho}$ —the latter term found by substituting Eq. (11) into Eq. (10)—and used to describe the stress wave propagation by substitution of Eq. (11) into Eq. (8) and integrating,

$$T = e^{\jmath\omega t} \left[\frac{kc^D}{\omega}\left(-V_1 e^{-\jmath kz} + V_2 e^{\jmath kz}\right) + \jmath \frac{eI_0}{\omega\varepsilon^S A}\right]. \tag{12}$$

Notice that the wave is *electroelastic*, with a propagating electric field wave in addition to the elastic behavior, and that $I = I_0 e^{\jmath\omega t}$.

The relationship between the mechanical and electrical behavior may now be determined using the stress and particle velocity fields for a piezoelectric element of homogeneous composition, finite thickness t, and constant cross-sectional area A as shown in Fig. 3. Note the polarization of the material indicated by the arrow adjacent to P. The stress T, when expressed on the faces of the piezoelectric element normal to the z-axis, becomes the force delivered by the element:

$$\begin{aligned} F_1 = AT|_{z=z_1} &= e^{\jmath\omega t} \cdot \left[\frac{Akc^D}{\omega}\left(-V_1 e^{-\jmath kz_1} + V_2 e^{\jmath kz_1}\right) + \jmath \frac{eI_0}{\omega\varepsilon^S A}\right], \\ F_2 = AT|_{z=z_2} &= e^{\jmath\omega t} \cdot \left[\frac{Akc^D}{\omega}\left(-V_1 e^{-\jmath kz_2} + V_2 e^{\jmath kz_2}\right) + \jmath \frac{eI_0}{\omega\varepsilon^S A}\right]. \end{aligned} \tag{13}$$

The velocities on the faces $z = z_1$ and $z = z_2$ are given by

$$\begin{aligned} v_1 &= -v|_{z=z_1} \\ &= -e^{\jmath\omega t}\left(V_1 e^{-\jmath kz_1} + V_2 e^{\jmath kz_1}\right), \\ v_2 &= v|_{z=z_2} \\ &= e^{\jmath\omega t}\left(V_1 e^{-\jmath kz_2} + V_2 e^{\jmath kz_2}\right) \end{aligned} \tag{14}$$

Using Eq. (14), it is possible to eliminate V_1 and V_2 from the force Eq. (13);

$$\begin{aligned} V_1 e^{\jmath\omega t} &= -\frac{v_1 e^{\jmath kz_2} + v_2 e^{\jmath kz_1}}{2\jmath \sin kd}, \\ V_2 e^{\jmath\omega t} &= \frac{v_1 e^{-\jmath kz_2} + v_2 e^{-\jmath kz_1}}{2\jmath \sin kd} \end{aligned} \tag{15}$$

where $d = z_2 - z_1$, giving

$$\begin{aligned} F_1 &= \frac{kc^D A}{\jmath\omega}\left[\frac{v_1}{\tan kd} + \frac{v_2}{\sin kd}\right] + \jmath \frac{eI_0}{\omega\varepsilon^S} \\ F_2 &= \frac{kc^D A}{\jmath\omega}\left[\frac{v_1}{\sin kd} + \frac{v_2}{\tan kd}\right] + \jmath \frac{eI_0}{\omega\varepsilon^S} \end{aligned} \tag{16}$$

making use of several trignometric identities.

From the field displacement equation in Eq. (5), the applied voltage V is given by

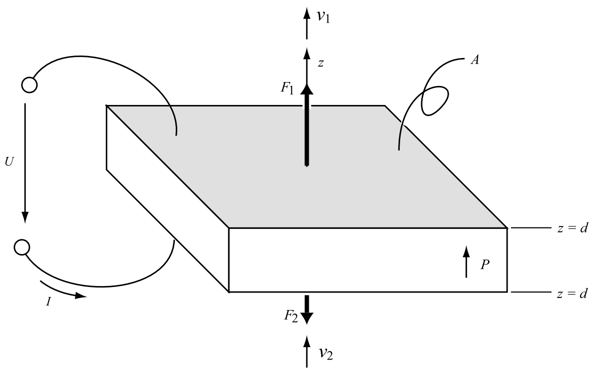
$$\begin{aligned} V &= \int_{z_1}^{z_2} E\, dz \\ &= \int_{z_1}^{z_2}\left(-\frac{e}{\varepsilon^S} S + \frac{D}{\varepsilon^S}\right) dz \\ &= -\frac{e}{\varepsilon^S} u|_{z=z_1}^{z_2} + \frac{1}{\varepsilon^S}\int_{z_1}^{z_2} D\, dz \\ &= \frac{e}{\varepsilon^S}\left(u|_{z=z_1} - u|_{z=z_2}\right) + \frac{I_0 d}{\jmath A\omega\varepsilon^S} \end{aligned} \tag{17}$$

since $D = (1/A)\int I_0\, \mathrm{d}A = I_0/(\jmath\omega A)$, implying $\int_{z_1}^{z_2} D\, \mathrm{d}z = I_0 d/(\jmath\omega A)$. Since $u = -\jmath\omega v$ and the *static* or *shunt capacitance* is $C_0 = \frac{\varepsilon^S A}{d}$,

$$V = -\jmath\left[\frac{\omega e}{\varepsilon^S}(v_1 - v_2) + \frac{I_0}{\omega C_0}\right], \tag{18}$$

forming the third of three equations which may be combined to give a matrix relationship between the input voltage and current and the output forces and velocities on the

P



Piezoelectric Materials for Microfluidics, Figure 3 Schematic of a piezoelectric element to illustrate the process of analysis

faces of the piezoelectric element:

$$\begin{bmatrix} F_1 \\ F_2 \\ V \end{bmatrix} = -\jmath \begin{bmatrix} \frac{\zeta}{\tan kd} & \frac{\zeta}{\sin kd} & -\frac{e}{\omega\varepsilon^S} \\ \frac{\zeta}{\sin kd} & \frac{\zeta}{\tan kd} & -\frac{e}{\omega\varepsilon^S} \\ \frac{\omega e}{\varepsilon^S} & -\frac{\omega e}{\varepsilon^S} & \frac{1}{\omega C_0} \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ I \end{bmatrix} \tag{19}$$

if $\zeta \equiv \frac{kc^D A}{\omega}$ as the mechanical impedance, with units of mass/time. Notice that

- The output forces F_1 and F_2 are linearly proportional to the input current I and piezoelectric stress coefficient e, and inversely proportional to the permittivity ε^S and circular frequency ω.
- The change in velocity across the element $v_1 - v_2$ is linearly proportional to the input voltage V and permittivity ε^S, and inversely proportional to the circular frequency ω and piezoelectric stress coefficient e.

Approximating Transducer Behavior with Equivalent Circuit Equations

From the expression in Eq. (19) most forms of equivalent circuit models of piezoelectric elements may be found. The Van Dyke circuit [14] is the simplest, using discrete electrical components combined to approximate the piezoelectric element's behavior. I tis used to represent the electrical impedance about one resonance of a freely suspended piezoelectric element, using a shunt capacitor in parallel with an inductor, resistor, and capacitor placed in series to represent the *motional* or resonance behavior of the element. A multivibrator Van Dyke model may be formed by adding additional motional legs, each representing another resonance. Since it lacks any explicit treatment of the output force and velocity, it is not especially useful beyond electrical characterization (see Smits' method below). Other circuit models incorporate the mechanical behavior, and the most prevalent of these are the *Mason* [14] and Krimholtz–Leedom–Matthaei [7] (KLM) circuits.

The Mason equivalent circuit may be derived directly from Eq. (19). It is sometimes called a *transmission-line* circuit model since the transcendental terms in the matrix appear in the same way when modeling power transmission lines. Most importantly, the circuit represents more than one resonance with these transcendental terms. Consider first an element that does not have piezoelectricity, implying the piezoelectric stress coefficient $e = 0$. The force-velocity relationships in the nonpiezoelectric element would then be

$$F_i = \frac{v_1 + v_2}{\jmath \sin kd}\zeta + (\jmath\zeta \tan kd/2)\, v_i \tag{20}$$

for $i = 1, 2$. This relates the force and velocity on one face of the nonpiezoelectric element to the other face. For an element that is piezoelectric, $e \neq 0$, and we can use the third equation in Eq. (19) to determine the actual force due to the applied voltage by substitution in the top two equations.

Piezoelectric Coefficient Relations

Typically, a piezoelectric material's properties are measured through a series of experiments on a set of samples, and these measurements give results easily substituted into the matrix representations of the material. Unfortunately, very few of the components within each of the matrices are defined with the measured data, but the remaining data may be calculated using relations between the coefficients. At times, not enough data are provided to do this; for whatever reason, the data set is incomplete. This problem is especially common with piezoelectric material manufacturers. Further complicating the problem, companies sometimes provide redundant data that are inconsistent—calculated results from some of the provided data does not match the rest of the data that are provided.

The simplest relationship between the electrical property tensors is the inverse relationship between the permittivity, $\boldsymbol{\varepsilon}$, and the inverse permittivity, $\boldsymbol{\beta}$. The equations are

$$\boldsymbol{\beta}^S = \boldsymbol{\varepsilon}^{S^{-1}} \quad \text{and} \quad \boldsymbol{\beta}^T = \boldsymbol{\varepsilon}^{T^{-1}}. \tag{21}$$

Other relations transform the matrix representation of the permittivity or inverse permittivity from one set of boundary conditions (either fixed stress or fixed strain) to the other; for the permittivity,

$$\boldsymbol{\varepsilon}^S = \boldsymbol{\varepsilon}^T - \mathbf{d}\,\mathbf{c}^E\tilde{\mathbf{d}} = \boldsymbol{\varepsilon}^T - \mathbf{e}\,\mathbf{s}^E\,\tilde{\mathbf{e}}, \tag{22}$$

and for the inverse permittivity,

$$\boldsymbol{\beta}^S = \boldsymbol{\beta}^T + \mathbf{h}\,\mathbf{s}^D\,\tilde{\mathbf{h}} \;=\; \boldsymbol{\beta}^T + \mathbf{g}\,\mathbf{c}^D\,\tilde{\mathbf{g}} \tag{23}$$

Again, there is a simple inverse relationship between the mechanical coefficient matrices, namely, the stiffness, **c** and the compliance, **s**;

$$\mathbf{c}^E = \mathbf{s}^{E^{-1}} \quad \text{and} \quad \mathbf{c}^D = \mathbf{s}^{D^{-1}}. \tag{24}$$

The boundary conditions on the mechanical property matrices may be changed with the following transformations:

$$\mathbf{c}^D = \mathbf{c}^E + \tilde{\mathbf{e}}\,\boldsymbol{\beta}^S\,\mathbf{e} \;=\; \mathbf{c}^E + \tilde{\mathbf{h}}\,\boldsymbol{\varepsilon}^S\,\mathbf{h}, \tag{25}$$

for the stiffness, and

$$\mathbf{s}^D = \mathbf{s}^E + \tilde{\mathbf{g}}\,\boldsymbol{\varepsilon}^T\,\mathbf{g} \;=\; \mathbf{s}^E + \tilde{\mathbf{d}}\,\boldsymbol{\beta}^T\,\mathbf{d}, \tag{26}$$

for the compliance.

Unfortunately, there are no inverse relations between the piezoelectric coefficients. But, there are a wide collection of equations that describe one piezoelectric quantity in terms of the others. The following is a complete list of these equations:

$$\mathbf{d} = \boldsymbol{\varepsilon}^T\mathbf{g} = \mathbf{e}\mathbf{s}^E, \tag{27}$$

$$\mathbf{g} = \boldsymbol{\beta}^T\mathbf{d} = \mathbf{h}\mathbf{s}^D, \tag{28}$$

$$\mathbf{h} = \boldsymbol{\beta}^S\mathbf{e} = \mathbf{g}\mathbf{c}^D, \tag{29}$$

and

$$\mathbf{e} = \boldsymbol{\varepsilon}^S\,\mathbf{h} \;=\; \mathbf{d}\,\mathbf{c}^E. \tag{30}$$

Through substitution between these equations, many more relations between the variables can be expressed. Written differently, the relations are clearer. In the following equation, the dots within the parentheses represent where the variable at the top of each column would be placed to form the equation for the variable on the left side of each row:

$$\begin{array}{ccccc} & \mathbf{d} & \mathbf{g} & \mathbf{h} & \mathbf{e} \\ \mathbf{d} = & (\cdot) & \boldsymbol{\varepsilon}^T(\cdot) & \boldsymbol{\varepsilon}^T(\cdot)\,\mathbf{s}^E & (\cdot)\,\mathbf{s}^E \\ \mathbf{g} = & \boldsymbol{\beta}^T(\cdot) & (\cdot) & (\cdot)\mathbf{s}^D & \boldsymbol{\beta}^S(\cdot)\,\mathbf{s}^D. \\ \mathbf{h} = & \boldsymbol{\beta}^S(\cdot)\,\mathbf{c}^E & (\cdot)\,\mathbf{c}^D & (\cdot) & \boldsymbol{\beta}^S(\cdot) \\ \mathbf{e} = & (\cdot)\,\mathbf{c}^E & \boldsymbol{\varepsilon}^S(\cdot)\,\mathbf{c}^D & \boldsymbol{\varepsilon}^S(\cdot) & (\cdot) \end{array} \tag{31}$$

Experiment and Use

Physically measuring the coefficients of a piezoelectric material can be pursued in several different ways. Two of the most popular are the IEEE method [14] and Smits' technique [11]. Smits' technique has the advantage in that it requires fewer samples to be made by eliminating the radial resonator shape, especially important when considering the time necessary to make, machine, electrode, pole, and test piezoelectric material. Further, Smits' method uses exact equations in the calculation of the material constants, makes possible the calculation of loss data at the same time, and the electric and mechanical constants are measured at the same frequency unlike the IEEE method.

The technique is iterative, but the iteration process is strongly convergent. To determine all of the coefficients of a given piezoelectric material, four different geometries must be used. Each of these geometries encourage a particular vibration mode shape which reduce the number of material coefficients that are participating in the motion to a reasonable number. Named after the desired mode shape, the *thickness/shear* resonator, the *length expansion* resonator with perpendicular field, the *thickness expansion* plate resonator, and the *length expansion* resonator with parallel field provide different material constants when using Smits' technique on each of them. Convergence criteria and proof are provided in Smits' paper [11], but he claims that convergence to the correct values is usually achieved in eight iterations.

P

Manufacturing Methods

There are numerous ways to manufacture piezoelectric materials, roughly divided into crystal-growth methods for the single crystal media and a collection of techniques for polycrystalline piezoelectric media. The most obvious and troublesome difference in fabricating piezoelectric materials is the presence of lead in lead-based polycrystalline piezoelectrics like PZT; the lead is present in solid solution and tends to leach from the ceramic during sintering unless a source of lead is provided to maintain equilibrium. For all piezoelectric materials that exhibit remnant polarization, charging effects can be a problem during processing, enough to cause arcing and device failure or substrate cracking.

Among the crystal-growth techniques, the Czochralski (CZ) crystal growth technique is most common, particularly for lithium niobate, lithium tantalate, barium gallium orthophosphate (BGO), langasite, There are other techniques, and this is an active area of research. The development of single-crystal high-strain relaxor ferroelectrics like lead manganese niobate-lead titanate (PMN-PT) [8]

using the high-temperature flux technique is a notable example of another approach.

For ceramic materials, there are many approaches available to a researcher for fabrication, including the simple pellet press, tape casting, screen printing, sputter deposition (especially PZT and ZnO), sol-gel techniques for thin films, pulsed-laser deposition, and the hygrothermal technique [10] for deposition of quality PZT onto titanium.

Key Research Findings

During World War II, the discovery of PZT was a fortuitous and remarkable improvement on the state of the art in piezoelectric materials engineering. Since then, modest improvements in performance of piezoelectric materials have been made, with the discovery of single-crystal high-strain PMN-PT materials [8] an important milestone. In the past few years, however, methods for studying and manipulating the structure of ceramics on the scale of the unit cell and lower—the grain structure, the ferroelectric domains, and the structure of the unit cells themselves—have appeared [5]. These techniques are especially well-suited for improving the quality of piezoelectric materials; a recent potassium-sodium niobate/lithium tantalate/lithium antimonate ceramic has a piezoelectric performance equivalent to PZT while eliminating toxic lead [12]. Further, given the need to fabricate ► thin-film devices with features measured in nanometers in conjunction with micro- and nanofluidics, an understanding of the nature of polarization and ferroelectric domain growth in materials compatible with fabrication at these scales is vital. The applications for this technology span many disciplines: nonvolatile memory for computer technology, sensors and sensors for medical and biological diagnostics and actuators and microwave devices for consumer applications [9].

Future Directions for Research

The development of characterization and fabrication methods approaching the unit-cell size of known piezoelectric materials has reenergized the area of piezoelectric materials research in the past few years. By tailoring the structure of piezoelectric materials to maximize the polarizability, strength, and maximum strain, major advances are just beginning to appear. Work on applying the replete knowledge of bulk piezoelectric materials to thin-film materials research remains incomplete, from fabrication of PMN-PT to lead-free ceramics at small scales.

Looking beyond ceramic materials to electrets, polymer and elastomeric piezoelectric materials, and so-called electroactive materials, a wide-open field of research in high-strain piezoelectric materials is appearing. Using the same technology to manipulate the chemical and physical structures of complex ionic or nanotube-imbibed polymers, strains of well over 50 % have been obtained in this new class of material, many examples of which are biocompatible. Improvements in reliability, tolerance of extreme ambient conditions, and modeling are important areas that remain to be considered.

Synonyms

Piezoelectric ink jet; Piezoelectric drop-on-demand; Droplet generator; Piezoelectric micro/nanoliter droplet dispenser

Definition

A fluid-filled chamber that has one or more exit orifices (nozzles) through which the fluid is driven by piezoelectric material causing either a rapid increase in pressure within the fluid or an acceleration of the orifice with respect to the fluid body. Additional fluid is provided through an inlet orifice by external pressure or through a suction mechanism designed into the microdispenser. The fluid, once forced through the nozzles, forms one or more droplets through an instability mechanism – main and perhaps ► satellite droplets – that propagate away from the nozzle, usually at a speed several times the diameter of the droplet per second at speeds up to 10 m/s. The droplets characteristically have a diameter of the same order as the nozzle diameter, usually 1 to 100 μm, and have a volume of several picoliters to nanoliters as they form over a period of about 100 μs. To deliver the fluidic pressure wave required to form the droplets, a pulse or tailored electric drive signal must be provided to the piezoelectric material at a voltage of 5 to 200 V.

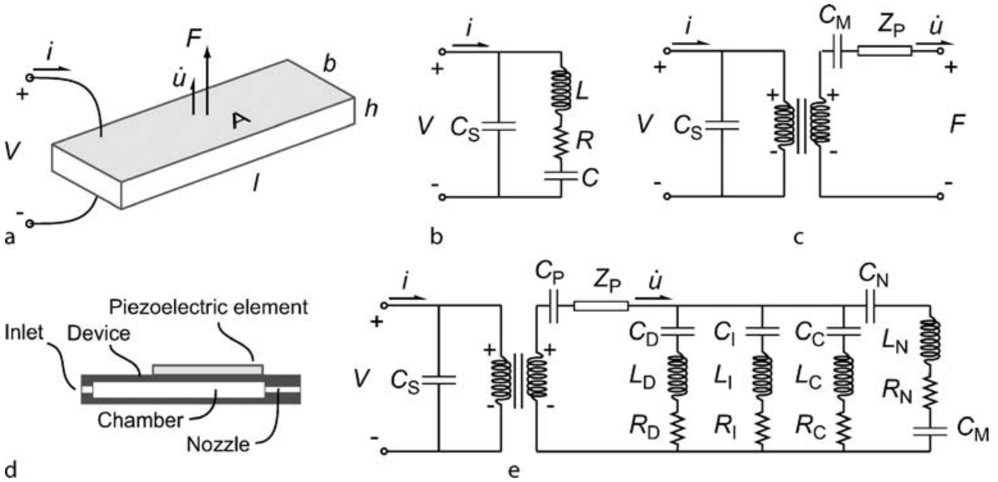
Overview

The ► piezoelectric microdispenser, closely related to ► piezoelectric ink-jet printing, a specific application of the microdispenser traditionally for consumer printing, encompasses three separate operating schemes depending on the intended application. A single ► droplet on demand may be delivered by a dispenser through either impulse excitation of the piezoelectric element or continuous vibration of the nozzle with short-term contact onto an application surface. Continuous droplet generation may be obtained through formation of a long-term Rayleigh instability of the fluid surface at the nozzle. ► Fluid jetting is another method to form fibers or droplets, the latter through subsequent breakup of the jet after it has left the microdispenser's exit nozzle due to Rayleigh or Kelvin–Hemholtz instabilities. Another less common method, ► free-surface atomization, makes use of sessile droplets or relatively large fluid volumes placed on the surface of an ultrasonically vibrating structure which induces breakup through an as-yet poorly understood combination of Rayleigh instability and ► cavitation mechanisms.

Piezoelectric microdispensers have existed since the 1950's, though their use increased dramatically with a need for inexpensive printing from the early 1980's, an application shared with thermoelectric (bubble) microdispensers. Generally, piezoelectric microdispensers offer superior flexibility, simplicity, and scalability compared to other known droplet-forming technologies. However, the use of piezoelectric materials causes problems, particularly in the use of lead zirconate titanate (PZT) and its higher-performance doped variants, which are not generally compatible with standard micromachining processes. As a consequence, scaling down dispensers that make use of PZT is difficult. Though other piezoelectric materials have been used over the years, including quartz, aluminum nitride, and zinc oxide, PZT is favored for its large ► electromechanical coupling and relatively large ► piezoelectric strain coefficients. The generation of a sufficient electric field in the piezoelectric materials, particularly for pulsed drop-on-demand dispensers, can require high voltages not directly compatible with integrated-circuit voltages (5 or 12 V). The placement, diameter, and configuration of the inlet and outlet orifices is critical to obtain suitable droplet formation from input strain pulses along the boundary of the fluid chamber, and microdispenser design is a challenge met through a combination of approximate analytical methods, computational modeling, and experimental development, using many versions of a design to discover the one most suitable for the application. Over the years, different operating schemes have been considered for piezoelectric microdispensers, and current technology [1] is essentially a refinement of the spectrum of configurations available over 25 years ago [2].

Regardless, a majority of the systems operate through direct squeezing of the fluid volume present within the dispenser, and as a consequence the volume of fluid ejected from the dispenser at the nozzle is a linear function of the applied voltage, that is, once the stability of the fluid ► meniscus present across the nozzle is overcome. This is in contrast to the generation of jets and droplets via ► acoustic streaming, which would result in an ejected fluid volume proportional to the square of the applied voltage. Applying low voltage signals to the piezoelectric element will result in a deformation of the meniscus, and as the applied voltage is increased, the deformation grows until the meniscus becomes unstable.

If the capillary wavelength is approximately the same size or larger than the nozzle diameter, the formed droplet diameter will be related to the nozzle diameter, and will increase with an increase in the applied voltage. At a certain threshold voltage, more than one droplet will form from the extension and breakaway of the meniscus. Typically, each of the extra droplets – a ► satellite drop – is smaller in size than the primary droplet, but as the voltage continues to increase, these droplets tend to increase in number and volume. There may be yet another transi-



Piezoelectric Microdispenser, Figure 1 Equivalent circuit modeling of (**a**) planar, thickness-polarized, thickness-vibrating piezoelectric transducers using (**b**) a simple lumped-element Van Dyke model and (**c**) a more complex transmission-line model. A model of a piezoelectric microdispenser (**d**) may be formed by connecting the output terminals to the equivalent circuit model of the remaining components (**e**)

tion to chaotic droplet and stream generation as the voltage continues to increase, and cavitation within the chamber or at the nozzle may also occur.

However, if the capillary wavelength is much less than the diameter of the nozzle, the droplet diameter will instead be related to the capillary wavelength: the droplets form from crest instabilities on the free surface of the fluid. The droplet dimensions for this arrangement follow similar trends as the voltage is increased. Using this technique, it is possible to generate droplets less than 1 μm in diameter through the use of frequencies beyond 10 MHz generated from ▶ surface acoustic wave devices.

This review considers the variety of device designs for piezoelectric microdispensers, methods to model their overall behavior, in addition to the characteristics of atomization mechanisms available for dispensing droplets using piezoelectric materials.

Basic Methodology

Device modeling

Equivalent circuit models have been used to represent piezoelectric material behavior for many years, but are not without limitations. The most common representation for a piezoelectric material, as recommended by the IRE/IEEE standards on piezoelectricity, is the Van Dyke model as described in detail in ▶ piezoelectric materials in microfluidics, with a capacitor, resistor, and inductor in series representing a single resonance, or motional component of the piezoelectric element, all set in parallel with a second capacitor, representing the ▶ shunt capacitance. Additional resonances may be included by placing additional capacitor-resistor-inductor sets in parallel, but therein lies some of the limitations of equivalent circuit modeling: accurate determination of the equivalent circuit components requires either a physical prototype or an accurate computational model to provide the data. Further, assuming the loss mechanisms are isolated to a single resistance in the motional component per resonance may lead to error in predicting both the system response and the resonance frequencies. Computational models using finite-element analysis or the like require similar physical data, and so a physical prototype becomes absolutely necessary in the prediction of microdispenser behavior.

Additional matters to consider in using piezoelectric materials that require a physical prototype include the aging of the piezoelectric material and the temperature change during operation. Over time, the resonance frequency and static capacitance will change in an exponential fashion; most of the aging will occur in the first two months, but the subsequent aging can be important in circuit and resonant chamber design. As an electric field is applied to a piezoelectric element, the element will heat due to electromechanical losses in the material. The heating can be significant for soft piezoelectric materials, and can affect the resonance frequencies and capacitance for both hard and soft piezoelectric media.

Equivalent circuit modeling is a useful and commonly applied analysis approach for designing piezoelectric microdispenser systems. The method has limited accuracy, and the ▶ lumped analysis approach requires the wavelength of the input signal to be larger than any characteristic length within the device. In a microdispenser with an internal cavity, for example, the ▶ Hemholtz resonance

of the orifice, nozzle, and cavity structure should be far higher than the frequency of excitation of the device used to perform the dispensing. The time required to transmit a change in the applied electric field on the piezoelectric element to a change in the meniscus shape at the nozzle is therefore negligible. Using ▶transmission-line models of the piezoelectric element, fluid chamber, and other components in the microdispenser permit analysis without the wavelength limitation [3], and provide the ability to analyze the approximate interaction between multiple resonances in the complete system.

In this situation the coupling coefficient of the piezoelectric material is especially important. Though there are many specific forms of the coupling coefficient, an effective coupling coefficient may be used for a transducer operating near a particular resonance;

$$k_{\text{eff}} = \sqrt{\frac{\text{mechanical energy stored}}{\text{electrical energy input}}} = \sqrt{1 - \frac{f_r^2}{f_a^2}}$$

where f_r is the resonance frequency and f_a is the antiresonance frequency (▶resonance and antiresonance frequency) associated with the vibration mode that dominates the motion induced by the applied voltage signal, if one such mode can be assumed to exist. The mechanical energy stored in the piezoelectric device may then be used to perform work on the fluid meniscus, and in this way the amount of energy applied to form a droplet for a microdispenser as a fraction of the input electrical energy may be estimated once one knows the resonance and antiresonance frequencies. The resonance and antiresonance frequencies are typically near the frequencies of minimum and maximum impedance, respectively, for a specific resonance.

Choosing a thickness-polarized, thickness-vibrating piezoelectric element as an example, we can define the applied voltage V, current i, dimensions b, h, and l, and the output force and velocity F and $\dot{u}$; the cross-sectional area bounded by b and l can be defined by A; here it is assumed this area is electroded on the top and bottom faces of the element and that b and l are much greater than h. Treating it as a collection of discrete circuit elements as shown in Fig. 1b, the Van Dyke circuit, allows the analysis of one resonance within the isolated element. Most piezoelectric materials are capacitive insulators, and the ▶shunt capacitance $C_S = bl/\beta_{33}^S h$ is the constant capacitance present across the element. The additional branch in the circuit represents the specific resonance being analyzed, the motional branch with inductance L, resistance R, and capacitance C. Many impedance analyzers provide this circuit as a means to model the electrical behavior of the piezoelectric element. The coupling coefficient for this specific arrangement is $k_T = \sqrt{h_{33}^S \varepsilon_{33}^S / c_{33}^S}$. Unfortunately, the model only accounts for one resonance and provides no information on the output force F and velocity $\dot{u}$. By treating the element as a transmission-line impedance Z_P as shown in Fig. 1c, one can incorporate an arbitrary number of resonances, where $C_M = -h_{33}^S bl/\beta_{33}^S h$ and $Z_P = \frac{k}{j\omega} \frac{\omega h/c}{\tan(\omega h/c)}$ where $c = \sqrt{c_{33}^D/\rho}$ is the longitudinal wave velocity for an open-circuit element. The resonances appear when $(\tan \omega h/c)$ goes to infinity. The quantities h_{33}, β_{33}, e_{33}, and c_{33} represent the piezoelectric field to strain coupling, permittivity, inverse permittivity, and material stiffness along the thickness direction in this model. The S superscript on these quantities represents constant strain (clamped) values, and the D represents constant electric field displacement (open-circuit) values. By connecting the output of the piezoelectric element, or port, to a microfluidics structure (see Fig. 1d) with nozzle, chamber, inlet and compliant structure, a microdispenser can be formed. A simple representation of this situation can be modeled as a collection of RLC resistance-induction-capacitance branches in Fig. 1e connected to the output of the piezoelectric element represented by the open terminals on the right in Fig. 1c. Note the inclusion of RLC sets for the device, inlet, device, and nozzle, each treating a specific resonance of the component. Transmission-line impedances could be used for these components as well to handle multiple resonances. There is an additional capacitor for the meniscus to take into account the formation of capillary waves; the charging of the capacitor is tied to the appearance of the capillary waves and can suggest whether a droplet will be formed as a consequence of an input signal V. The values of the resistance, inductance and capacitance may be related back to the dimensions and configuration of the microdispenser as shown by Berger and Recktenwald [3].

P

Generation

Modeling of piezoelectric microdispensers provides useful information on the potential for further optimization and insights into the operating mechanism underlying their behavior. However, the reliable formation of stable, monodisperse droplets from a device generally requires a tedious process of trial-and-error design of the driving scheme, fluid, nozzle, chamber, and inlet. Many factors affect the behavior of microdispensers, only a few of which can be incorporated into a mathematical model of the overall device at present. Most of the difficulty is associated with the behavior of the fluid at the exit nozzle. Generally, if the fluid to be dispensed has a low viscosity of about $1-50\,\text{cS}$, is slightly hydrophobic, and does

not contain particles greater than 10% of the diameter of the nozzle, droplet generation becomes a function of the design of the microdispenser alone [4].

The generation of droplets can be divided into three schemes depending on the form of the fluid leaving the orifice. Individual droplets may be formed on demand through discrete signals applied to the microdispenser, droplets may be formed continuously, with a short transition to and from steady droplet formation upon the application and removal of the driving signal from the microdispenser, or jets of fluid can be generated from a microdispenser, which may later break up into droplets as the jet interacts with the environment. A comparison of a characteristic length of the fluid leaving the microdispenser with the nozzle meniscus size provides another way to categorize the generation mechanism of a device. If the characteristic length – droplet diameter, for example – and the meniscus diameter are similar, the characteristic length is typically controlled by the meniscus size. If, however, the characteristic length is significantly smaller than the meniscus size, the characteristic length is controlled instead by the instability mechanism that generated it.

Droplets from Nozzles

Piezoelectric microdispensers that generate droplets of a size defined by the nozzle diameter function either through the interaction of a pressure wave induced in the fluid with the meniscus located at the nozzle, or a rapid acceleration of the meniscus. Either way, a column of fluid is pushed from the nozzle into the surrounding atmosphere. If the column reaches a sufficient length before being drawn back into the nozzle after passage of the pressure wave (πd_{noz} as predicted by Rayleigh [5], where d_{noz} is the nozzle diameter), the free surface will become unstable and pinch off, forming at least one droplet; the droplet diameter he predicted as a consequence of this process, $d_{\text{Rayleigh}} = 1.89 d_{\text{noz}}$, represents an upper bound for the actual droplet diameter. This instability mechanism is not the free-surface Rayleigh instability as commonly understood and described later.

Lee and Lal [6] summarize the work of Lord Rayleigh, Weber, Sterling and many others quite well, and consultation of references in their work provides an introduction to the literature. Rayleigh's result represents the upper bound since it ignores the drag on the column and droplet from the surrounding atmosphere, and subsequent research considered these factors in the analysis. Through the inclusion of a drag model, the droplet size prediction can be made to be more accurate. Consider the column of fluid pushed from the nozzle, and treat the velocity of the column as U, the fluid's density, surface tension, and dynamic viscosity as ρ, σ, and μ, respectively, and the ambient atmosphere's density as $\hat{\rho}$. The ► Weber number of the ambient atmosphere and ► Ohnesorge number of the fluid may then be defined as

$$\hat{\text{We}} = \frac{\hat{\rho} U^2 d_{\text{noz}}}{\sigma} \tag{1}$$

$$\text{and } \text{Z} = \frac{\mu}{\sqrt{\rho \sigma d_{\text{noz}}}} \,. \tag{2}$$

Typically, the Weber and Ohnesorge numbers are dimensionless measures of the relative strength of the inertia to the surface tension in a fluid, and the viscosity to the surface tension of a fluid, respectively. Here the Weber number is modified (with a hat, $\hat{\text{We}}$) to consider the inertia of the surrounding atmosphere in comparison to the surface tension of the fluid extending from the nozzle.

As the fluid column extends from the nozzle, the instability of the free surface is exhibited across several length scales, represented by a collection of solutions of Sterling's equation of motion describing the instability. One of these solutions grows in amplitude more rapidly than the others, which caused Sterling to assume that it would come to dominate the droplet formation process. The selected solution describes the maximum column length that can be obtained without actually causing sufficient surface instability to form a droplet. It further describes the diameter of the droplet formed as a consequence of the instability once the fluid column surpasses that maximum length. The wavelength of the instability as it forms a droplet may be written as $\lambda = \pi d_{\text{noz}} \hat{\vartheta}$, where

$$\hat{\vartheta} = \sqrt{2(1 + 3\text{Z})}\, \text{e}^{-0.035\hat{\text{We}}} \tag{3}$$

represents the reciprocal non-dimensional wavenumber of the most rapidly growing disturbance. For water being ejected from a $10\,\mu\text{m}$ diameter nozzle at $U = 1\,\text{m/s}$, the modified Weber number is $\hat{\text{We}} = 1.81 \times 10^{-4}$, the Ohnesorge number is $\text{Z} = 0.0373$, and so $\hat{\vartheta} = 1.49$ and the wavelength of the instability is $\lambda = 46.9\,\mu\text{m}$. The diameter of the droplet may be taken as one-half the instability wavelength, $d = 23.4\,\mu\text{m}$, because one-half of the wavelength forms the droplet while the other half forms the neck region that separates the droplet from the remaining portion of the fluid column. The fluid's density, surface tension, and dynamic viscosity were treated as $\rho = 1002\,\text{kg/m}^3$, $\sigma = 0.072\,\text{N/m}$, and $\mu = 1.002 \times 10^{-3}\,\text{kg/(m} - \text{s)}$, respectively, and the ambient atmosphere's density was set at $\hat{\rho} = 1.3\,\text{kg/m}^3$.

The formation of additional droplets – ► satellite droplets – in addition to the desired or primary droplet for each

extension of the fluid column induced by an applied pressure wave or acceleration of the nozzle is a troublesome problem with microdispensers. Dong, et al., in a thorough work [7], examined the formation of the primary and satellite droplets and suggested a criteria for avoiding the formation of satellite droplets. As the primary droplet forms from the liquid column extending from the nozzle, a fluid thread may form from the neck. In some cases, this fluid thread may become quite long in comparison to the nozzle diameter, the ratio of which could be defined as l_b/d_{noz}. If the fluid thread length is larger than a limiting value l_b^*, the thread will break up into satellite droplets. There is the possibility that the satellite droplets will merge with the primary droplet if the relative velocities are in the correct direction and large enough to induce recombination.

In any case, the limiting value of the fluid thread length may be written as

$$l_b^* = d_{noz}\left(\frac{(C_2 - C_1)a}{2\alpha^*_{max}} + 1\right), \tag{4}$$

where

$$\alpha^*_{max} = \sqrt{\frac{2\vartheta^2 - 2 + 9Z^2}{4\vartheta^4}} \tag{5}$$

is a term related solely to the nozzle and fluid characteristics; $\vartheta = \sqrt{2(1+3Z)}$ here, an approximation similar to Dong, et al., in line with Sterling's analysis given by Eq. (3) with the omission of the Weber-related air drag term. The nondimensional constants C_1 and C_2 are related to the pinch-off time of the liquid thread from the nozzle and primary droplet, respectively, while a represents another nondimensional constant that relates the speed of the wave disturbance along the periphery of the fluid column to the speed of the retreating fluid column back towards the nozzle after the formation of the droplet and fluid thread stretching between the column and droplet. Dong, et al., claim the product $(C_2 - C_1)a$ is between 0.9 and 1.1 for their experiments with water and glycerin compounds ejected into air. For the water/air system considered in this section, the limiting fluid thread length is $l_b^* = 22.8\,\mu m$ if $(C_2 - C_1)a$ is 0.9. Experimental visualization would be necessary to determine the actual fluid thread length. Dong, et al., suggest that the most effective method to eliminate satellite droplet formation is an increase in the fluid viscosity which would increase the Ohnesorge number and reduce α^*_{max}.

Most piezoelectric microdispensers use the single-droplet nozzle ejection mechanism to form droplets. Through careful design, droplets may be rapidly ejected one after another from the meniscus at frequencies of up to 10 kHz, though there are limitations from refill speed, cavitation, bubble ingestion from the nozzle into the fluid chamber, and satellite droplet formation. Generally the piezoelectric material is not a limitation in droplet delivery speed unless soft PZT is used, which has a larger electromechanical transduction loss and is susceptible to heating at operating frequencies above 1 kHz.

Jetting from nozzles in piezoelectric microdispensers is also possible, usually through a combination of constant applied pressure on the fluid with a lesser modulation of the pressure using the piezoelectric element. The modulation introduces an instability in the jet traveling out of the orifice which is amplified to cause the breakup of the jet into droplets through the interaction of the jet with the ambient environment; this instability mechanism is known as the ▶ Kelvin–Helmholtz instability and requires the jet to be moving at several meters per second in air to cause droplet formation [8]. Secondary breakup of the droplets into finer droplets may then occur via the Rayleigh–Taylor mechanism described later, though the conditions under which this can happen do not typically occur on the scales of most piezoelectric microdispensers.

Droplets from Free Surfaces

It is also possible to dispense microdroplets from free surfaces, either formed on a sessile droplet or along the meniscus formed at a nozzle. In the latter case, the critical difference with the previous section is that the primary droplet formed from the nozzle is much smaller than the diameter of the nozzle, eliminating the direct influence of the nozzle's size on the size of the droplet. The study of the formation of droplets from free surfaces has a long and controversial history, which has been suggested to be due to either capillary wave breakup, cavitation, cavitation-induced capillary waves which subsequently break up to form droplets, or even cavitation-screened capillary wave breakup, where a cavitation layer beneath the surface acts to suppress atomization. It is likely that over the wide range of operating frequencies and configurations available each of these physical mechanisms is possible, but for microdispensing fluids, capillary wave breakup appears to be the most likely mechanism [9]. Even so, the complexity of the analysis and nonlinear behavior [10] should not be underestimated in considering the use of free surfaces.

In 1950 Taylor studied the formation of sinusoidal waves on the free surface of a fluid in air undergoing acceleration perpendicular to the free surface and in the direction of the force of gravity, and almost a century prior Rayleigh considered the formation of similar waves if the denser fluid was placed above the free surface; both illus-

trate a similar mechanism that has come to be described by the Rayleigh–Taylor instability. Curiously, the instability will appear between the interfaces of other phases of media, including even solid-solid interfaces, and the form of the equations that describe the instability will remain essentially the same [11]. The formation of droplets from capillary waves may be described by the Rayleigh–Taylor instability.

Loosely following Piriz, et al. [11], if $\xi = \xi(x, t)$ represents the transverse displacement of the inviscid fluid surface where x is the position coordinate along the fluid interface[1], $\ddot{\xi} = A_T \kappa g \xi$ is the equation of motion of the surface if we ignore surface tension and let the ▶ Atwood number be $A_T = \rho_2 - \rho_1/\rho_2 + \rho_1$, $\rho_2 > \rho_1$, where ρ_2 is the density of the fluid above the interface, and g and κ be the gravitational acceleration ($9.8065\ \mathrm{m/s^2}$) and the perturbation wave number, respectively. This can be integrated to give the exponential growth of the interface amplitude at a rate of $\sqrt{A_T \kappa g}$. The wavenumber is related here to the frequency of the applied oscillation through $\kappa = f/c$, where f is the frequency of the applied oscillation and c is the bulk sound speed within the fluid carrying the acoustic energy to the interface. If we place the dense fluid beneath the interface so that now ρ_2 is the density of the fluid below the interface, and incorporate surface tension, dynamic viscosity, and the acceleration of the fluid interface $\ddot{\psi}(t)$ in the direction of the gravity force g, the equation of the transverse displacement of the surface $\xi(t)$ becomes

$$\ddot{\xi} + \left[A_T \kappa \left(g - \ddot{\psi}(t)\right) + \sigma/\rho_1\right] \xi + 2\frac{\mu_1 + \mu_2}{\rho_1 + \rho_2} \rho_2 \kappa^2 \dot{\xi} = 0 . \tag{6}$$

Lamb recognized in 1932 that the surface tension acts to stabilize disturbances with wavenumbers greater than the cutoff value of

$$\kappa_C = \sqrt{\frac{g(\rho_1 + \rho_2)}{\sigma}} .$$

Above this value, oscillations induced on the free surface are stable, while below this value, it is possible to induce instability on the surface and form droplets. Viscosity cannot prevent the instability, but it does increase the acceleration $\ddot{\psi}(t)$ necessary to cause the instability to appear. In the equation of motion (6), acceleration due to gravity, g, also acts to stabilize the interface. There are different ways to destabilize the surface, the simplest of which is to $\ddot{\psi}(t)$ to a constant value above $g + \sigma/(\rho_1 A_T \kappa)$, forming a gravity wave. Other ways include harmonic excitation with $\ddot{\psi}(t) = \Psi\, e^{i 2\pi F t}$ where $i = \sqrt{-1}$, Ψ is the amplitude, and F is the frequency of excitation. Lang [9] found the diameter of the droplets formed from the free surface closely follows Kelvin's equation for the capillary wavelength,

$$\lambda = \sqrt[3]{\frac{2\pi\sigma}{\rho f^2}} , \tag{7}$$

where f represents the frequency of the most easily excited capillary waves on the free surface. Based on experimental results, it has been shown that the frequency of the capillary waves is one-half the excitation frequency F if it is assumed to be harmonic, and Lang showed that the droplet diameter is 0.34 times the capillary wavelength based on experimental results across a wide range of frequencies:

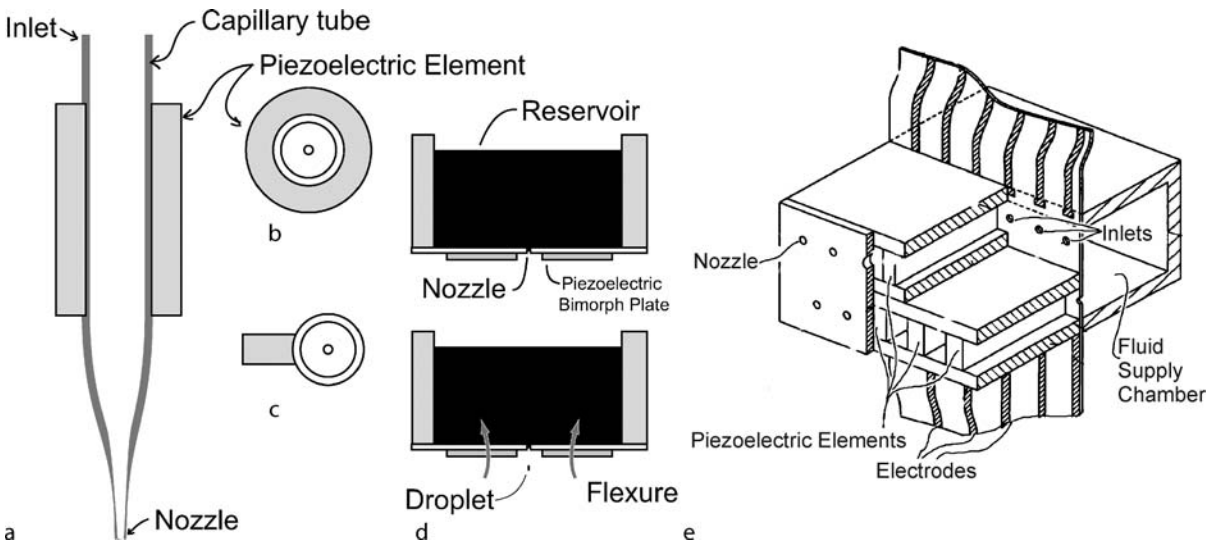
$$d = 0.34 \sqrt[3]{\frac{8\pi\sigma}{\rho f^2}} .$$

Similar to the droplet breakup model in the previous section, many different vibration modes may be excited on the surface by the acceleration $\ddot{\psi}(t)$, but the one represented by λ in equation is assumed to dominate in the generation of droplets. This assumption is valid at powers just sufficient to cause the generation of droplets, but as the amplitude Ψ is further increased, other modes may become large enough to form droplets, increasing the droplet size distribution and the complexity of analysis.

Impulsive excitation may also be used to form droplets from a free surface in this way. Continuous wave excitation can provide very monodisperse distributions of droplets with diameters much less than the characteristic size of the free surface [12], but impulsive excitation has also been used with success in commercial applications by Xerox [4]. A critical part of their success has been in finding ways to form a single droplet from the surface per excitation pulse; typical free surface droplet generators form n droplets where $n = (1/2)\pi(d_{\mathrm{surf}}/\lambda)^2$, d_{surf} is the diameter of the free surface, and λ is the capillary wavelength. Impulsive excitation has the advantage of offering droplet-on-demand operation at the expense of requiring thorough analysis of the free surface to ensure reliable formation of individual droplets.

Jetting from the free surface may also be obtained, and droplets could be formed from these jets through secondary breakup mechanisms if the Ohsenorge number is less than about 0.1 and the Weber number is above 5. The conditions necessary to obtain free-surface jetting from piezoelectric microdispensers are fairly challenging; even though there are examples of high-frequency free-surface

[1] A 2-D assumption is implicit here, as it is throughout most literature on instability calculations.



Piezoelectric Microdispenser, Figure 2 The capillary tube microdispenser, viewed from the side (**a**) and top (**b**), with a variation (**c**) by Lee and Lal [6]. Though almost unrecognizable after years of refinement and adoption of a parallel layout scheme, the Konica-Minolta device (**d**) is also a capillary tube microdispenser

jetting [13], they at present remain little more than curiosities.

Droplet Motion After Ejection

Once formed, most piezoelectrically-dispensed droplets have a drag force proportional to their velocity. In contrast to the viscous drag force on macroscopic objects,

$$F_{\text{Viscous Drag}} = \tfrac{1}{2}\rho C_{\text{d}} A v^2 \,, \tag{8}$$

which scales with the square of the velocity of the object relative to the surrounding fluid, the drag force due to Stokes' law scales linearly with velocity:

$$F_{\text{Stokes}} = 6\pi\eta r v \,; \tag{9}$$

$r, v, A, C_{\text{d}}, \rho$, and η are the drop's radius, velocity, and cross-sectional area, the coefficient of drag, and the surrounding fluid's density and viscosity, respectively. The viscous drag scales inversely to the square of the diameter of the droplet, and so is negligible in air for droplets less than about 25 μm in diameter. The most common figure of merit used in choosing the appropriate drag force is the ► Reynolds number.

For droplets in air less than about 5 μm in diameter, the actual drag force is even lower, since the surrounding air is not a continuum at these scales. Millikan's resistance factor (or ► Cunningham's correction) multiplies the terms on the right-hand side of equation (9) to form the corrected drag force

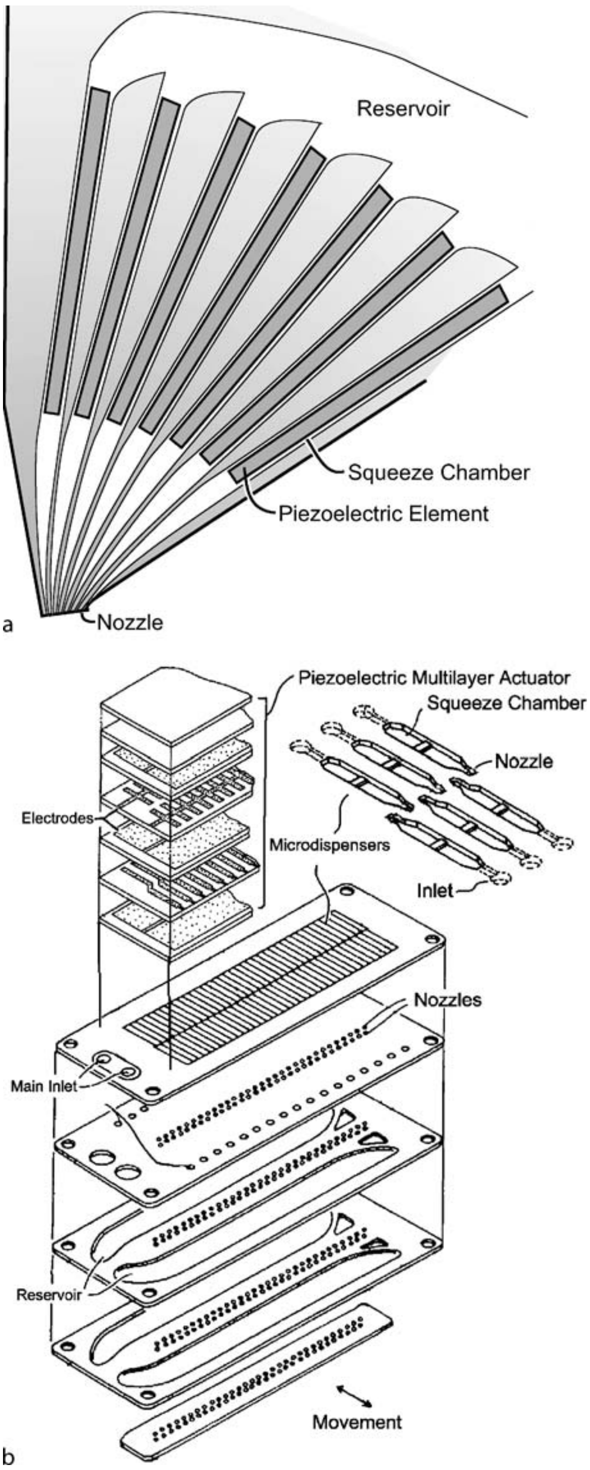
$$F'_{\text{Stokes}} = 6\pi\eta r v\left[1 + \left(\frac{0.130\,\mu\text{m}}{d}\right) \times \left(1.252 + 0.399\,\mathrm{e}^{-1.100 d/0.130\mu\text{m}}\right)\right] \tag{10}$$

A 10 μm diameter droplet moving at 1 m/s in air would have 14.1 pN, 1.72 nN, and 2.00 nN of force on it from viscous drag, uncorrected Stokes' drag, and Cunningham-corrected Stokes' drag, respectively. More importantly, the deceleration of a 10 μm diameter water droplet moving at 1 m/s would be 3820 m/s^2 due to the Cunningham-corrected Stokes drag calculated from

$$\dot{v} = \mathrm{F}'_{\text{Stokes}} \Big/ \left(\frac{\pi}{6}\rho d^3\right) \tag{11}$$

where the term in parentheses is the droplet mass. The deceleration decreases rapidly as the droplet slows; the velocity is an exponential function of time. Under gravity, the terminal velocity can be found by setting the drag force equal to the force of gravity, though this is far less than the ejection velocities for most dispenser systems; for example, a 10 μm droplet has a terminal velocity of only 3 mm/s.

In addition to the correction on the drag force from the noncontiguous surrounding fluid, there is also an randomizing effect on the droplets' motion due to the interaction with the environment: ► Brownian motion. This motion can cause error in droplet placement or



Piezoelectric Microdispenser, Figure 3 The side-shooter design as conceived by Kyser and his associates at Silonics in the 1970's (**a**), and a modern version by Brother (**b**) using planar micromachining technology. Note the dramatic increase in nozzles and the more detailed cross-sectional design. The chamber cross-section in the Kyser design is rectangular

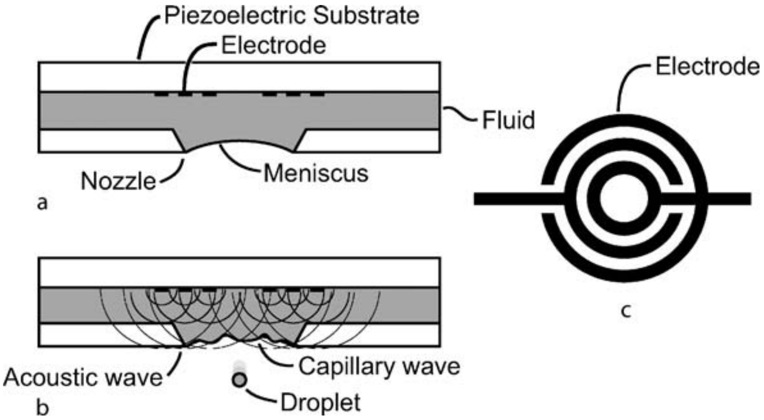
agglomeration of droplets in continuous droplet formation or atomization systems. The mean displacement of a droplet, δ, due to Brownian interaction over time t is a function of the temperature T, ►Boltzmann's constant $k = 1.38065 \times 10^{-23}$ J/K, and drag force, F_{Drag}, which is a choice between Eqs. (8) through (10) suited to the diameter of the droplet under consideration,

$$\delta = \sqrt{\frac{2kTt}{F_{\text{Drag}}}}. \quad (12)$$

For a 5 μm droplet, the average displacement after one second at 20 °C is about 2.66 μm, over half the droplet's radius, using Eq. (10) for the drag force.

Key Research Findings

The devices resulting from the combination of piezoelectric materials and fluidic microstructures to provide dispensing of small amounts of liquid fall into several distinct categories based on their construction. Most common of these is the capillary tube drop-on-demand system, shown in Fig. 2, first developed by Zoltan at Clevite in the early 1970's, and commonly called the Gould or Bogy device. Many variations on this design exist due to the simplicity of the configuration and ease in forming the micropipette tips from which droplets may be dispensed; one can even manufacture their own capillary tube microdispenser for very little cost [4]. Fig. 2a illustrates the typical form of this device, though there have been many variations in the shape of the piezoelectric element used, as shown with the top views in Fig. 2b and c; the latter from Lee and Lal [6], and an interesting variation (see Fig. 2d) from Percin and Khuri-Yakub [14]. Through mass production and microfabrication techniques, the concept has been refined to the form shown in Fig. 2e by Konica-Minolta [15]. The device functions either by squeezing the fluid or accelerating the meniscus through actuation of the piezoelectric material; in most devices both mechanisms are in part responsible for the ejection of droplets. Note even in the Konica-Minolta device the piezoelectric material is a simple shape that may be constructed from machining bulk pieces of PZT. Another design that has been used for microdispensers is the so-called side-shooter design originally developed by Kyser and others in the late 1970's, as illustrated in Fig. 3 in its original configuration, and a modern configuration by Brother making use of planar micromachining technology. A relatively unique version of droplet generation from a free surface is focused acoustic beam ejection by Elrod, et al., at Xerox PARC in the early 1990's [4] illustrated in Fig. 4; it represents a refined version yet lower-frequency ver-



Piezoelectric Microdispenser, Figure 4 Focused acoustic beam ejection technology by Elrod and associates at Xerox PARC. Using a piezoelectric element with electrodes immersed in a thin layer of fluid below a nozzle (**a**), an electrical impulse will induce an acoustic wave that, when interacting with the meniscus, forms a capillary wave that ejects a single droplet (**b**). The form of the electrode (**c**) and the driving signal are two of the features of the design that must be carefully designed

sion of the surface acoustic wave atomizer by Shiokawa et al. [13].

Future Directions for Research

Recently, many new piezoelectric materials have appeared as a consequence of the ability to observe and tailor crystal, polycrystalline, and polymer structures on the nanoscale. Indeed the evolution of high-performance piezoelectric materials like PMN-PT, polypyrrole, IPMC, and other electroactive polymers promise to usher in a new generation of materials that offer advantages over PZT for dispensing applications. Meanwhile, compatibility problems in the fabrication of silicon, PZT, and other standard micromachining materials are being solved, offering the ability to apply PZT in ways not currently possible.

In analysis, most microdispensing work assumes the working fluid is Newtonian, while many fluids that are useful for dispensing in the printing, biomedical and microfabrication industries are strongly non-Newtonian. A return to the fundamentals is in order to revisit the use of these fluids in forming droplets. Improved computational algorithms capable of dealing with the free surfaces and multiple physical phenomena of piezoelectric media, structural deformation, and nonlinear acoustic wave propagation will be central to this effort. As the excitation frequencies and power per unit volume are increased, the incorporation of cavitation models will also be beneficial.

Definition

Structures that regulate the flow of fluids using piezoelectric materials, either composed of active regulation through deflection of a structure to block or allow passage of the fluid using electrically-driven piezoelectric elements, or as a piezoelectric pump in combination with mechanical or passive diffuser valves.

Overview

Active piezoelectric valves offer a unique combination of large closing forces – hundreds to thousands of newtons – against fluid loads and small displacements measured in the tens of microns. Such valves may be designed to close or open upon the application of an electric field to the piezoelectric material, and offer flow rates from nearly arbitrarily low amounts to tens of liters per minute for gases, water, and similar fluids [1]. Given the limited strain, 0.1% or less, available from typical high-performance piezoelectric ceramic materials, a majority of the research and development effort has been in amplifying this strain to permit efficient valving action. Flap or cantilever valves seated across an orifice actuated as a piezoelectric ►bimorph or ►unimorph or ball or grooved structures seated against an orifice and moved using a large-displacement ►linear multilayer piezoelectric actuator is typical of this approach.

Passive piezoelectric valves function in an entirely different manner, though they also make use of piezoelectric bimorph or unimorph structures. Forming one side of a small fluid chamber, or ►Helmholtz cavity, the piezoelectric element can excite chamber resonances when driven at appropriate frequencies via an oscillatory electric field, usually from 10 Hz to 100 kHz depending on the device dimensions and fluid. With two or more orifices connecting the chamber to the outside, fluid may be passed into and out of the chamber; by using orifices with different shapes the flow direction may be regulated without requiring a mechanical blockage of the flow [2] or moving parts. Though these configurations are effective as pumps [3], they also can serve as valves for applications where some leakage is tolerable, or where ball or flap valves may be used as passive mechanical restrictions on the orifices to augment the sealing action and improve performance.

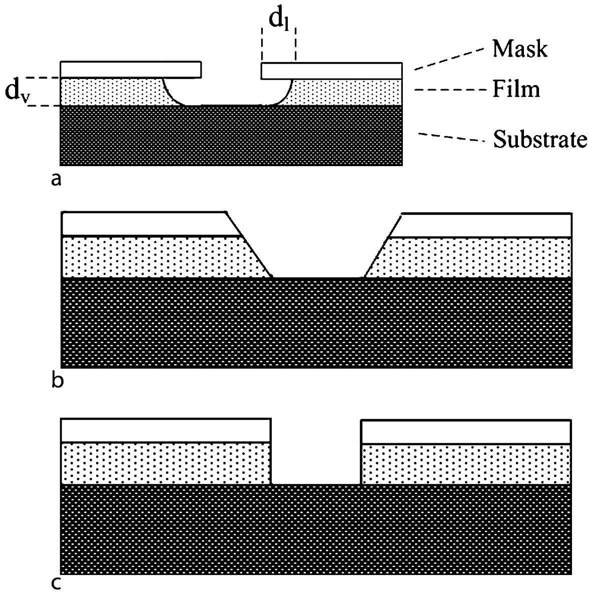
Definition

Plasma etching is the removal process of materials performed using a plasma, which involves the physical, chemical and mixed etching mechanisms. Ion-enhanced ► chemical etching, i. e., a reactive radical dominated etching process with ion assistance, is used in microelectronics and MEMS fabrication. ICP (inductively coupled plasma) etching is the etching process using a high-density plasma generated by the inductive coupling of RF power through an antenna, which is widely used in Si micromachining for high aspect ratio and deep microstructure fabrication. DRIE (deep ► reactive ion etching) is another term for ► ICP etching due to the deep or high aspect ratio microstructure fabricated by RIE principles, which is also called high aspect ratio Si etching or Advanced Silicon Etching (ASE™, a trademark for this technology of the company Surface Technology Systems, STS).

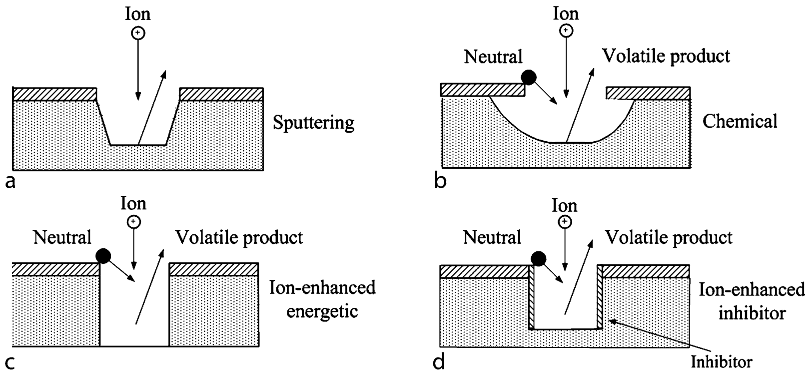
Overview

Etching is used in microelectronic processing and MEMS for pattern transfer during fabrication of devices. The pattern transferred is defined using lithographic techniques by UV exposure on a photoresist through a mask. The photoresist material often loses adhesion in solutions during wet etching processes. Therefore, the pattern dimensions can vary and there can be a lack of control of line width. The process also etches laterally at approximately the vertical rate during wet chemical etching downward into the film and loses the etching directionality. So, wet etching in many semiconductor processes has been replaced by plasma-assisted etching [1, 2]. The driving force of plasma-based etching technology in semiconductor manufacturing is primarily due to the achievement of ► etch directionality and the ability for true pattern transfer from lithographically defined photoresist patterns into underlying layers. The isotropy, undercutting and adhesion problems encountered in wet ► chemical etching can be overcome by anisotropic dry plasma etching; other advantages are its cleanliness and compatibility with automation and vacuum processing technologies. Plasma etching is performed using a discharge gas formed by reactive radicals, ions and electrons to create ion sputtering or reactive radical species that react with surfaces with or without ion assistance to form volatile compounds. The physically sputtered or chemically reacted products evaporate from the surface and proceed to etch the film or substrate. When plasma etching is used, adhesion is no longer a major problem, undercutting can be controlled by varying the plasma chemistry and parameters, and directional or anisotropic profiles can thus be achieved.



Plasma Etching, Figure 1 Three types of plasma etching of a film on a substrate under a mask: (**a**) isotropic etching, (**b**) sloped wall via etch and (**c**) vertical wall (anisotropic etching)

P



Plasma Etching, Figure 2 Four types of reaction mechanism during plasma etching: (**a**) sputter etching, a purely physical process, (**b**) chemical etching, or chemical volatilization, a purely chemical process, (**c**) ion-enhanced energetic, i. e., ion-enhanced chemical, etching, a combination of physical and chemical processes and (**d**) ion-enhanced inhibitor, i. e., inhibitor ion-enhanced chemical, etching, also a combination of physical and chemical processes but that involves an inhibitor that passivates the surfaces that are not exposed to ion bombardment. The last two types (**c**) and (**d**) are related to reactive ion etching (RIE)

The ►etch directionality in plasma etching is due to directed energy input to an etching reaction at a surface and can be accomplished by radical atoms, electrons, photons or ion bombardment of a surface exposed to a chemical etchant. It can be obtained by controlling the interaction between the plasma physical and chemical mechanisms to achieve the required etching profiles using a suitable reactor and adjusting the plasma parameters. Figure 1 shows three types of plasma-etched profiles of films on a substrate under a mask: isotropic etching, sloped wall via etch and vertical wall (anisotropic etching) [2]. Anisotropic etching occurs when it proceeds much faster in one direction as compared to other directions. The directionality, or anisotropy, is defined by the ratio of vertical to lateral etching rate. The degree of isotropic etching, IE, can be defined in Fig. 1a by equation (1) [2]:

$$\mathrm{IE} = \frac{d_\mathrm{l}}{d_\mathrm{v}} = \frac{V_\mathrm{l}}{V_\mathrm{v}} \tag{1}$$

where d_l is the amount of undercutting due to the lateral etching in rate of V_l, and d_v is the amount of the etched thickness of film due to the vertical etching in rate of V_v. So, the degree of anisotropic etching, AE, is correspondingly given by

$$\mathrm{AE} = 1 - \mathrm{IE} = 1 - \frac{V_\mathrm{l}}{V_\mathrm{v}} \tag{2}$$

In addition to isotropic and/or anisotropic behavior, another important etching characteristic is the ►etch selectivity. Etch selectivity between two materials is defined as the ratio between their etching rates at identical plasma conditions. High selectivity is usually preferred in etching and is related to a high etching rate ratio between chemically different materials or between the etched and the underlying layer. In addition, high selectivity is required between the substrate and etching mask or between different substrate materials.

Also, a plasma etching process should satisfy a number of requirements, including [2]:

- high etching anisotropy for the desired etching profile
- high etching selectivity
- high etching rate
- good uniformity of etching across wafer surface
- minimal material damage
- smooth surface without residues after etching.

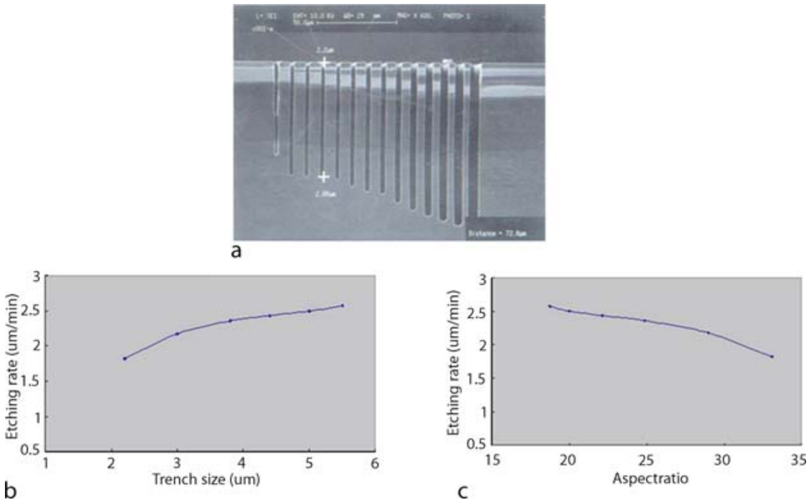
Since plasma etching is related to the reactant activated by input energy to active radicals, electrons and ions, it occurs through the following steps for physical or chemical processing [2]:

1. Active species are formed in the plasma from non-reactive gases.
2. The active species formed in the plasma adsorb on the surface of the substrate and react with the surface to form volatile products.
3. The volatile products with a high vapor pressure leave the surface at the substrate temperature and are pumped out with the effluents of the plasma.

The reaction during plasma etching can be categorized into four types of mechanism [2, 3] as illustrated in Fig. 2.

(a) ►Sputter etching, a purely physical process caused by surface bombardment with high-energy ions, leading to anisotropic etching; also with poor selectivity, high surface damage, and low etching rates.

(b) ►Chemical etching, or chemical volatilization, caused by neutral species generated in the plasma, which react with the etched layer to form volatile compounds.



Plasma Etching, Figure 3 High aspect ratio silicon trenches with nearly vertical sidewall profile obtained by inductively coupled plasma (ICP) etching: (**a**) SEM micrograph, (**b**) RIE lag and (**c**) aspect ratio dependent etching phenomena

Chemical etching is typically isotropic and is characterized by high etch rates, usually good ►etch selectivity, and low substrate damage.

(c) Ion-enhanced energetic, i. e., ion-enhanced chemical, etching, a combination of physical and chemical processes in which the chemical reactions at the surface of the processed sample are enhanced by ion bombardment, enabling one to achieve material selective etch anisotropy.

(d) Ion-enhanced inhibitor, i. e., inhibitor ion enhanced, chemical etching, also a combination of physical and chemical processes but that involves an inhibitor that passivates the surfaces that are not exposed to ion bombardment. It is used in the sidewall passivation process for anisotropic etching.

The last two types, types (c) and (d), are related to ►reactive ion etching (RIE).

Plasma chemical etching is generally performed under low ion bombardment and chemical reactions with plasma species under conditions at which the physical effects are negligible and is usually an isotropic etching process. The pressure used in plasma chemical etching is relatively high, greater than 0.2 torr, often about 1 torr [2, 3]. If a parallel plate reactor is used, the substrates are placed on the ground electrode at a low potential relative to the plasma and the ion bombardment on the substrates is very weak. It is also performed in barrel reactors often with an etch tunnel to limit the discharge to a region outside the substrates. The substrates interact only with plasma species diffusing out of the plasma and are only chemically etched by atoms and radicals. RIE is generally performed in a parallel plate reactor. The substrates are placed on an electrode, which is capacitively coupled to a generator, usually operated 13.56 MHz. The pressure used in RIE is intermediate in the range 0.01 – 0.2 torr. The problem is the increase of ion bombardment damage with increasing substrate bias as high RF power is required for a high etching rate. To solve the surface damage problem in RIE, a high-density low-pressure (HDLP) system has been developed with the substrates placed out of the high density plasma region. The plasma diffuses downstream to the substrates biased at low power for etching. The benefits of HDLP are high etching rate with low damage, high selectivity and good directionality control for high anisotropy. Electron cyclotron resonance (ECR) and ICP are the two popular excitation techniques for generating HDLP plasma. In MEMS, ►ICP etching is a very powerful tool for the fabrication of deep and high aspect ratio (HAR) Si microstructures. It will be discussed in detail in the following sections. The common applications of plasma/reactive ion etching in Si technology are listed in Table 1.

Many materials, e. g., single/poly-Si, SiN_x, SiO_x, glass, metals, slicides and polymers, can be etched by plasma-assisted etching to get anisotropic profiles by changing the etching chemistry. A large variety of fluorine-, chlorine-, bromine- and oxygen-based etching plasmas with a few gas additives, e. g., H_2, Ar and He, are used in the semiconductor industry as listed in Table 2 [1–3]. A process recipe involving the specific etching gas mixture and operation parameters is generally based on a large amount of empirical evidence obtained for a particular etching application rather than a real fundamental understanding of the rele-

vant plasma chemistry. In practice, etching is performed by selecting a typical etching recipe and adjusting using a certain basic understanding of plasma physics and chemistry for process improvement.

Basic Methodology

Anisotropic etching is desired in the fabrication of numerous devices, especially the high aspect ratio microstructure (HARM) for MEMS applications. Many phenomena become pronounced in HARM etching compared to the low aspect ratio features ($< 3:1$), e. g., ►RIE lag, ►aspect ratio dependent etching (ARDE), bowing (barreling) of sidewalls, faceting, profile shape dependence, mirotrenching and notching (footing). These effects result from several mechanisms as follows [4]:

- angular dispersion of ions and neutrals as etchants due to collisions within the plasma sheath;
- ion and etchant transport within the feature onto the sidewalls;
- depletion of the reactant as microscopic loading under conditions of high probability at the surface;
- charging of feature sidewalls, as local charging of substrate surface or microstructure sidewalls deflects ions and prevents them from reaching the bottom surface to be etched;
- etching yield dependency upon the angle of incidence;
- deposition of material produced in the discharge within the feature; and
- redeposition of material released by ion-induced etching and reaction of the neutrals on the sidewalls to form passivation layers.

In order to obtain HARM with plasma-assisted etching, the significant issue is to reduce the lateral etching rate by controlling the ratio of ion flux to radical flux and sidewall passivation through the precursor gases and process parameters. Ion-assisted reactions at the bottom surface lead to highly anisotropic etching with the assistance of sidewall passivation or reduction of lateral reactive radical reactions. The key factors for controlling the microscopic etch uniformity in HAR etching are the selection of reactant chemistry, process conditions and the transport behavior of reactant to the surface and product away from the surface. Kassing and Rangelow [4] reported two main etching strategies for reducing the adverse effects listed above: controlled formation of sidewall-inhibitor films, and ►reactive ion etching at low substrate temperatures. Also, Laermer and Schilp [5] used alternating etching and passivation steps in the Si etching process, known as Bosch patented technology, which has become the main technique in the fabrication of Si HARM devices. Based on the Bosch technology, Surface Technology Systems (STS) continues promoting the *ASE* process in equipment design and process enhancement [6], which has been widely used in many universities, research institutes and industries. Figures 3a–c show an SEM micrograph, feature-dependent ►RIE lag and ARDE phenomena of HAR Si trenches with nearly vertical sidewall profile, respectively [7]. The structure was obtained using the *ASE* process with an STS Multiplex ICP system. The feature sizes of trenches from the fourth to the ninth trenches from the left side are between 2.2 μm and 5.5 μm. The etch rates measured range from 1.82 μm/min to 2.58 μm/min while the aspect ratios obtained are from 33.1 to 18.7. The larger the trench size, the higher the etching rate, and the lower the aspect ratio.

In the following, the STS Multiplex ICP system and *ASE* process, etching performance and chemistry, end point detection and experiment will be introduced for anisotropic plasma etching.

Plasma Etching, Table 1 Common applications of plasma/►reactive ion etching in silicon technology

Application	Etch step
Device formation	Polysilicon/polycide gate; sidewall; storage node; emitter contact
Isolation	Deep trench; shallow trench or recessed oxide
Interconnection	Contacts; metal; interlevel vias
Other	Multilayer resist definition; resist strip; backside strip; planarization

STS Multiplex ICP Etching System and ASE Process

Figure 4 shows schematically the STS Multiplex ►ICP etching system. The source plasma is generated by an inductively coupled coil supplied by a 1 – 3 kW 13.56 MHz RF generator. Another 13.56 MHz generator is used to power the platen electrode which allows independent control of the bias potential of the wafer relative to the source plasma. The wafer temperature is maintained at typically less than 80 °C through temperature-controlled, pressurized helium supplied to the back of the wafer. Wafers may be either mechanically or electrostatically clamped to the platen electrode. Typical base pressures are in the 10^{-7} torr range. The system is equipped with an automatic pressure control valve which can operate in one of two modes. In fixed automatic pressure control (APC) mode, the APC position remains constant and the chamber pressure is a function of gas flows and RF powers. In automatic APC mode, the APC valve adjusts to maintain the chamber pressure at a constant value. The tool has been developed to produce excellent

Plasma Etching, Table 2 Materials and reactive gases used for plasma/reactive ion etching in Si technology

Material	Reactive chemistry	Remarks
Si	CF_4/O_2, SF_6, NF_3 Cl_2, BCl_3, CCl_4 HBr, CF_3Br	Anisotropic; difficult Directional; good SiO_2 selectivity Directional
Oxide	CF_4/H_2, CHF_3/C_2F_6, CHF_3/CO_2	Etching selectivity to Si
Nitride	CF_4, CHF_3, SF_6, NF_3	Characteristics intermediate to Si, SiO_2

repeatability from cycle to cycle for the switched *ASE* process.

The ASE process uses sequentially alternating etching and passivation steps based on Bosch technology for anisotropic Si etching with feature sizes ranging from submicrometer to several millimeters. SF_6 and C_4F_8 are the primary gases used for etching and passivation purposes, respectively. O_2 is generally added to SF_6 in the etching step for prolonging the turbo pump life with reduction of sulfide coating on turbo blades [6] and for reducing the bowing profile at high bias with the enhancement of side-wall passivation [8]. The STS *ASE* procedure is shown schematically in Figures 5a–c: (a) passivation step after one cycle, (b) the etching step after one cycle, i. e., the second etching, and (c) profile after four cycles. Fig. 5d shows a cross-sectional SEM micrograph of the etched holes with scalloped surface due to the cycling *ASE* process. The etching and passivation mechanism can be explained with the following Eqs.:

$$C_4F_8 + e^- \rightarrow CF_x^+ + CF_x^{\cdot} + F^{\cdot} + e^- \quad (3)$$

$$nCF_x^{\cdot} \rightarrow nCF_{2(\mathrm{ads})} \text{ (on surface)} \rightarrow nCF_{2(\mathrm{f})} \quad \text{(polymeric passivation film)} \quad (4)$$

$$SF_6 + e^- \rightarrow S_xF_y^+ + S_xF_y^{\cdot} + F^{\cdot} + e^- \quad (5)$$

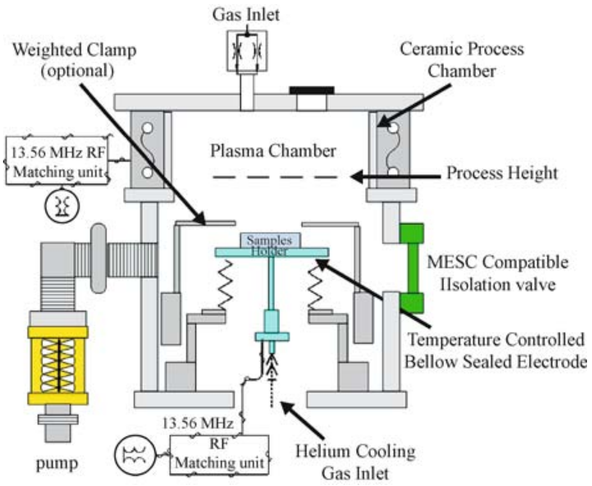
$$nCF_{2(f)} + F^{\cdot} \xrightarrow{\text{ion energy}} CF_{x(\mathrm{ads})} \rightarrow CF_{x(\mathrm{g})} \text{ (passivation film removed)} \quad (6)$$

$$Si + F^{\cdot} \rightarrow Si - nF \quad (7)$$

$$Si - nF \xrightarrow{\text{ion energy}} SiF_{x(\mathrm{ads})} \quad (8)$$

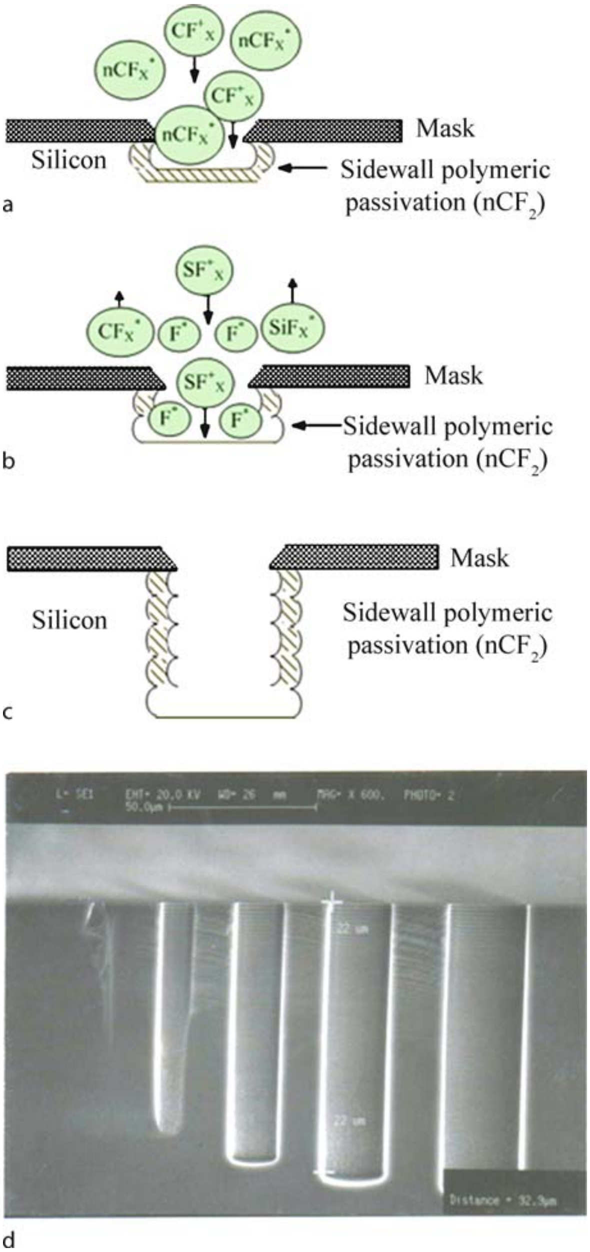
$$SiF_{x(\mathrm{ads})} \rightarrow SiF_{4(\mathrm{g})} \text{ (final Si etched product)} \quad (9)$$

The ionization and dissociation of C_4F_8 plasma deposits a $n\mathrm{CF}_2$ or $(C_xF_y)_n$ polymeric passivating film on the sidewalls and the base of the features (Eqs. (3) and (4)). This polymer, $nCF_{2(f)}$, is preferentially removed from the base of features by the directional ion bombardment energy during the following etching cycle to expose Si for spontaneous etching (Eqs. (5) and (6)). The sidewalls remain protected by the polymer which receives no ion bombardment and subsequently no ►chemical etching either. SF_6 gas supplies fluorine radicals (Eq. (5)) for spontaneous isotropic etching of exposed Si (Eqs. (7)–(9)). Si is mainly etched by the fluorine radicals ($F^{\cdot}$) and assisted by ion bombardment. The ion bombardment only serves to remove polymer from the base of the features. Then the passivation and etching steps are repeated for Si etching. The balance between etching and passivation determines the final process results and can be controlled by a wide variation of process parameters, e. g., the cycle time, flow rate, coil power, platen power and pressure in the etch-



Plasma Etching, Figure 4 Schematic diagram of the STS Multiplex ICP etching system

P



Plasma Etching, Figure 5 Schematic diagram of the STS *ASE* procedure: (**a**) passivation step after one cycle, (**b**) the etching step after one cycle, i. e., the second etching, (**c**) profile after four cycles and (**d**) cross-sectional SEM micrograph of the etched holes with scalloped surface

ing and passivation step, as well as the substrate temperature and the distance from the source plasma. Table 3 lists the typical characteristics of Si etching using the STS *ASE* process [3, 6].

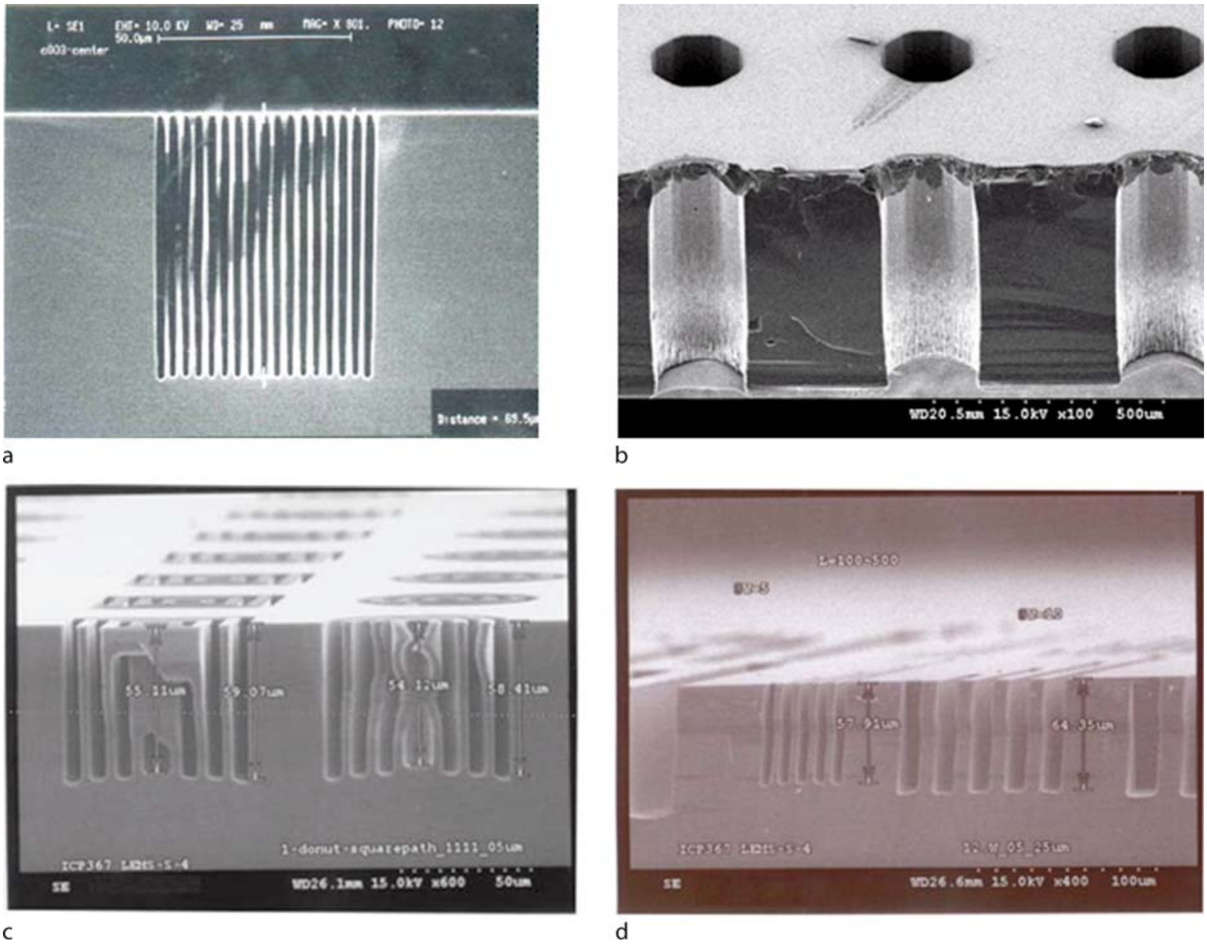
Figures 6a–d show cross-sectional SEM micrographs of etched profiles in different geometry [7]: (a) high aspect ratio microstructure of holes with the same nominal diameter of 1.5 μm and nearly the same etching depth of 69.5 μm, (b) through-wafer etching of 525 μm thick Si holes with a diameter of 200 μm, (c) rectangular and circular donut trenches with constant width or radius of 5 μm and (d) trenches with feature length from 100 to 500 μm at constant width of 5 – 10 μm, respectively. Compared to Fig. 3 with the larger feature width for the deeper etching depth, the larger continuous feature area also leads to the deeper etching depth. The rectangular donut has a larger area than the circular donut, which leads to the higher etching rate or depth. In addition, the etching depth of trenches is nearly the same as the feature width is fixed. But the etching depth varies as the feature width is changed. The feature width of pattern geometry is a dominating factor affecting the ►RIE lag in ►ICP etching while secondary factors are feature area, shape as well as length-to-width ratio. Etching rates of rectangular trenches are sensitive to width while the ring trenches are sensitive to both width and area. Process parameters can be adjusted to control RIE lag magnitude.

Plasma Etching, Table 3 Typical characteristics of Si etching using the STS *ASE* process [3, 6]

SF_6 flow	30 – 150 sccm
C_4F_8 flow	20 – 100 sccm
Etch cycle	5 – 15 s
Deposition cycle	5 – 12 s
Pressure	0.25 – 10 Pa
Temperature	20 – 80 °C
Etching rate	1.5 – 4 μm/min
Aspect ratio	$> 20:1$
Etch depth capability	10 – 800 μm (/through wafer)
Sidewall angle	$90° \pm 2°$
Selectivity to photoresist	50 – 100
Selectivity to SiO_2	100 – 200

Etching Performance and Chemistry

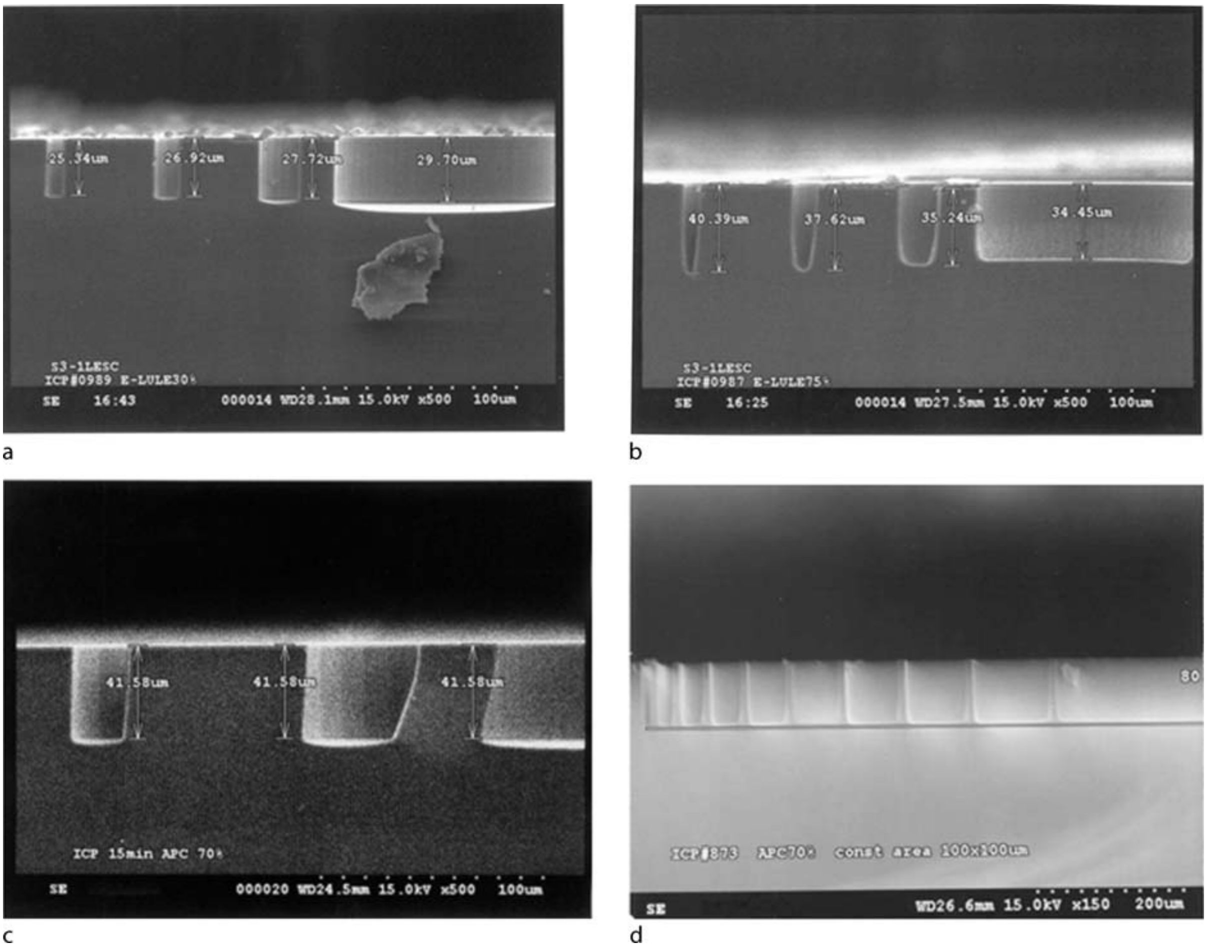
The performance of anisotropy etching can be evaluated from the etching rate, selectivity, profile (directionality), loading effect, ►RIE lag, ►aspect ratio dependent etching (ARDE) and uniformity. Besides the design of equipment configuration, it is related to the process condition, pattern geometry and reactant chemistry. In general, there is a compromise between the etching rate, selectivity and profile. The higher the etching rate, the better the throughput. Etching rate can be enhanced by high plasma power, substrate bias, process pressure and gas flow and a reduced total etching area. But the high ion energy from high bias,



Plasma Etching, Figure 6 Cross-sectional SEM micrographs of: (**a**) high aspect ratio microstructure of holes with the same nominal diameter of 1.5 µm and nearly the same etching depth of 69.5 µm, (**b**) through-wafer etching of 525 µ m thick Si holes with a diameter of 200 µm, (**c**) rectangular and circular donut trenches with constant width or radius of 5 µm and (**d**) trenches with feature length from 100 to 500 µm at constant width of 5 – 10 µm

which is increased with RIE power or independently controlled in ICP, leads to low selectivity and surface damage. Good selectivity, profile control and uniformity are more easily obtained at lower etching rate and shallower depth. In HARM with high etching rate, ►RIE lag and ARDE will become pronounced, thus reducing the uniformity. The larger the feature size, the higher the etching rate while the higher the aspect ratio, the lower the etching rate. Most isotropic etchants, e. g., SF_6 gases, exhibit a loading effect which can be reduced to some extent by using large-volume reactors and be eliminated as etchant loss, i. e., surface reaction instead of diffusion mechanism, dominates the etching behavior [1, 2]. The high ion energy for HAR features will result in bowing of the profile due to the scattering of ions at high pressure, which can be eliminated by enhanced sidewall passivation with the addition of O_2 in the etching gas [8]. In the ASE process [6], the primary dominant factors for etching rate enhancement are increase of etching step time, decrease of passivation step time and decrease of passivation gas flow. Increasing plasma power, etching step pressure and platen power also increase the etching rate. In order to create a vertical sidewall angle, the process parameters may be adjusted by increasing passivation gas flow, substrate bias, substrate temperature and etching gas flow. The reverse adjustment is made to obtain sloped or tapered sidewall profile for a wafer-level package. To reduce the scallop size for a smooth profile, it can be controlled by decreasing the etching step time, increasing the deposition step time and decreasing the etching gas flow. The patented *Parameter Ramping* has been developed to continually adjust the key parameters in ASE to meet the requirements for good profile in HARM etching [6].

As listed in Table 2, a large variety of fluorine-, chlorine-, bromine- and oxygen-based etching plasmas are used in the Si semiconductor industry. Etching of Si can be accom-



Plasma Etching, Figure 7 Cross-sectional SEM micrographs of etched donut trenches with constant area at pressures: (**a**) APC 30% and (**b**) APC 75% for $\pi \times 52.5^2 \mu m^2$, (**c**) APC 70% for $\pi \times 105^2 \mu m^2$ and (**d**) APC 70% for the etched rectangular trenches with constant area of $100 \times 100 \mu m^2$, in which the width varies from 10 to 100 μm while length varies from 1000 to 100 μm

plished using F-, Cl- and Br-based chemistries and the etch products include volatile SiF_4 and $SiCl_4$. The etching of Si can be carried out in a CF_4 or SiF_6 plasma with negligible ion bombardment of the Si substrate [1]. The correspondence of Si etch rate and atomic fluorine emission is as a function of the RF power through the intensity variation of the 704 nm atomic fluorine-related optical emission. Reactive F atoms are directly involved with Si etching. The gas phase density influences the etching rate in simple CF_4 or SiF_6 plasmas and a large undercut occurs in F-based plasma etching due to the isotropic chemical etch. The directionality in SiF_6 plasma etching can be improved by cooling the substrate to a temperature of −110 to −120 °C, as cryogenic etching enables one to get near vertical profiles [1]. The spontaneous ▶chemical etching reactions are suppressed at *cryogenic* temperatures. The etching at the bottom of the feature dominated by ion-assisted etching reactions is not affected at low substrate temperature while the vertical etching rate increases with decreasing temperature, attributed to condensation of etchant for high density. The drawbacks of Si etching at cryogenic temperature are the cracking of resist mask, the increase of surface contamination (leading to black Si) and the increase of equipment complexity. A hard mask, e. g., oxide or metal, is needed in cryogenic etching. Anisotropic Si etching can also be obtained by Cl- and Br-based plasmas at room temperature. Si and oxide passivation are not spontaneously etched by chlorine and bromine atoms for directionality improvement. The size of the halogen relative to the Si atom plays an important role in the spontaneous etching. The spontaneous etching of Si exposed to large Cl atoms is absent compared to small F atoms for isotropic profiles. Although Cl- and Br-based plasma chemistries may achieve highly anisotropic structures, the shallow depth (< 20 μm) obtained limits the potential for MEMS applications. Modified F-based

plasmas for Si etching by sequentially switching etching and passivation gases, i. e., Bosch technology, demonstrate anisotropic etching for high aspect ratio microstructure and through-wafer at room temperature. It has become the main method in Si etching as described in the previous sections.

End Point Detection (EPD)

The most direct need for plasma diagnostic techniques results from the determination of the etch end point for a given process. In addition, plasma diagnostic techniques are used for process monitoring and provide information on the types of species present in a plasma etching, the concentration and the energy content. Laser interferometry (or reflectance) and optical emission spectroscopy (OES) are two commonly used techniques for EPD and require only an appropriate optical window attached to the chamber. They are easily implemented to obtain information about etching plasmas [1].

Laser Interferometry (Reflectance)

This technique measures the laser light reflected from the surface of a wafer being etched. For transparent films, e. g., SiO_2, an oscillation is observed for the reflected laser light intensity due to interference of the reflected light from surfaces of both the film and the substrate. The spacing between adjacent maxima (or minima) is $\delta d = \lambda/2n$, where λ is the wavelength of the laser light and n is the refractive index of the transparent layer. Etch rates can be examined in real time. For nontransparent films, e. g., metals, one measures the change in reflectivity before and after complete removal of the metallic film. For patterned wafers without an etch stop layer, we determine the depth of the etched pattern in situ through the used pattern as a diffraction grating. There are two principal drawbacks of these techniques. Firstly, they usually require a special test site especially as the features being etched, e. g., contact holes into a SiO_2 film, are too small for measurements. Secondly, the obtained EPD information is only for one specific area on the wafer, and not suitable for batch processing.

Optical Emission Spectroscopy (OES)

OES is the most widely used techniques for etch end point detection. The change in emission from a characteristic species is observed as etching of a film is completed. Either the decrease in emission of a suitable etch product species or the increase in etchant species at the end of the etching process is monitored. By measuring the wavelengths and intensities of the emitted spectral lines, one can identify the end points both in research laboratories and in manufacturing for production control. Some important electronic materials and common optical emission lines of etching gases used for EPD are listed in Table 4. The OES technique is limited to the monitoring if light-emitting species and the emission intensities are not always directly related to the concentration of the species in the plasma. The sensitivity of this technique depends on how much etchant is consumed or how much film material is etched per unit. If the etch rate is too slow or the size of the etched pattern too small, e. g., contact hole etching into SiO_2 layers, this technique may not be suitable for EPD.

Experimental

Si wafers are initially cleaned in a solution of $H_2SO_4 : H_2O_2$ at 3 : 1 ratio. Thick resist or thermal oxide SiO_2 are used as ICP etch mask of Si. Standard lithography and RIE are used to transfer the photo mask pattern to thick resist or oxide mask. Si deep etching is performed using the *ASE* process in an STS Multiplex ICP system. The etching and passivation gases are (SF_6 + O_2) and C_4F_8, respectively, and are switched during the process. Three major kinds of patterns of constant length, constant width and constant area with different feature sizes of 2 to 100 μm are divided to understand the dominating factor of geometry for ► RIE lag in ► ICP etching. Process pressure is adjusted by auto pressure control (APC) from 30% to 75% to understand the process pressure effect on RIE lag. The plasma source is generated by a 600 – 800 W 13.56 MHz RF generator

Plasma Etching, Table 4 Common optical emission lines of etching gases used for EPD [1]

Material	Etchant gas	Emitting species	Wavelength (nm)
Si	CF_4/O_2, SF_6	F (etchant)	704
	CF_4/O_2, SF_6	SiF (product)	440, 777
	Cl_2, CCl_4	SiCl (product)	287
SiO_2	CHF_3	CO (product)	484
Si_3N_4	CF_4/O_2	N_2 (product)	337
	CF_4/O_2	CN (product)	387
	CF_4/O_2	N (product)	674
W	CF_4/O_2	F (product)	704
Al	Cl_2, BCl_3, CCl_4	Al (product)	391, 394, 396
	Cl_2, BCl_3, CCl_4	AlCl (product)	261
Resist	O_2	O (etchant)	777, 843
	O_2	CO (product)	484
	O_2	OH (product)	309
	O_2	H (product)	656

and biased by a 10 – 15 W 13.56 MHz RF generator at the platen during the etching step. The wafer is electrostatically clamped and cooled by backside helium flow. Scanning electron microscopy (SEM) is used to examine the etching result after the *ASE* process.

Key Research Findings

Fabrication of Deep/HAR Si Microstructure with High Etching Rate and Good Uniformity to Large Diameter Wafers (Up to 200 mm)

For the requirements of full-scale commercial production, Si DRIE for MEMS applications and advanced packaging are needed for high etching rate with excellent uniformity. The wafer size up to 200 mm is expected and important for high throughput and yield for a cost-effective end product. In mid-2005, STS [6] introduced a new generation of Si etch system, known as Pegasus, for the above purposes. Pegasus employs a revolutionary new de-coupled ICP source design by enhancing both the throughput and the yield to reduce the cost per die.

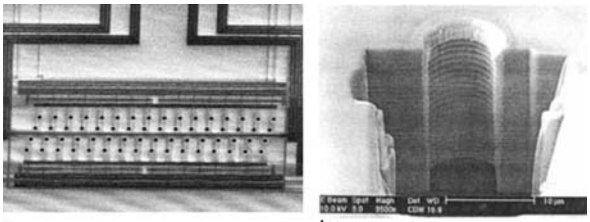
In conventional plasma processing with the *center-high* spatial profile of both ions and neutral radicals, the density profile variation of the ions will usually be more extreme than for the radicals, leading to large uniformity deviation. Two new de-coupled plasma sources are patented technologies of STS for ramping and SOI modules. They offer the following benefits:

- To reduce the volume of the plasma source for more efficient breakdown of the precursor gas due to the higher power density delivered from the RF power supply.
- To adjust the geometry and volume of the plasma source region to match the silicon's loading characteristics for the ions and neutral radicals diffusing down to the wafer with the desired profiles to obtain high etch uniformity.
- To alter the balance between numbers of ions and neutral radicals reaching the wafer to control selectivity to mask and/or ion damage to feature profiles.

With the appropriate magnitude of parameter values during an etching and precise control of notching at the surface of Si to the insulator, a high etch rate with good uniformity can be achieved. For example, Si etch rates of more than 30 μm/min can be achieved at a more realistic exposed area of around 10% and exceeding 50 μm/min for a 1% exposed area have been observed using the Pegasus source with the *ASE* process. Yield is optimized by improving absolute etch depth uniformity and by reducing trench tilting artifacts observed with conventional ICP plasma sources. The very high etch rate uniformity and feature profile control is relevant for up to 200 mm wafers.

Inverse RIE Lag and Lag Elimination

A ► RIE lag phenomenon occurs in many patterns and becomes more severe at smaller feature width and higher etching depth. In general, the smaller the feature size, the



a b

Plasma Etching, Figure 9 SEM micrographs of (**a**) plane-view nozzle array with circuit layout and (**b**) cross-section of one nozzle for a high-resolution inkjet head application

lower the etching rate and the more obvious is the RIE lag. Experimental results reveal that the primary dominating factor is feature width and a secondary factor is feature area together with length-to-width ratio. Chung [7] reported the effect of geometrical pattern and process parameters on the transition between RIE lag, inverse RIE lag and eliminated RIE lag. Figures 7a and b show SEM micrographs of etching donut trench structure with constant area of $\pi \times 52.5^2 \mu m^2$ at a pressure of APC 30% (20 mtorr (etching)/10 mtorr (passivation)) and APC 75% (54 mtorr (etch)/32 mtorr (passivation)) for 30 min, respectively. The RIE lag exists at low pressure of APC 30% while an inverse RIE lag appears at high pressure of APC 75%. The inverse RIE lag means the higher etching rate occurs at smaller feature width. It implies that other mechanism exists in Si DRIE with respect to previous reports [4, 9]. The possible new reaction mechanism is C_xF_y radical dissociated from C_4F_8 passivation gas playing an important role to affect the etching rate ratio of different feature sizes. The formation and removal of C_4F_8 passivation film impedes the increase of etching depth while the arrival of SF_6 etching gas enhances the etching processing. As the pressure increases, the increasing C_xF_y radical density for the formation of passivation film and reducing S_xF_y ion density to remove passivation film at the bottom will delay longer the start of etching of Si surface at the bottom in a large feature than a small one. The etching rate is enhanced more for small width than for large width. This will lead to the reduction of RIE lag. If the pressure is much higher, inverse RIE lag occurs. Since RIE lag and inverse RIE lag have been achieved, we could find an optimum condition at a pressure of APC 70% to obtain the RIE lag-eliminated feature as shown in Fig. 7c and d, respectively, for donut trenches with constant area of $\pi \times 105^2 \mu m^2$ and rectangular trenches with constant area of $100 \times 100\ \mu m^2$.

SOI MEMS and Other Microstructures Using Pure Isotropic Etching or in Combination with Anisotropic Etching

Silicon-on-insulator (SOI) MEMS has the advantages of RIE lag elimination and enabling multilevel HARM for optical MEMS applications. Milanovic [10] reported multilevel beam SOI–MEMS fabrication and its applications to optical scanners. The multilevel beam was fabricated by 4-mask DRIE: two for front-side and two for back-side etching to high degree of freedom motion (both upward and downward vertical pistoning motions as well as bi-directional rotation). One problem of notching or footing will occur at the bottom of Si on oxide due to charging effect. Docker et al. [11] used the notching effect as lateral etching for the fabrication of suspended MEMS structure in one dry single-step process. Mita et al. [12] used DRIE SOI and contour lithography methods for fabrication of nanometer-to millimeter-scale coexisting microsystems. Marty et al. [13] reported that three-dimensional Si structure for Fresnel lens or staircase structure can be fabricated by pure SF_6 isotropic etching in RIE lag condition. In a combination of isotropic and anisotropic etching, a single crystal reactive etching and metalization (SCREAM)-like process has been demonstrated for a suspended Si MEMS structure without the need for an SOI wafer. Other multistep structures from isotropic and anisotropic etching can be fabricated for applications in the photonics and microfluids.

P

ICP LIGA-Like Process and Nanoimprinting

ICP LIGA-like process is a process to duplicate deep polymer microstructure for applications in microfluid or micro-devices at low cost and easy fabrication compared to the X-ray LIGA process. Figures 8a–c show SEM micrographs of an electroplated Ni mold, hot embossed poly(methyl methacrylate) (PMMA) replica and PMMA adhesive bonding, respectively, in ICP LIGA after Si DRIE process. The PMMA channel width is about 300 μm and the depth nearly 285 μm with vertical sidewall profile without any distortion. It indicates that a cheap plastic chip can be obtained for microfluidic applications using the ICP LIGA process. With the development of nanoimprinting, it requires Si or quartz stamps in a nanoscale pattern for nanolithography pattern transfer. ►ICP etching has been used for the manufacture of Si stamps used to pattern the resist in hot embossing or in different etching chemistry for the transparent quartz stamps used in UV light curing the resist [6].

Examples of Applications

Many examples of applications have been reported in the STS Innovations magazine issues 1 – 3 since April 2006 [6]. They include MEMS inertial and pressure sensors, Si springs for luxury wristwatch components, optical switches and resonators for communication, microphones for portable electronic equipment, advanced packages (system-in-package), and inkjet channels and nozzles. For example, Figs. 9a and b show SEM micrographs of a plane-view nozzle array with circuit layout and cross-section of one nozzle, respectively, for high-resolution inkjet head application. It combines the fabrication of backside wet anisotropic etching and front-side dry DRIE etching. The nominal nozzle diameter is 10 μm with vertical profile as well as scallop rings due to the *ASE* switching process. The emerging nanoscale etching has been applied in photonic crystals, magnetic nanostructures (magnetoresistive random access memory, MRAM), high-Q MEMS resonators, sub-micrometer pilar array or HAR structures made of Si for bioanalysis and lab-on-a-chip, microchannels and inkwells for dip pen nanolithography, and Si or quartz stamps for nanoimprint lithography.

Future Directions for Research

ICP is an important technology for micro- and nanoscale patterning processes. High etch rate, high aspect ratio and anisotropic, good profile control, high uniformity and RIE lag elimination are important issues in the development of MEMS and nanotechnology devices. In MEMS fabrication, it is steadily moving from the development and pilot stages to full-scale production. In nanofabrication, it is promising to enable nanometer–micrometer–millimeter multiscale structures in device design and application. In combining isotropic and anisotropic etching, different promising HARM or three-dimensional structures may be realized for the application of Si-MEMS or SOI MEMS. ICP technology will be required in many applications including MEMS inertial and pressure sensors, optical switches and resonators for communication, inkjet channels and nozzles for high-resolution printheads, microphones for portable electronic equipment, advanced packages, and so on.

Definition

Gas plasma, a fourth state of matter, is a neutral composition of ions, electrons, radicals, and photons that is synthesized by applying energy to a gas at atmospheric pressure or within a vacuum. Gas plasma can be used to enhance the functionality of microdevices for various biological and chemical applications. The effects of plasma in microchannels are regulated by parameters such as the type of gas, power intensity, chamber pressure and duration of the treatment.

Overview

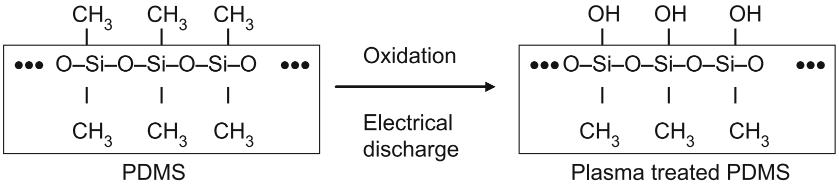
Microchannels that range in diameter from tens to hundreds of microns have emerged as potentially powerful tools for a variety of biomedical applications. They can be used to minimize sample volume and reduce costs, as well as to increase throughput and analysis sensitivity. Since microfluidic devices operate at small length scales, their functionality is greatly dependent on their surface properties, which vary depending on the type of material that is used to fabricate the channel and the subsequent surface modifications.

Microchannels have traditionally been fabricated from commonly used materials from the semiconductor industry, such as silicon. Silicon offers many advantages for microchannel fabrication, such as standardized fabrication procedures and easy integration with electronics. Despite these merits, silicon is opaque and brittle and cannot be used for fabricating transparent microfluidic devices that require light based sensors. To overcome these difficulties, glass microfluidic channels have also been developed, however, the fabrication of these devices, similar to those of silicon microchannels is time consuming, expensive and requires the use of a clean room facility. As a result, polymeric microchannels have recently emerged as potentially valuable alternatives. Polymers that have previously been investigated for microchannels include: polycarbonate (PC), polystyrene (PS), poly(dimethylsiloxane) (PDMS) and poly(methylmethacrylate) (PMMA). One of the main advantages of using polymeric materials to make microchannels is that they can be fabricated from soft lithographic techniques such as micromolding. Furthermore, the ability to tailor the mechanical and optical properties of polymers can be used to fabricate microchannels with a wide range of properties. Despite the great advancements in the materials used to fabricate microchannels, the surface properties of these channels often require additional modifications based on the specific needs of the device. Thus, approaches to activate microchannel surfaces have been of great interest in fully realizing the potential of these techniques.

During the 1920s and 1930s, Dr. Irving Langmuir proposed the term *plasma* while he was studying the physical properties of gases and the balance of charges between ions and electrons. Commonly considered as the fourth state of matter, basic gas phase plasma contains a neutrally charged mixture of negative and positive ions, photons, electrons and radicals that are produced by applying energy to a gas at low pressure (from 10^{-6} to 10^{-4} bar). In this process, the temperature of plasma electrons is extremely high (on the order of 10^4 K), however, the plasma gas remains close to ambient temperature. This is because plasma components found at higher temperatures (such as the sun) are made of equilibrium (thermal) plasmas while low-pressure gas plasmas are non-equilibrium (non-thermal) type. Plasma is formed by the exposure of free electrons to an external energy source that increases the kinetic energy, resulting in the formation of radicals and ions. These excited molecules then form photoemissions, ions and free radicals due to a loss of excess energy from the plasma. The energy released from these chemical species is capable of breaking covalent bonds and altering the surface chemistry of many materials.

The bombardment of a surface with reactive chemical species can be used to drastically change its surface properties and create functional surfaces within microchannels. Traditionally, corona discharge and oxygen plasma treatment have been used. Corona discharge is the formation of sparks at the tip of a wire created by electromagnetic fields that result in the ionization of nearby molecules at low temperatures and pressures. Corona discharge can be used to oxidize a surface near the tip of the wire. Although widely used in various industrial processes, a negative aspect of corona discharge is its tendency to modify the surface non-uniformly. To overcome this limitation, surface plasma treatment can be used. Plasma treatment of microchannel surfaces is particularly attractive, as it does not require the tedious placement of a wire inside microscale channels. In addition, plasma treatment of a surface is faster and more reproducible compared to corona discharge.

The reaction between the plasma and a surface is highly complex and comprised of numerous and simultaneous chemical reactions [1]. Upon the initial application of energy, the gas molecules, such as oxygen, are converted to various unstable intermediates that can react with the surface. Some of the initiation mechanisms between plasma



Plasma in Microchannel, Figure 1 Schematic of the oxygen plasma treatment of a PDMS substrate

(which may include oxygen radicals) with a surface are shown below:

$$RH + O\bullet \;\rightarrow\; \begin{matrix} R\bullet + H\bullet + O_2 \\ R_1\bullet + R_2O\bullet \\ R\bullet + OH\bullet \end{matrix}$$

These radical species then induce chain scission, radical transfer, oxidation and disproportionation to generate functional surface groups such as hydroxyl and carboxyl moieties (Fig. 1). For some materials, such as PDMS, these activated surfaces can be bonded to fabricate channels, as shown in Fig. 2. Plasma treatment of microchannels can also be used to control surface properties by incorporating reactive molecules or by increasing the hydrophilicity of the surfaces that eases the flow of fluids and minimizes the formation of bubbles.

In addition to adding surface functional groups, plasma can be used to remove organic contaminants and sterilize surfaces. In this process, plasma radicals break the covalent bonds and oxidize the surface contaminants, which are then cleared by the vacuum. Here, we will outline the basic methodology of gas plasma modification in microchannels, including theory, experimental methods, pertinent process parameters and characterization methods. Additionally, key research findings will be discussed.

Basic Methodology

In this section we will outline the basic methodology of the plasma treatment process. First, the theory behind plasma treatment will be presented. Following this, experimental protocol outlining the treatment process, pertinent parameters and their relevance will be discussed. Finally, surface analysis methods for plasma treated surfaces will be described, such as X-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM), and contact angle measuring tools.

Theory

To establish an analytical framework of plasma formation and initiation, thermodynamic models have been developed. For example, for low pressures and high frequencies that generate plasma gases at ambient temperatures the power required to generate plasma can be determined from molecular collision analysis. In this model, the reactive species within the plasma process are created from inelastic collisions between electrons and ground-state atoms [2], where electrons have energy, u, given by

$$u = \frac{(mw^2)}{2}$$

where w is the electron velocity and m is the electron mass. The excitation rate coefficient, C_j, of a particular species is then given by

$$C_j = \left(\frac{2}{m}\right)^{\frac{1}{2}} \int_0^\infty \sigma_j(u) F_0(u) u du$$

where $\sigma_j(u)$ is the particular process cross-section and F_0 is the electron energy distribution function. Nearly all processes at this level that are important possess energy threshold, u_j, where

$$\sigma_j(u) \equiv 0, \quad u \le u_j$$

There is also a dependence of the number density $\dot{n}_j$ of species j produced per second in the plasma from ground state molecules (of number density Ncm^{-3}) on the electron density n, where

$$\dot{n}_j = C_j N n.$$

The applied electromagnetic field (where frequency $f = \omega/2\pi$) and the plasma has a power balance that is expressed by

$$P_a = \xi n V,$$

where the power absorbed is P_a, the volume of plasma is V and the average power absorbed per electron is ξ. ξ also refers to the power necessary to sustain an electron–ion pair in the plasma.

Experimental

To plasma treat a surface, samples are initially placed within a plasma vacuum chamber. Gas plasma is then generated using various energy sources such as alternating current (AC), radio frequencies (RF) or microwaves (MW) (Fig. 3). For example, in apparatuses that use RF, two electrodes apply energy in the form of magnetic and electric fields to a gas at low pressure (∼ 266 – 800 mbar) inside the vacuum. The application of appropriate amount of energy to the gas discharge results in the formation of a neutral gas plasma. During this process, a characteristic glow is emitted from the apparatus indicating the plasma state of the gas.

Parameters

There are a number of parameters that affect the surface modification during the plasma treatment process. These parameters can be separated into internal process parameters, which are dependent on the plasma, and external process parameters, which are external to the plasma but within the system. Examples of internal parameters include the type and the degree of dissociation of the gas and the residence time of the active species in the vacuum chamber. Examples of the external parameters include, but are not limited to, the substrate material, amount of time that the material is exposed to the plasma, gas pressure, energy frequency, power and substrate temperature. It is important to note that the internal parameters of the plasma are indirectly controlled by the external process parameters. Figure 4 depicts the relations among several parameters. This entry will discuss how the type of gas, exposure time, gas pressure and power affect the plasma initiated surface modifications and the resulting bonding strengths of substrates.

The type of gas is a key parameter in any plasma surface modification process. Plasma treatments using inert gases, such as argon, have been shown to increase the hydrophobicity of oxygen-containing polymers without adding detectable chemical species to the surface. These properties are a result of the degradation and rearrangement of molecules on the surface of the polymer. Degradation is caused by an increase in the kinetic energy in the plasma treatment chamber when inert plasmas are present. This increased energy breaks molecular bonds on the surface, which result in the degradation of the impurities on the surface of the substrate. Rearrangement of chemical species occurs as a result of cracks that are introduced onto the surface of the substrate. These cracks enable molecules from beneath to rearrange with molecules present on the surface. This is indicated by a decrease in the oxygen/carbon ratio within the treated surface, possibly resulting from loss of CO or CO_2. In contrast, plasma treatment by using reactive gases results in the direct conjugation of the reactive molecule on the surface. For example, in the case of oxygen plasmas, hydroxyl and carboxyl functional groups are formed on the surface and can react with each other between two treated surfaces through a dehydration reaction to produce covalent linkages that result in bonding of two substrates.

The exposure time of the plasma to the surface can greatly affect its surface properties. For example, the bonding of PDMS to PDMS for the fabrication of microchannels has been shown to be time dependent (Table 1). If the substrate is not adequately treated with plasma then there will not be enough functional groups present to achieve bonding. If the substrate exposure exceeds an optimal time. Then there will be excessive oxidation of the PDMS surface and the formation, which leads to the formation of a brittle layer of silica. Thus, prolonged plasma treatment results in polymer reorganization on the substrate surface that causes decreased bonding strength due to induced hydrophobic properties.

It has also been determined that the internal pressure of the treatment chamber has a significant impact on the surface properties of treated substrates (Table 1). When the internal pressure is high, the mean free distance between molecular collisions within the plasma is significantly reduced. For example, for PDMS substrates the upper pressure region is characterized as greater than approximately 0.1 mbar. The molecules within this condensed plasma increasingly interact with the polymer surface molecules, resulting in increased bonding strength. Conversely, if the pressure within the chamber is too low (i. e. less than approximately 0.1 mbar) there is reduced interaction between the plasma and the surface and the bond strength is not optimized.

Finally, power variation has also been shown to affect the surface properties of the substrate (Table 1). In the case of PDMS at low power settings, plasma electron speeds are reduced and there is less interaction between the radicals in the plasma and the substrate. This minimizes the formation of functional groups on the surface. Conversely, extreme voltages result in reduced bonding strengths because of the formation of Si–O–Si groups on the PDMS surface. The dissociation energy of these specific bonds is larger than the dissociation energy of the Si–C bonds in the backbone of the polymer, therefore causing substrate degradation and less functional group formation for PDMS-PDMS bonding. At optimal power levels the number of functional groups present on the surface of the substrate is high enough to encourage bonding but low enough to not affect the siloxane backbone of the PDMS.

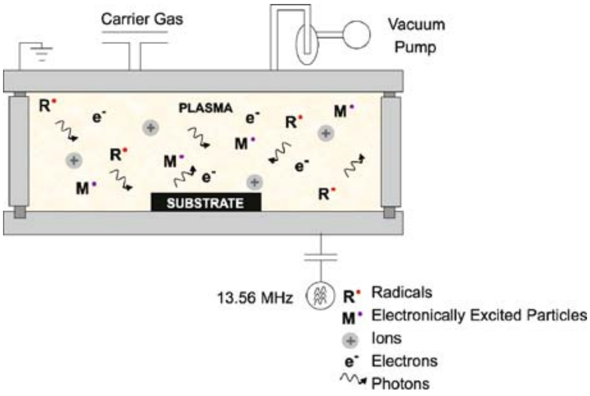
Evaluation of Plasma Treated Surfaces

Surface chemical composition, structure and functional properties can be characterized by various techniques, such as XPS, AFM, and contact angle measurements. XPS measures the short range of photoelectrons leaving the surface. The sensitivity ($\sim 1-10$ nm) is semi-quantitative and detects chemical bonding information at the surface. Composition depth profiles, known as XPS spectra, can be generated from this method. Conversely, AFM utilizes a nanoscale probe to characterize surfaces and produce 3D surface profiles. AFM can determine the surface roughness and elastic modulus through phase imaging and nanoidentations, respectively. In addition to analyzing the surface of substrates, cross-sections can be imaged by using AFM to picture the stiffer surface layer and determine thickness. Furthermore, contact angle analysis can also be used to study surface wetting behavior. Contact angle measuring devices measure the angle of a liquid–vapor interface with a solid surface to assess surface hydrophilicity. Water droplets on hydrophilic substrates spread out and have relatively low contact angle measurements. Conversely, they maintain a more spherical shape on hydrophobic substrates, thereby producing higher contact angle measure-



Plasma in Microchannel, Figure 3 Schematic of a radio frequency plasma treatment chamber

ments. Common contact angle analysis methods include drop–bubble, reflective light and interference microscopy.

Key Research Findings

Various research findings on the effects of plasma treatment on microchannels have reported improved surface characteristics within microfluidic channels. Researchers have also been able to adapt plasma treatment technologies to develop novel applications in the field of engineering. Furthermore, applications of plasma in microchannels include the development of on-chip light sources and the fabrication of micropatterns and gradients for cell adhesion studies.

Hydrophobic Recovery and Bonding Enhancement Techniques

As previously mentioned, surface properties of a substrate can be tailored by applying various plasma treatments. The stability of plasma treatment is dependant on the material properties. For instance, for PDMS, oxygen plasma treated surfaces regain their hydrophobicity over time. This may be due to

- surface silanol groups reorienting into the bulk;
- movement of free PDMS chains from the bulk phase to the surface through cracks in the Si–O–Si structure;
- silanol groups at the surface condensing;
- volatile oxygen or other species escaping into the atmosphere;
- changes in the surface roughness [4].

Conversely, other explanations suggest hydrophobic recovery can be described in two distinct phases: adsorption of atmospheric contaminants and surface reorganization. Within the first few hours, the initial phase of adsorption of atmospheric contaminants begins. These atmospheric species react with the surface moieties that were introduced during treatment and reduce their functionality. In the case of PDMS, surface reorganization begins when siloxane groups from the backbone of the polymer migrate through cracks created during surface modification and reorganize to yield the original properties of the polymer. Similarly to hydrophilicity, bonding characteristics are also dependent on time (Table 2). It has been shown that the adsorption of contaminants and surface reorganization also has an adverse effect on the bonding properties of PDMS.

To increase the stability of a surface treated substrate a variety of approaches have been developed. For example, different plasma gases can be applied to reduce the amount of surface reorganization. Specifically, nitrogen treated surfaces maintain their hydrophilicity longer than oxygen plasma treated surfaces. Also, to maintain stable hydrophilic PDMS it is possible to fabricate C-F bonds or react poly(HEMA) bonds on PDMS microchannel surfaces [6].

Enhancing Microchannel Functionality

Plasma treatment of microchannels can be useful for improving the functionality of microdevices. For example, previous studies have shown that PDMS microchannels can be made hydrophilic by the addition of silane molecules with polar head groups [7]. In this process (3-mercaptopropyl)trimethoxysilane (3-MPS) was absorbed to PDMS to increase the hydrophilic properties of microchannels. Additionally, plasma polymerization has been used to induce in the long-term hydrophilic surface modification by covalently bonding a polymer layer to the surface. Barbier et al. [8] describe a method based on plasma polymerization modification with acrylic

Plasma in Microchannel, Table 2 Aging of activated PDMS surfaces. Bonding metric is based on permanently bonded area after aging the activated surfaces (no bonding = 0 ~ whole area bonded = 10). Adapted from [11]

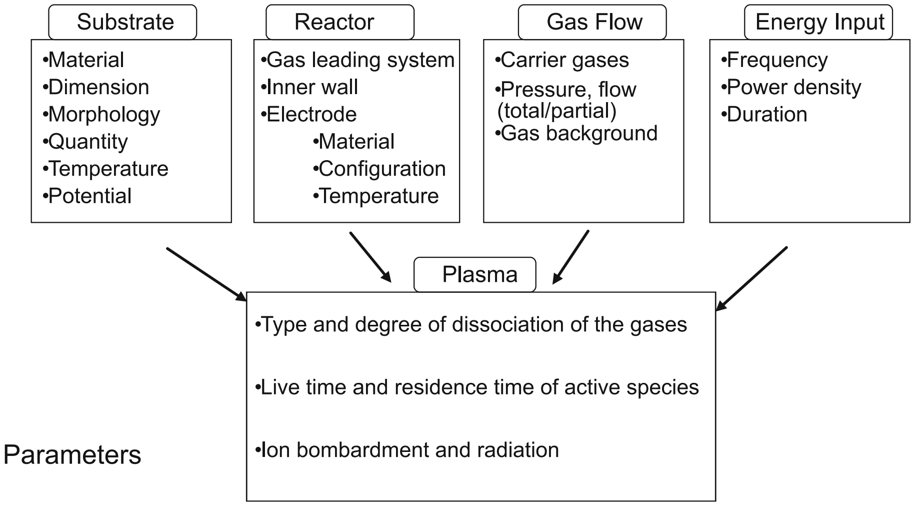
P



Plasma in Microchannel, Figure 4 External parameters that influence the quality of surface plasma treatment

acid coatings. First, argon plasma pretreatment was used to activate trace oxygen molecules in the chamber, which partially oxidize the top layer of the substrate. This step crosslinked the surface to reduce ablation of silicon during deposition as well as limits the movement of siloxane chains for hydrophobic recovery. Secondly, plasma with acrylic acid was deposited onto the pretreated PDMS. Finally, helium plasma treatment was used to crosslink the deposited polymer film to reinforce the cohesion. This process provides a homogeneous stable hydrophilic polymer layer for robust applications within microfluidics and nanofluidics.

Applications

Applications of plasma in microchannels include the development of chromatography detectors and on-chip light sources. Evju et al. [9] describe the creation of microdischarges or microplasmas by direct current within microfluidic channels on polystyrene. The three different gases tested included helium (He), water-saturated helium (H_2O/He), and hexafluoroethane (C_2F_6/He). These gases were released through a microchannel and ignited at atmospheric pressure. The treatments were completed in several seconds to reduce heat formation. XPS confirmed that oxygen and fluorine on the surfaces contributed to hydrophilic and hydrophobic regions, respectively.

Complex biomolecular micropatterns and microgradients have also been synthesized with the use of plasma treated surfaces, with possible future applications in tissue engineering, biosensors, and immunoassays. Various methodologies, such as microcontact printing and micromolding, have been used to create micropatterns where wettability was controlled through selective plasma treatment. These micropatterns are made up of many ligands and cell types for spatial control and cellular organization. This organization can induce cell–cell signaling and recreate the hierarchy lost in standard in vitro methods to produce more tissue-like structures. These advances are critical in understanding biology and enabling improved tissue culture and tissue engineering techniques.

An application of plasma treated surfaces has also been shown in microcontact printing, where elastomeric stamps are *inked* with chemical species and ligands, which can then be patterned onto different surfaces. Langowski et al. [10] have shown that by applying oxygen plasma to the original *stamp* there is a reduction in low-molecular-weight silicon containing fragments transferred to PMMA substrates. The effect of the treatment increased ligand bioactivity, cell function and proliferation due to reduced contamination from the initial untreated substrate. This finding allows for proper modification for applications desiring the removal of low-molecular-weigh silicon fragments, especially for biological applications.

Microgradient textures within microchannels have also been synthesized by utilizing plasma treatments. By having gradients of ligands, microchannels enable visualization of the effects on cell behavior, such as differentiation, migration and adhesion. Because of the quick and inexpensive nature of soft lithographic techniques and plasma treatments, biological applications can be done more cost effectively and in a faster manner.

Future Directions for Research

Plasma treatment of microfluidic surfaces can be used to improve microdevice functionality, to build devices through bonding processes and to activate and sterilize surfaces. Future directions for this technology include improved modeling of techniques with respect to parameter and surface plasma interaction. The development of refined experimental methods, theoretical models, and experimental studies is required to have more control over plasma treatment within microchannels.

Definition

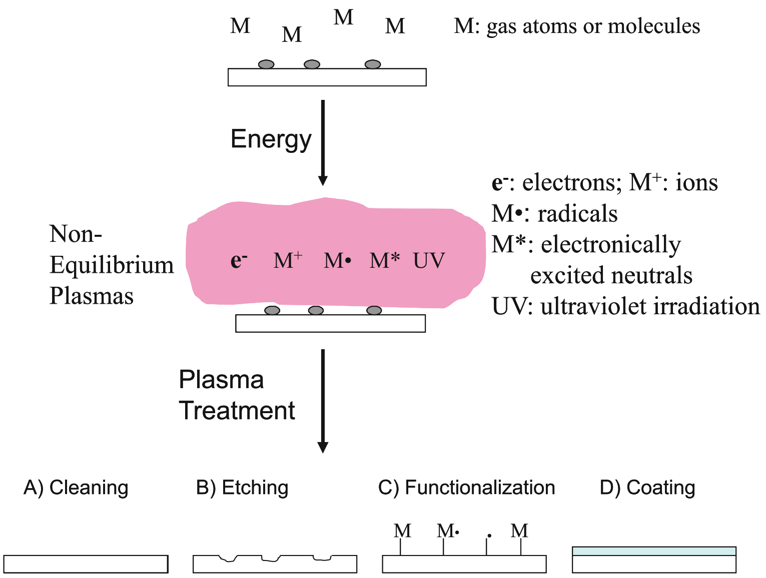
Plasma treatment refers to the surface modification processes of materials using non-equilibrium gas plasmas. Non-equilibrium plasmas with a low degree of ionization, so-called cold plasmas or low-temperature plasmas, are mainly composed of electrons, ions, free radicals, and electronically excited atomic and molecular species. These highly reactive plasma species interact non-thermally with material surfaces, and can react with and bond to various substrate surfaces, or combine together to form an ultra thin layer of plasma coating, and consequently alter the surface chemistry and surface properties. The plasma treated nanoparticles with desired surface functionalities can strongly interact with liquid molecules and thus better disperse into the base fluid to form stable suspension.

Overview

Plasma Treatment

Non-equilibrium plasmas, i. e., low-temperature plasmas, which can be easily created by electrical discharges under reduced pressures (e. g., 10 mtorr to 10 torr), are composed of electronically excited atomic, molecular, ionic and free radical species. Depending on the plasma chemistry or gas

P



Plasma Treatment of Nanoparticles for Nanofluids, Figure 1 Plasma treatment effects on materials surfaces

composition, these highly reactive plasma species react with, clean, and etch surface materials, bond to various substrates, or combine to form a nanoscale thin layer of plasma coating, and consequently alter the surface characteristics. Figure 1 schematically illustrates the plasma-surface interaction results when a material substrate is exposed to low-temperature plasmas. Such plasma-surface interactions are limited to only the material surface without affecting bulk properties of the substrate materials. Since the gas phase is close to room temperature, low-temperature plasmas are suitable and very efficient in surface modification of various materials such as metals, polymers, and ceramics. Plasma treatments with and/or without deposition are currently being widely used in surface modification of various materials for improving adhesion, wettability, printability, corrosion resistance, surface etching or cleaning, and biocompatibility etc. [1–6].

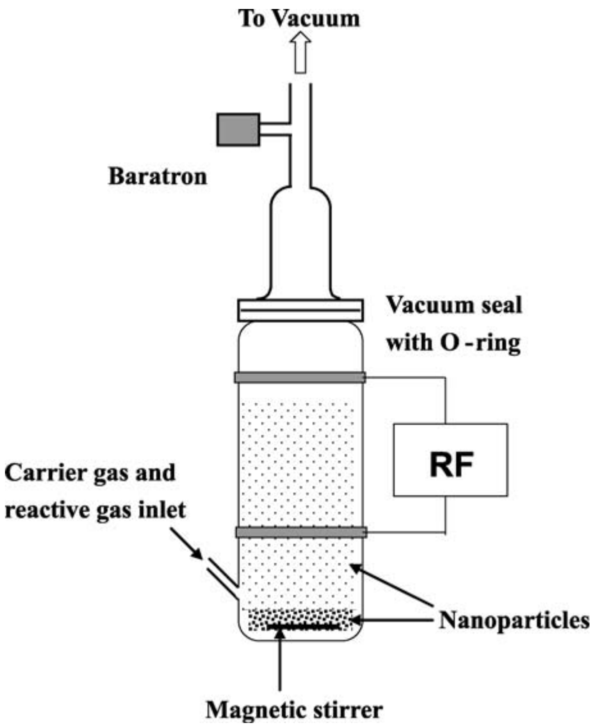
Plasma treatment for material surface modification can be achieved using either simple gas plasmas without deposition or organic vapor plasmas to deposit an ultra-thin layer of plasma coatings on the surfaces. Plasma treatment possesses many unique advantageous features in surface modification of materials. Among these are:

1. plasma treatment processes are usually reliable, reproducible, non-line-of-sight, and applicable to different sample geometries;
2. plasma deposition creates an ultra-thin (in nano-scale) film coating, which are conformal, chemically inert and robust, corrosion-resistant, and strongly bonded to various substrates including both organic and inorganic materials;
3. plasma treatment is relatively inexpensive, easily operated, dry and rapid;
4. plasma treatment can tailor the surface with desired functionalities and properties through simply adjusting the plasma chemistry.

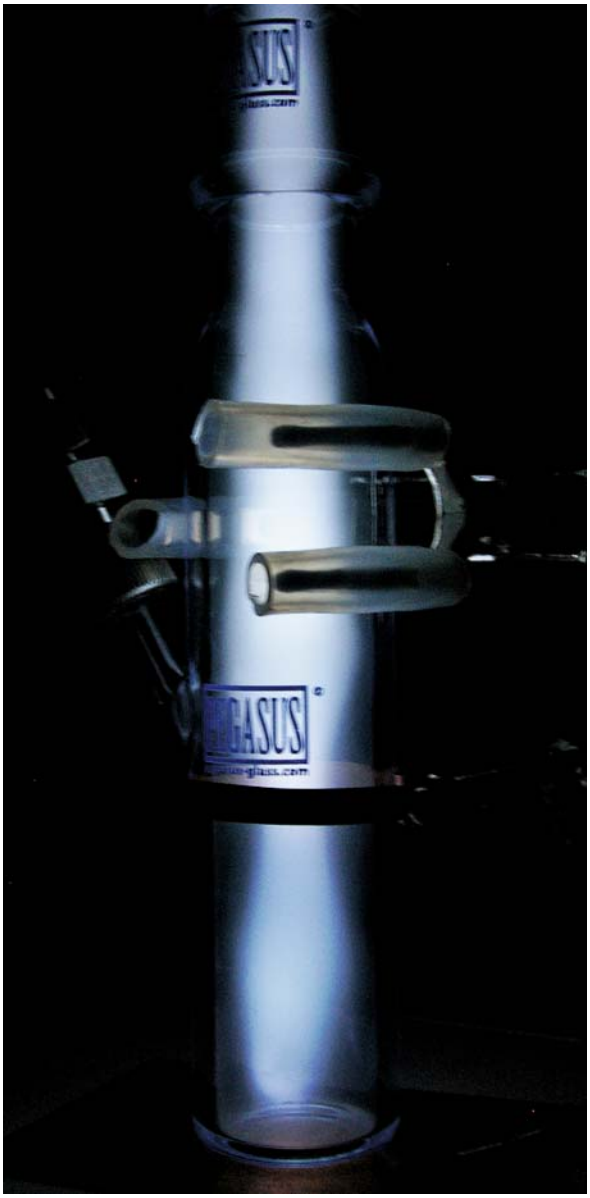
These advantageous features have been demonstrated in the continuous operation of plasma deposition and plasma etching processes in semiconductor manufacturing industry.

Recently, low-temperature plasma treatment has been explored for surface modification of various nanosized materials [7–13]. Surface functionalization of carbon nanotubes (CNTs) using plasma treatment was recently attempted by several research groups. Oxygen plasmas generated at both radiofrequency (RF) and microwave (MW) were used to treat CNTs [7, 8]. It was found that acidic groups were implemented to the CNT surfaces with improved surface wettability. Several other studies [9, 10, 13] reported the surface modification of both CNTs and nanoparticles using plasma treatment. With a simple fluidized-bed plasma apparatus, plasma coatings of 2 nm from pyrrole and 15 nm from acrylic acid were able to be uniformly deposited on 10 – 150 nm Al_2O_3 and 50 nm ZnO nanoparticle surfaces respectively [11]. It was also reported that uniform plasma coating with 1 – 3 nm thickness was achieved on carbon nanotubes with inner diameter of 20 nm [12].

Plasma treatment of nanoparticles for nanofluids can be obtained by plasma treatment using low-temperature plasmas. The diamond nanoparticle surfaces, for example, can be modified by the low-temperature plasmas of methane



Plasma Treatment of Nanoparticles for Nanofluids, Figure 2 Schematic diagram of the magnetically assisted fluidized bed plasma reactor system



Plasma Treatment of Nanoparticles for Nanofluids, Figure 3 Pictorial view of the plasma reactor system

and oxygen mixtures, which can improve their dispersion characteristics including dispersibility and suspension stability in water for nanofluid. Plasma treatment of diamond nanoparticles with selected plasma chemistry imparted various functional groups on the particle surfaces and tailored the surface energy to the required levels. Plasma coated nanoparticles with desired surface functionalities, e. g., polar and/or charged groups, can strongly interact with water molecules and thus better disperse into water to form stable suspension through mechanism of *electrostatic repulsion* or *steric repulsion*, or combination of both.

Nanofluids

Nanofluids, a concept developed by Choi at Argonne National Laboratory [14], is a new class of heat transfer fluids that are composed of suspended nano-sized metallic or nonmetallic solid particles in liquid media. Nanofluids when properly prepared display significantly enhanced heat transfer capacities relative to those of traditional heat transfer fluids. From the practical application viewpoint, the most critical concerns are the agglomeration and poor suspension stability of the metallic or non-metallic nanoparticles in a given fluid medium.

For most fine powders including nanoparticles, strong interparticle attractions tend to stick the particles into agglomerates, which make the independent dispersion of the powders difficult and, more importantly, deteriorates the final property including the thermal conductivity, viscosity, suspension stability, reliability and reproducibility. There is a great difference of density between metallic particles and fluids. As a result, the stability of the suspension of metallic particles in liquid media is usually poor, especially with the relatively high-density and large-size parti-

cles. The agglomerates of particles have a great tendency to precipitate and thus further worsen the suspension stability. The particle precipitation will not only decreases the heat transfer capacity of the nanofluids but also adversely limits the application of nanofluids in practical devices. The consequence of the agglomerate precipitation may cause clog issues of the nanofluids-based devices in which the fluids need to flow through mini and/or microchannels.

One approach to achieve the homogeneous dispersion and stable suspension of fine particles is using various dispersing agents (or surfactants) to stabilize the particle suspension via a steric and/or electrostatic repulsion [15]. It is well known that, however, the synthesis of stable dispersion of nanosized inorganic materials in liquid requires amounts of stabilizers several orders of magnitude higher than the available space on the surface of nanoparticles can accommodate [16]. The presence of excess amount of stabilizers could significantly alter the fluids characteristics, such as viscosity and thermal conductivity, and could be a big concern in the practical application of the fluids. In contrast, plasma treatment of nanoparticles provides a new promising approach in producing well-dispersed and stably suspended heat transfer nanofluids via fabrication of surface-functionalized nanoparticles without using dispersing agents (or surfactants).

Basic Methodology

Plasma Treatment

A magnetically-assisted fluidized bed plasma reactor, which is schematically shown in Fig. 2 and pictorially shown in Fig. 3, can be used to treat diamond nanoparticles (average size of 50 nm). The reactor shown in Fig. 3 is a long cylinder with an inside diameter of 2.54 cm and a length of 15.24 cm. The plasma reactor is pumped down to a base pressure less than 3 mtorr. Then, methane and oxygen mixture at various ratios is used as the plasma fuel and introduced into the reactor to a preset pressure for plasma treatment. Methane and oxygen gases both have a purity of 99.997%. The flow rates of the methane and oxygen were controlled and adjusted using needle valves. The gas pressure in the reactor was monitored using a Baratron (MKS instruments, Inc.). A radio-frequency plasma source (RFX-600, Advanced Energy Industries, Inc.) was used to ignite the plasmas for plasma treatment of the nanoparticles.

Surface Energy and Polar Interactions of Nanoparticles

The surface energy of diamond nanoparticles can be measured and calculated through Lifshitz–van der Waals/acid-base (LW-AB) approach by surface contact angle measurements using three different liquids with known surface tensions, including HPLC grade water, acetone, and hexane. The surface contact angles of the untreated and plasma treated diamond nanoparticles were determined using sessile drop contact angle measurements with a VCA 2500XE system (Advanced Surface Technologies, Inc., Billerica, MD). Before each measurement, the diamond nanoparticles were sticking to a glass slide with a piece of double-layer tape, and then pressed and smoothened using another glass slide under ~ 1.0 kg weight. For surface contact angle measurement, a sessile droplet of 0.4 μl liquid was placed on the smoothened nanoparticle surfaces to obtain an optical image of the liquid droplet. The computer user manually traced the arc that was created by the droplet and a computer program was used to calculate the contact angles of liquid on the nanoparticle surfaces. Six measurements for each sample were performed and the average number was reported in this study. The experimental error for the static contact angle measurement was within ± 2.0 degree from the average value.

Plasma treatment of diamond nanoparticles can functionalize the nanopartcicles' surfaces with polar groups that have improved interactions with water molecules and thus strong affinity to water medium. Lifshitz–van der Waals/acid-base (LW-AB) approach can be used to quantify the contributions of these plasma-induced polar groups to surface energy increase of the plasma treated nanoparticles. As described by Van Oss et al. [17], the total surface energy of nanoparticle, which combined both Lifshitz–van der Waals and Lewis acid-base (LW-AB) interactions, can be expressed by following expression:

$$\gamma = \gamma^{LW} + \gamma^{AB} \tag{1}$$

In other words, the total potential energy of nanoparticle-liquid interactions is the sum of a Lifshitz–van der Waals interaction (γ^{LW}), which means the surface free energy (dipole–dipole and dipole-induced dipole interaction), and Lewis acid-base interaction (γ^{AB}). The Lewis acid-base interaction (γ^{AB}) for the component i is simply calculated by the geometric mean of electron acceptor (γ^{+}) and donor (γ^{-}):

$$\gamma^{AB} = 2\sqrt{\gamma^{+}\gamma^{-}} \tag{2}$$

In order to calculate the surface energy of nanoparticles from our experimentally measured surface contact angle

data, Young–Dupre equation can be used:

$$(1+\cos\theta)\gamma_L = 2\left(\sqrt{\gamma_S^{LW}\gamma_L^{LW}} + \sqrt{\gamma_S^{+}\gamma_L^{-}} + \sqrt{\gamma_S^{-}\gamma_L^{+}}\right) \quad (3)$$

By measuring the contact angle (θ) of the diamond nanoparticles with three different liquids including at least two polar solvent with known γ_L^{LW}, γ_L^{+}, and γ_L^{-} values, the γ_S^{LW}, γ_S^{+} and γ_S^{-} of the untreated and plasma treated diamond nanoparticles were determined.

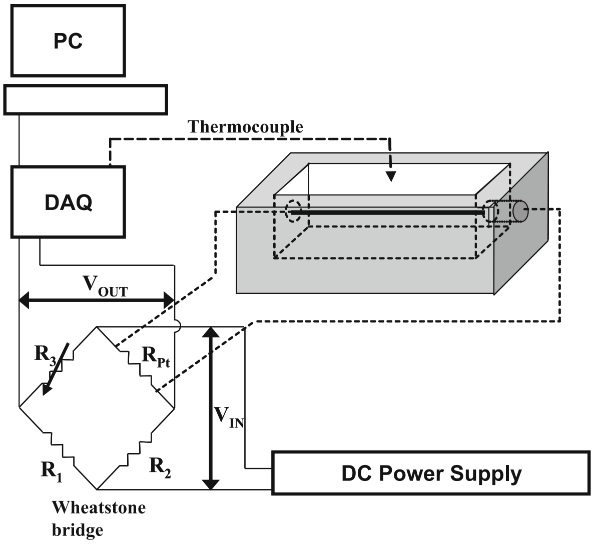
Fourier Transform Infrared Spectra (Ftir)

FTIR measurements can be used to identify and semi-quantitatively verify the surface functionalities/polar groups on diamond nanoparticles' surface induced by plasma treatment. Nicolet 6700 FT-IR Spectrometer (Thermo Scientific Inc.) was used to take Fourier Transform Infrared Spectra (FTIR) of the untreated and plasma treated diamond nanoparticles. Well-ground mixtures of nanoparticle and KBr powders (IR grade) were kept in an oven and baked at 200 °C for 48 h to get rid of moisture before performing the FTIR measurements.

Thermal Conductivity Measurement

The transient hot-wire method can be used to measure the thermal conductivity of nanofluids in this study [18]. As schematically shown in Fig. 4, the transient hot-wire measurement system contains a DC power supply, the wheatstone bridge, a data acquisition system, a nanofluid container, and a computer system to analyze the measurement data. The wheatstone bridge was constructed to determine the change of resistance. The input voltage of 5 V was supplied by an Agilent E3645A DC power supply and the output voltage was measured by a National Instruments SCXI-1000 DAQ. This data acquisition system was also used to measure the temperature of the liquid during the measurement. Each dataset was collected at a rate of 500 points per second. The relation between the output voltage and the resistance of the platinum wire is given by following Eq. (4):

$$R_{Pt} = R_2 \frac{\left(\frac{V_{OUT}}{V_{IN}} + \frac{R_3}{R_1+R_3}\right)}{\left(1 - \frac{V_{OUT}}{V_{IN}} - \frac{R_3}{R_1+R_3}\right)} \quad (4)$$



Plasma Treatment of Nanoparticles for Nanofluids, Figure 4 Schematics of the transient hot wire system for thermal conductivity measurement

Using the linear relation between resistance and temperature, Eq. (5) is derived.

$$T = \frac{1}{\alpha}\left(\frac{R_{Pt,T}}{R_{Pt,T=0}} - 1\right) \quad (5)$$

where α is

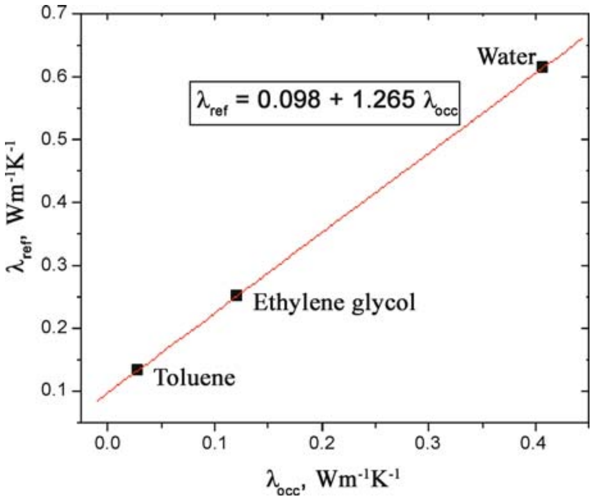
$$\alpha = \frac{\partial \frac{R_{Pt}}{R_{Pt,T=0}}}{\partial T} \quad (6)$$

Finally, thermal conductivity (k) can be found from the following liner heat source model:

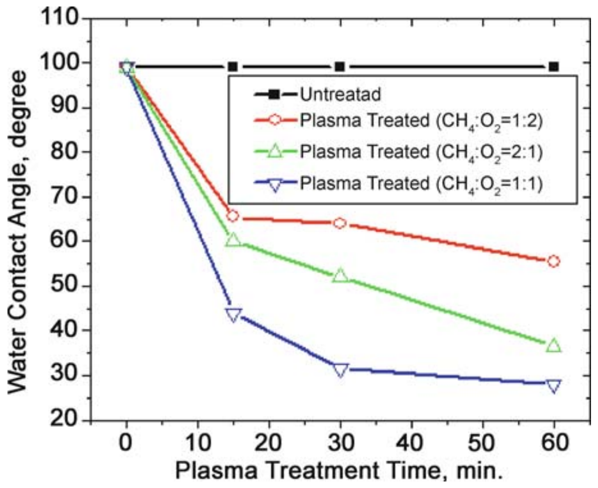
$$k = \frac{q}{4\pi(T_2 - T_1)} \ln\left(\frac{t_2}{t_1}\right) \quad (7)$$

In order to eliminate the effect of convection of the nanofluid, time interval in Eq. (7) must be within the region where thermal conduction is dominant.

The rectangular nanofluid container was designed so that the wire was at least 10 cm long and would contain about 100 ml of fluid. The fluid container was constructed out of 1.49 cm thick Plexiglas. A 1.27 cm diameter hole was drilled through the container wall in each end. A 0.0254 mm diameter pure platinum wire was attached to 12 gage copper wire. The copper wire was crimped onto each end of the platinum wire at a spacing of 10 cm. The connections between platinum and copper wires were soldered to ensure a good contact and the two copper wires were inserted into the fluid container through two rubber stoppers. The copper portion that would be in contact with



Plasma Treatment of Nanoparticles for Nanofluids, Figure 5 Calibration curve for thermal conductivity measurements of nanofluids



Plasma Treatment of Nanoparticles for Nanofluids, Figure 6 Contact angle change of diamond nanoparticles with plasma treatment time. Plasma treatment conditions were: 60 mtorr pressure, 4 W RF power

the test fluid was covered with Omegabond "100" epoxy to eliminate galvanic corrosion. A T type thermocouple was also placed in the fluid so that the temperature of the fluid could be monitored. The temperature measurements using this thermocouple gave reading with an error of $\pm 1\,°C$. To relate the resistance of the wire to temperature, the resistance of the platinum wire over a range of temperatures should be known. Therefore, HPLC grade water of varying temperatures was placed into the container and the resistances of the platinum wire and the temperature of the water were measured.

The thermal conductivity measurement of nanofluids was conducted with the fluid without any vibration. Each test was conducted at ambient condition and the data were collected for 131 s. After repeated trials it was found that the variable resistor should be balanced slightly above the known resistance of the platinum wire. Once the bridge is properly balanced the variation of voltage with time was measured and recorded. The measured thermal conductivity data was calibrated using three kinds of fluids, which was HPLC grade water, ethylene glycol and toluene. Figure 5 shows the calibration curve obtained by recording the thermal conductivity of those liquids measured. The calibration curve gave a linear calibration equation of $\lambda_{\mathrm{ref}} = \boldsymbol{a} + \boldsymbol{b}\lambda_{\mathrm{acc}}$, with $\boldsymbol{a}$ and $\boldsymbol{b}$ were 0.098 and 1.265. All the measured thermal conductivity data of nanofluids was corrected using this calibration equation.

Key Research Findings

Surface Energy of the Plasma Treated Nanoparticles

Figure 6 shows that the water surface contact angle change of plasma treated diamond nanoparticles with plasma treatment time under different plasma conditions. It can be seen that the untreated diamond nanoparticles had a water surface contact angle of 99°. In contrast, plasma treatment significantly reduced the water surface contact angle to less than 30°, which indicated very hydrophilic surfaces with increased surface energy. Using Lifshitz–van der Waals/acid-base (LW-AB) approach, Table 1 summarized the surface energy data analysis results contributed from Lifshitz–van der Waals interaction (γ^{LW}) and Lewis acid-base interaction (γ^{AB}). Evidenced from the data shown in Table 1, the significant surface energy increase of the plasma treated diamond nanoparticles resulted from the contributions from enhanced Lewis acid-base interaction (γ^{AB}), which includes γ_S^+ and γ_S^-, the surface energies contributed from electron acceptors and the electron donors, respectively. This indicates that increased amount of polar functionalities on plasma treated diamond nanoparticles.

Fourier Transform Infrared Spectra

FTIR measurements were used to determine the surface functionalities induced by plasma treatment. Figure 7 presents the FT-IR spectra of untreated, plasma-treated diamond nanoparticles in plasma gas mixtures of methane and oxygen with ratios of 1 : 1 and 1 : 2. The band at $1630\,\mathrm{cm}^{-1}$ is associated with the vibrations of C = C bonds which is corresponding to the characteristic of diamond. A wide band with its maximum at $3400\,\mathrm{cm}^{-1}$ in the IR spectrum is due to the vibration of OH groups. The peak at $1725\,\mathrm{cm}^{-1}$ is attributed by the vibration of C = O bonds in weak-acid carbonyl. The increased peak

intensity at 1725 and 3400 cm^{-1} indicates the incorporation of $C=O$ and $-OH$ polar functionalities on plasma treated nanoparticles' surfaces. Table 2 summarizes the peak area comparison of $C=O$ and $-OH$ relative to $C=C$ peaks to semi-quantitatively determine the polar groups on plasma treated nanoparticle surfaces, because the amount of $C=C$ group should be constant before and after the plasma treatment. From the Table 2, it is shown that, in comparison with the untreated control, the ratios of $C=O/C=C$ and $-OH/C=C$ groups for plasma treated diamond nanoparticles were significantly increased.

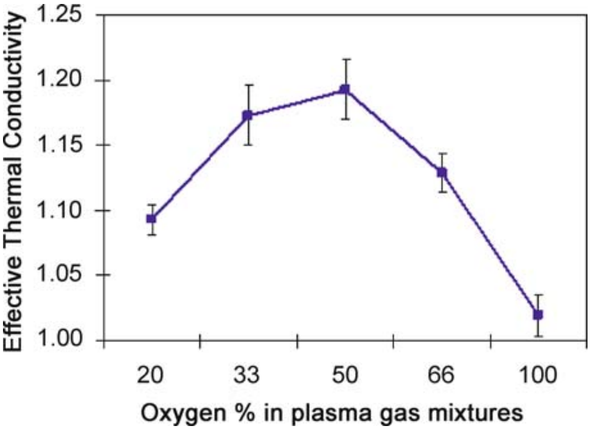
Thermal Conductivities of the Resulting Nanofluids

Effect of Oxygen/Methane (O_2/CH_4) Ratio in Plasma Gas Mixture

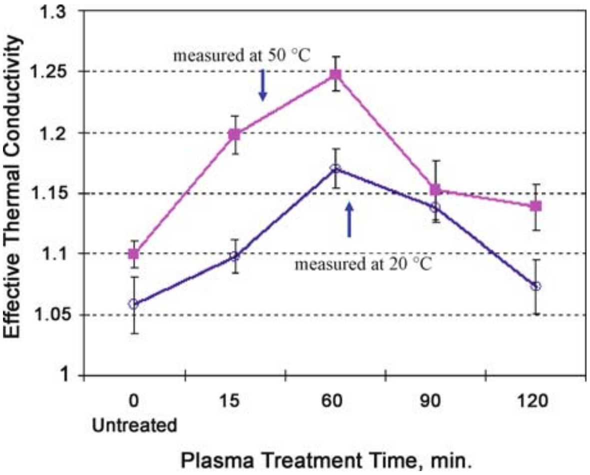
The untreated and plasma treated diamond nanoparticles were dispersed into HPLC grade water with the aid of mechanical agitation using a magnetic stirrer. We have reported that plasma treated diamond nanoparticles showed enhanced dispersibility and improved suspension stability in water as compared with the untreated controls [19]. After settled for one hour, the nanofluids thus prepared were characterized using the transient hot wire system shown in Fig. 4. Figure 8 shows the thermal conductivities of the nanofluids prepared using plasma treated nanoparticles with varying oxygen addition in plasma gas mixtures of methane and oxygen. When O_2/CH_4 ratio increased from 1 : 4 to 1 : 1 in the plasma gas mixture, the plasma treated nanoparticles gave increasing thermal conductivities of the resulting nanofluids with more oxygen addition. Further increasing the oxygen amount above 50% ($O_2/CH_4 = 1:1$), however, the thermal conductivity of the resulting nanofluids with the plasma treated nanoparticles started to decrease.

The thermal conductivity dependence of the resulting nanofluids on O_2/CH_4 ratios in plasma gas mixture shown in Fig. 8 is consistent with the water surface contact angle results shown in Fig. 6. 1 : 1 ratio of O_2/CH_4 gave the lowest water contact angles for the plasma treated diamond nanoparticles as compared with lower or higher O_2/CH_4 ratios. The lower water surface contact angle suggested higher amount of polar functionalities were introduced onto diamond nanoparticles' surfaces through

P



Plasma Treatment of Nanoparticles for Nanofluids, Figure 8 The effects of O_2/CH_4 ratio used for plasma treatment on thermal conductivity of the resulting nanofluids with addition of 0.15 Vol.% plasma treated diamond nanoparticles into water. The thermal conductivities were measured after 1.0 hour settling time. Plasma treatment conditions were: 60 mtorr pressure, 4 W RF power, 60 min treatment time



Plasma Treatment of Nanoparticles for Nanofluids, Figure 9 Plasma treatment time effects on thermal conductivity of the resulting nanofluids with addition of 0.15 Vol.% plasma treated diamond nanoparticles into water. The thermal conductivities were measured after 1.0 h settling time. Plasma treatment conditions were: 60 mtorr pressure, 4 W RF power, 1 : 1 ratio of $CH_4 : O_2$

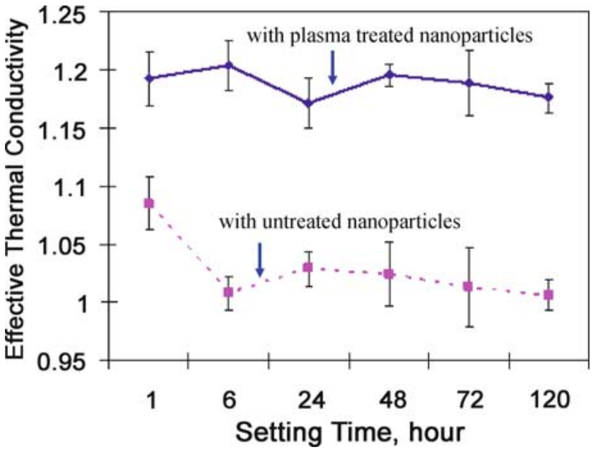
plasma treatment. As a result, a better dispersion of the nanoparticles in water medium was achieved and so was the thermal conductivity of the resulting nanofluids. It is believed that plasma treatment using higher amount of oxygen addition over 1 : 1 ratio of O_2/CH_4 could very likely result in a pronounced surface etching effect and etch the surface polar surface functionalities away.

Effect of Plasma Treatment Time

The water surface contact angle measurement and thermal conductivity measurement showed that plasma treatment of diamond nanoparticles with 1 : 1 ratio of O_2/CH_4 gave rise to the best surface wettability and the highest thermal conductivity of the resulting nanofluids. Using plasma gas mixture with a fixed O_2/CH_4 ratio of 1 : 1, therefore, effects of plasma treatment time on thermal conductivities of the resulting nanofluids were examined. In Fig. 9, the effective thermal conductivities of the resulting nanofluids at both 20 °C and 50 °C were plotted against the plasma treatment time for diamond nanopaticle treatment using plasma gas mixture of $O_2/CH_4 = 1 : 1$. With plasma treatment time varied from 15 to 120 min, plasma treatment of diamond nanoparticles for 60 min gave a nanofluids with the maximum thermal conductivity at both temperatures. The results in Fig. 9 are also consistent with the water surface contact angle measurement results shown in Fig. 6. The thermal conductivity decrease using plasma treatment time longer than 60 min could be due to the over treatment effects often observed in plasma treatment processes.

Stability of the Resulting Nanofluids

We have recently reported that plasma treatment of diamond nanoparticles significantly improved their suspension stability in water [19]. After 45 day sediment test, the nanofluids using plasma treated diamond nanoparticles didn't give any phase separation, while the nanofluids using untreated controls showed clear phase separation of water. In this study, the settling time dependence of the nanofluid thermal conductivity was monitored and the data are shown in Fig. 10. It can be seen that the nanofluids using untreated nanoparticles showed a decreasing trend with settling time. After 120 h settling, the effective thermal conductivity reached to ∼ 1.0, i. e., the same as pure water. In contrast, the nanofluids prepared using plasma treated diamond nanoparticles showed very little change in the effective thermal conductivity with settling time.
From Fig. 10, it was noted that, with the same amount nanopartcile addition of 0.15 Vol.%, nanofluids using plasma treated nanoparticles gave much higher thermal conductivity than that using untreated nanoparticles. It was usually observed that the thermal conductivity of nanofluids is proportional to the volume fraction of nanoparticles added in base liquid media [20]. Results shown in this study suggest that plasma treatment of diamond nanoparticles could well disperse the nanoparticles in water and thus increase the thermal conductivity of the resulting nanofluids. It is suspected that the enhanced interfacial interactions between nanopaticles – base water fluids due to introduction of polar surface functionalities by plasma treat-



Plasma Treatment of Nanoparticles for Nanofluids, Figure 10 Thermal conductivity change of the resulting nanofluids (with 0.15 Vol.% diamond nanoparticle addition in water) with settling time. Plasma treatment conditions were: 60 mtorr pressure, 4 W RF power, 60 min treatment time, 1 : 1 ratio of CH_4 : O_2

ment could be another important factor contributed to the thermal conductivity increase of the resulting nanofluids.

Future Directions for Research

Plasma treatment provides a new approach to functionalize nanoparticle surface for heat-transfer nanofluid preparation without using stabilizing agents. More experimental investigation is very necessary to optimize the plasma treatment process in term of plasma chemistry, plasma operating conditions, and proper plasma apparatus design. As pointed out in this paper, besides nanoparticle concentration, the enhanced interfacial interactions between nanopaticles – base fluids could be another important factor that contributed to the thermal conductivity increase observed in heat-transfer nanofluids. A detailed characterization of the nanofluids with the aid of theoretical simulations will help us to understand the fundamental mechanisms for the observed heat-transfer enhancement.

Elastomeric valve

Definition

Mechanical structure designed to control the flow of fluids in one channel through changes in pressure in a second channel from which it is separated by a membrane or equivalent structure.

Overview

Pneumatic valves rely on the deformation of a membrane, or other thin structure, by pressure, with the end result of altering the flow of a fluid in a channel. The size of the pneumatic valves is usually comparable to the size of the channels they control and consequently these valves are easy to integrate in the overall design of the microfluidic chips. Although several designs have been proposed over time, using different materials, the most successful valves in terms of applications have been the valves using elastomeric materials. Elastomeric materials are easily deformable, and are already widely used for microfluidic applications, making them ideal for developing pneumatic valves.

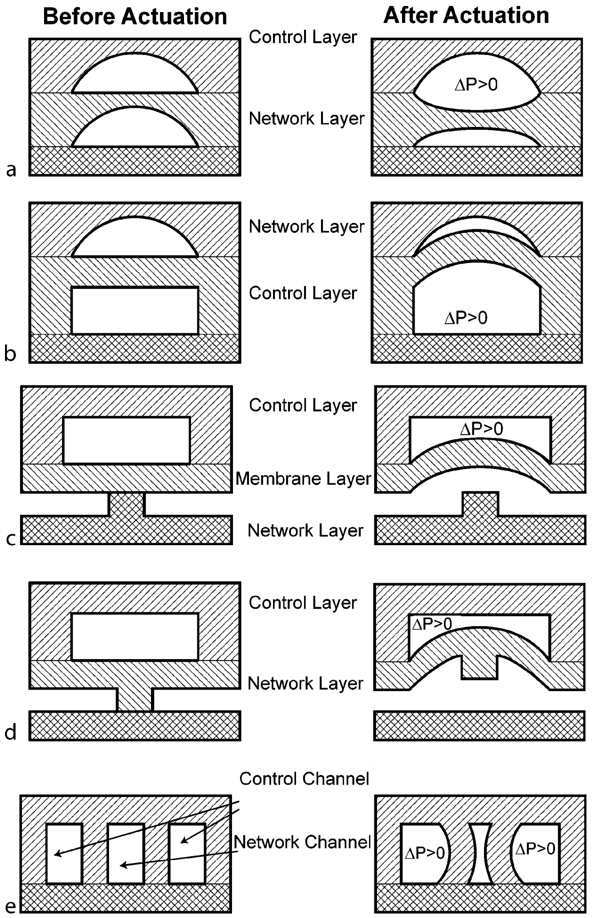
In the simplest design, the deformation of a circular membrane under uniform pressure on one side can be described by the following equation:

$$\Delta x = \Delta P \frac{3r^4}{16t^3} \cdot \frac{(1-\nu^2)}{E}$$

where Δx is the deformation of the membrane at its center, ΔP is the pressure difference on the two sides of the membrane, E and ν are characteristics of the membrane material (the Young modulus and the Poisson's ratio, respectively), and r and t are dimensional characteristics of the membrane (the radius and the thickness of the circular membrane, respectively). Although for more complicated shapes of the membrane the dependence of deformation to actuation pressure has to be calculated numerically using specialized software, the formula for the circular membrane already suggests a very important impact from the valve dimensions on valve functionality.

Basic Methodology

Pneumatic valves are fabricated using standard microfabrication and assembly technologies. The membrane of the valve can be one uniform film of elastomeric material, or can have microchannels already imprinted on one side (see ► microfabrication techniques). The actuation chamber is usually in a separate layer, either elastomer or a rigid material. The layer including the controlled microchannel, the membrane, and the layer containing the actuation chamber are then bonded together using standard techniques (e. g. oxygen plasma for elastomer and glass layers see ► microfluidic assembly and microfabrication techniques). The decision for the precise design and integration of pneumatic devices into the manufacturing of microfluidic devices is usually based on several criteria, each of which may have different weight in different applications. The first criterion is usually the compatibility of the technologies for the valve with the rest of the manufacturing. Some valve require the use of positive resist and overflow at higher temperature, other require glass etching, and some can be manufactured using only negative epoxy resist (SU8). Most of the pneumatic valves require the precise aligning and bonding of two layers of elastomeric material. The second criterion is the nature of the fluid to be handled. While most of the elastomeric materials are compatible with water solutions, only few materials could handle solvents and more aggressive chemicals. The third criterion is the number and size of the valves on one device. Smaller valve size is possible when controlling single rounded channels, while larger valves could incorpo-



Pneumatic Valves, Figure 1 Schematics of pneumatic valves. (a) Pneumatic valve using the compression of a rounded channel in the network layer. (b) A bulging membrane can be used to control flow in a rounded channel. (c) Negative pressure can deform a membrane and open communication in a network layer. (d) A microstructured membrane could be used to control flow in a complex network layer. (e) In a single layer valve the control channels are placed on the side of the network layer

rate more features or control multiple channels at the same time. Finally, valves that are normally closed or normally open have been described, and the choice depends on the functionality and actuation pressure available for operating the valves.

Key Research Findings

Several approaches have been described for the practical implementation of the pneumatic valves in microfluidic systems. In general, the control and network channels (Fig. 1) are placed in different layers and the membrane structure performing the actuation is in between the layers. Both higher pressure (Fig. 1a,b,e) and vacuum (Fig. 1c,d) have been use to control the fluid in the network layer. In the case of vaccum-actuated valves, the membrane could seal channels in the network layer in the absence of the actuation pressure, only by elasticity of the membrane pressing against the valve seat (Fig. 1c,d).

While smaller aspect ratios of the network layer usually lead to smaller dead volumes for the valves (Fig. 1), various designs that allow the control of higher aspect ratios has been described, especially for applications that require the transport of larger cells or particles (Fig. 1b-e). Pneumatic valves with rounded (Fig. 1a–c) as well as rectangular (Fig. 1d–e) channels in the network layer have been implemented. The control layer could be above or bellow the network layer (Fig. 1a–d), and at least in one implementation the control and network channels were implemented at the same level (Fig. 1 e). Hierarchical arrangements of pneumatic valves in microfluidic devices, where some microscale valves are used to control the operation of other microscale valves, have been demonstrated as a way to reduce the number of control lines and increase the sophistication of actuation patterns.

For most of the designs, the membrane is relatively flat and feature-less and in some implementations it can be different material from the control and network layer materials (Fig. 1c). However, the addition of microstructures to the valve membrane (Fig. 1d) has been demonstrated to result in higher degree of complexity of the functionality that can be achieved using pneumatic actuation.

Future Directions for Research

There are two main challenges for the development of applications using pneumatic valves. The first one has to do with the choice of materials for the valve. Although elastomeric materials are very good for prototyping, scaling up and reducing the fabrication costs would require the use of polymeric materials. Either these new materials would have to have comparable mechanical properties with the current elastomers, or different designs would have to be imagined. The second challenge is related to the control system and pressure generation that is usually off chip. Integrating these on the chip or at least standardizing and miniaturizing these would be needed for compact, reliable miniaturized devices.

Polyclonal

Definition

Polyclonal antibodies are antibodies that are derived from several different t B-cell lines. The selections of antibody molecules bind to different parts of the antigen, with different binding affinities. Within a polyclonal sample, some of the antibodies will be specific for the antigen with which the animal was immunised. The rest of the antibodies have been obtained from meetings with other foreign antigens that the animal has been exposed to through its life time.

Poly(dimethylsiloxane) (PDMS)

Definition

PDMS is popular polymer in the microfluidics community; often used for rapid fabrication of microchannel structures. PDMS is optically-transparent and is generally considered to be inert, non-toxic and non-flammable. PDMS is formed by mixing a *base* with a *curing agent* (typically mixed in a 10 : 1 ratio, but this can vary depending on the desired stiffness of the resultant polymer) and curing in a vacuum-oven for several hours. Cured PDMS will form a reversible-bond with various surfaces (glass microscope slides, for example). Irreversible sealing can be achieved by exposing the PDMS to oxygen plasma prior to bonding.

Polymer

Synonyms

Plastic; Organic material

Definition

A polymer is a material composed of large macromolecules. These macromolecules are formed by chains of hundreds or thousands of connected (polymerized) monomer molecules. The three main classes of polymers are thermoplastics, elastomers and thermosets. They differ in the degree of cross-linking of their macromolecules – from no cross-linking (thermoplastics) to moderate cross-linking (elastomers, rubbers) to high cross-linking (thermosets). Thermoplastics commonly used in microfluidics include materials like polymethylmethacrylate (PMMA), polycarbonate (PC), polyethylene terephthalate (PET) or cyclic olefin copolymers (COC). Silicones (like polydimethylsiloxane, PDMS) are a typical class of elastomers. Thermosets include photoresist materials like SU-8 and others.

P

Definition

Polymer synthesis requires strict control of reaction conditions such as temperature, reaction time, and mixing of reagents. Microfluidic reaction systems enable efficient mixing and rapid heat exchange. Moreover, a laminar stream in a microfluidic channel enables control of the resulting shape of a molecule. These features of microfluidic reaction systems are suitable for polymer synthesis.

Overview

Reactions involved in chemical polymerization should be highly controlled because polymer properties such as ►average molecular weight, molecular weight distribution, and size and shape of particles strongly affect the functions of polymer materials. When using polymers of less well known functions, the molecular weight or size and shape should be carefully selected, and the molecular weight or size distribution should be controlled to be as narrow as possible. Such requirements could be satisfied by utilizing microfluidic systems. Microfluidic reaction systems have several distinctive features. One of the unique features is the ability to control molecular weight distribution and simple control of the molecular weight of linear polymers. In addition, microfluidic systems enable efficient emulsification with controlled size and shape. Present-day investigations on polymer materials are directed towards the development of novel functional substances by using high-throughput and combinatorial synthesis methods. The microdevices developed for this purpose should be simple, controllable, and capable of continuous combinatorial synthesis process with high-throughput screening systems for polymer material libraries. Moreover, there is a requirement for accelerated multi-parameter optimization of reaction conditions. In this article, efforts towards the development of microreactors for linear polymer synthesis and preparation of complicated polymer particles are summarized.

Synthesis of Linear Polymers in Microfluidic Reactor

Microreaction systems involve microreaction apparatuses that enable high controllability of chemical reactions. Such controllability results from efficient heat transfer, mass transport, and/or a larger surface/interface area. Recent studies have shown the potential benefits of using microfluidic reactors for various chemical reactions. Reactions using micromixing devices give better results than batchwise reactions. This is because a micromixer enables rapid mixing and therefore yields excellent controllability of rapid reactions.

Application of microreaction technology for linear polymer syntheses was initially performed by several researchers, but the field is still in its infancy. Most of the work utilized a combination of micromixing and reaction parts.

The most popular polymerization method is ►radical polymerization. Wu et al. performed radical polymerization by using a chip-type microreactor [1]. The system is composed of a microstirrer mixer connected to a microchannel reaction part. The molecular mass of the polymer produced is governed by the flow rate or polymerization time. The monomer conversion agrees well with the bulk reaction kinetics reported in the literature. The reactor is convenient and inexpensive to manufacture, with a versatile design that can be reconfigured and prototyped in less than a day. The radical polymerization technique was also applied for ►block copolymerization of poly[(ethylene oxide)-*block*-(2-hydroxypropyl methacrylate)] [2]. A series of well-controlled polymerizations was carried out at different pumping rates or reaction times with a constant ratio of monomer to initiator. The stoichiometry of the reactants was also adjusted by varying relative flow rates to change the reactant concentrations. Another example of radical polymerization in a microreactor was described by Iwasaki and Yoshida, who reported a microreactor consisting of commercially available micromixers (T-shape, 500 μm internal diameter) connected with capillary tubes (500 μm internal diameter) [3]. Thermal decomposition of 2,2-azobis(isobutylronitrile) (AIBN) was examined first and subsequent polymerizations of butyl acrylate (BA), benzyl methacrylate (BMA), methyl methacrylate (MMA), vinyl benzoate (VBz), and styrene (St) were performed. The microreactor was quite effective in controlling the molecular weight distribution for highly exothermic reactions (BA, BMA, and MMA) but not so effective for less thermic polymerizations (VBz and St).

Cationic polymerization was performed in a microreaction system consisting of two micromixers connected by microcapillaries [4]. A method that used irreversible generation and accumulation of highly reactive cations in the absence of nucleophile was applied for polymerization. The molecular weight distribution was controlled by extremely fast micromixing, and the resulting polymer could be used for follow-up reactions.

The benefit of microreaction systems is not limited to cationic or radical polymerization. Amino acid polymerization using α-amino acid *N*-carboxyanhydride (NCA) yielded better molecular weight distribution when performed in a microreactor [5]. Also, the average molecular weight could be controlled by changing the flow rates.

Synthesis of dendric molecules has also been performed. Chang and coworkers synthesized ethylenediamine-cored polyamidoamine (PAMAM) dendrimer using an interdigital micromixer [6]. Using this method, synthesis of generation two through generation five PAMAM dendrimer was confirmed by microchip capillary zone electrophoresis. Furthermore, the synthesized polyamide dendron was deposited onto a functionalized glass surface through the formation of amide bonds using a facile coupling procedure via a microreactor. The dendron deposition process involved two major steps: functionalization of the native glass surface using 3-aminopropyl triethoxysilane, and coupling of the synthesized polyamide dendron with the aminosilanized surface.

Compared with conventional synthesis methods, the microreactor provides better yield and selectivity, and a considerably faster synthesis rate. Nanostructured polyamide G1 dendron thin films could be deposited in minutes using an impinging flux from this microreactor.

Not only have efforts been focused on the synthesis of linear or branched polymer molecules, but theoretical studies have also been performed. Serra et al. conducted numerical simulations of free radical polymerization in microfluidic devices [7]. Three microfluidic devices were modeled: two interdigital multilamination micromixers with a long and short focusing section, respectively, and a simple T-junction followed by a microtube reactor together considered as a bilamination micromixer with a large focusing section. The simulations showed that in spite of the heat released by the polymerization reaction, the thermal transfer in such microfluidic devices was high enough to ensure isothermal conditions. Moreover, for low radial ►Peclet number, microfluidic devices with a large focusing section could achieve better control over the polymerization than a laboratory-scale reactor as the ►polydispersity index obtained was very close to the theoretical limiting value. Serra et al. [7] concluded that the reactive medium cannot be fully homogenized by the diffusion transport before leaving the system resulting in a high polydispersity index and a loss in the control of polymerization as the characteristic dimension of the microfluidic device increases, i. e. for high radial ►Péclet number.

Complicated Polymer Particle Synthesis

There is an increasing demand for polymer particles by industry, particularly for painting formulations and drug delivery applications. A microfluidic reaction system provides superior controllability of fluid because the flow forms simple laminar streams. Thus, efforts have been exerted on polymer particle synthesis using microfluidics because of the unique capacity to generate microdroplets with very narrow size distributions. Polymer particles by simple emulsification have been widely studied and well summarized in other entries. Here, we focus on polymer synthesis by complicated emulsification. Nie et al. reported a novel approach to continuous and scalable production of core–shell droplets and polymer capsules in microfluidic devices [8]. They used laminar flow of three immiscible liquids, aqueous SDS, monomer, and silicon oil, in a microfluidic system. The described method is also useful for the synthesis of polymer particles with nonspherical shapes. They used capillary instability-driven break-up of a liquid jet formed by two immiscible fluids. Precise control of emulsification of each liquid allowed production of highly monodispersed core–shell droplets with a predetermined diameter of cores and thickness of shells. They also achieved control over the number of cores per droplet and the location of cores in a droplet. The authors carried out fast throughput photopolymerization of the monomeric shells and obtained polymer particles with various shapes and morphologies, including spheres, truncated spheres, hemispheres, and single and multicore capsules. Photolithography was also applied for the synthesis of polymer particles. Dendukuri et al. reported a one-phase method using a T-junction microchannel to create solid disk- and plug-shaped particles (Fig. 1) [9]. Snap-off at the junction yielded plugs containing Norland optical adhesive (NOA) 60, a photopolymerizable resin. When an ultraviolet (UV) beam was shone on the plug in the narrow channel, a plug structure was captured, but if the plug was allowed to expand laterally and then polymerized, a disk was formed. Because of the small dimensions of the plugs and disks, the photopolymerization occurred in less than 1 s, using only $3\,\mathrm{J\,cm^{-2}}$ of energy. They also developed an evolutionally advanced microfluidic system by combining the advantages of microscope projection photolithography and microfluidics to continuously form morphologically complex or multifunctional particles down to the colloidal length scale (Fig. 2) [10]. Exploiting the inhibition of free radical polymerization of diacrylate monomers near polydimethylsiloxane (PDMS) surfaces, they were able to repeatedly pattern and flow rows of particles in less than 0.1 s, affording a throughput of near 100 particles per second using the simplest of device designs. Polymerization was also carried out across laminar, co-flowing streams to generate ►Janus particles, which are chemically biphasic particles. They synthesized a Janus polymer by using co-flowing laminar streams of monomer, one of which contained a rhodamine-labeled crosslinker, and forming particles across this interface. The relative proportions of Janus particles could be easily tuned. This new high-throughput technique offers unprecedented control over particle size, shape, and anisotropy.

Polymer Synthesis within Microfluidic Reactor, Figure 3 Mechanism of NCA polymerization initiated by a base such as tertiary amine. Reproduced from [5]

Basic Methodology

Basically, a microreaction system for polymerization reaction consists of a microfluidic device for mixing or droplet formation followed by microchannels as reaction parts. In this article, linear amino acid polymerization reaction is used as a basic example of polymer synthesis using microfluidic devices. Amino acid polymer was synthesized using the NCA method. This reaction is an anion ring-opening reaction which consists of two stages (Fig. 3): initiation by tertiary amine, and propagation of the polymer chain. The initiation and NCA anion attack are known to be relatively fast reactions. It is assumed that these steps are important in controlling polymerization of NCA. However, control of polymerization would be difficult in conventional batchwise systems due to the tendency to locally generate concentration gradients of the reagents. As a remedy, strict reaction control of a microreaction system can be employed to synthesize biopolymers.

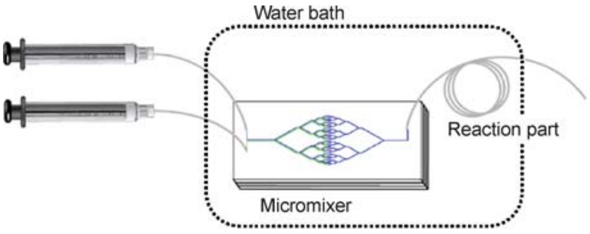
Preparation of Microreaction Device

Generally, mixing is extremely important in chemical reactions. When using microreactors for chemical reactions, micromixers are often incorporated in the microreactor for effective mixing. Mixing of the monomer and base principally depends on diffusion through the interface of the two solutions. A multilayered micromixer increases the interface area of two fluids and shortens the diffusion length, resulting in an increase in the mixing efficiency of reactants. Also, a characteristic feature of this mixer is that mixing efficiency increases with a decrease in flow rate. In order to gain long residence time required for polymerizations, low flow rate should be used in the microfluidic system; therefore, a multilayered micromixer was employed for NCA polymerizations in a microfluidic system.

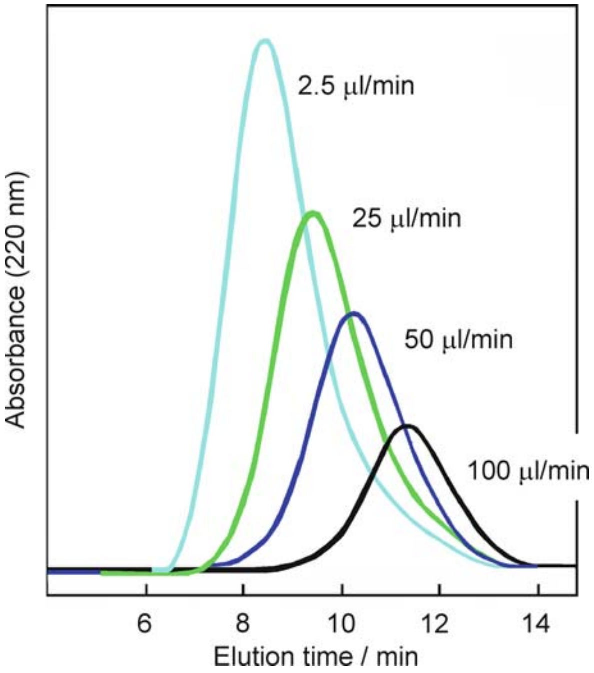
Figure 4 shows the setup of a microreaction system. The micromixer was attached to a PTFE microtube (length = 500 cm) and served as a polymer-propagating region. The volume of fluid channel of the micromixer was 4.4 μl, and the total inner product volume of this microreactor corresponded to 250 μl. In the microreactor setup, monomer and initiator solutions were each charged into a 1 ml Hamilton gastight syringe. The solutions were supplied to the microreactor using a syringe pump with a parallel syringe holder, which enable identical pumping rates so that the final mixed solution would have a constant reagent concentration.

Polymerization Reaction

Polymerizations were performed in DMF and initiated by triethylamine. Both solutions of monomer and base were separately introduced into the microreactor (Fig. 4) using a syringe pump. The resulting mixture was heated at



Polymer Synthesis within Microfluidic Reactor, Figure 4 Microreaction system used in this study. The system consists of a PDMS micromixer and PTFE microtubes. Two syringes containing reagents were coupled on the PDMS micromixer by PTFE microtubes (diameter = 250 μm, 10 cm). The PDMS micromixer was attached to a PTFE microtube (diameter = 250 μm, 500 cm) and served as a reaction region. The mixer and reaction region were kept at 30 °C in a water bath. Reproduced from [5]

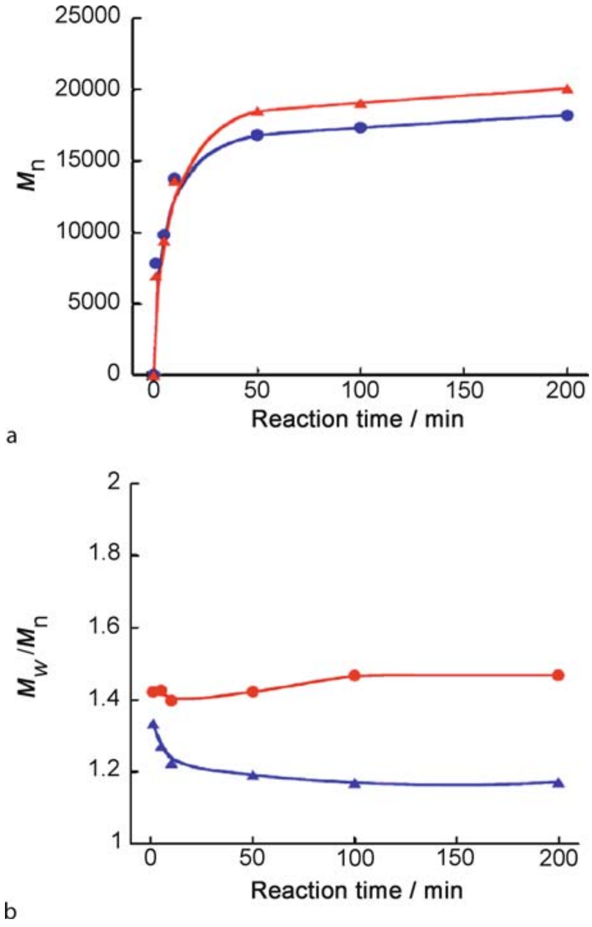


Polymer Synthesis within Microfluidic Reactor, Figure 5 Gel filtration chromatography analysis of poly(Lys) produced by the microreactor. The polymerizations were conducted with 0.1 M monomer and 0.01 M initiator for 1, 5, 10, and 100 min of reaction times corresponding to 250, 50, 25, and 2.5 μl/min flow rates, respectively. Reproduced from [5]

100 °C for termination, then deprotection of the side-chain protective group was performed using HBr in AcOH. The sample was analyzed by gel filtration chromatography after dialysis against water to remove HBr. Figure 5 shows the gel filtration chromatography data for the poly(Lys) produced using the microreactor at different flow rates. The molecular weights of the respective samples regularly increased with a decrease in flow rates, that is, as a consequence of the increase in time required for polymerization to occur. It was found that the molecular mass of the polymer produced using the microreactor is simply governed by the flow (pumping) rate. Also, polymers produced by the microreaction showed narrower molecular weight distribution than that of macroscale reaction in homo- and copolymers (Fig. 6).

Key Research Findings

Many polymers with interesting functionalities have been developed and applied in various fields. At present, a rapid and combinatorial synthesis system with highly controllable polymerization reaction is much required. However, it is generally difficult to control polymerization reactions in conventional batchwise systems. Synthesis of polymer molecules using a microreactor enables strict control of chemical reactions which serves as a model of polymer synthesis. The performance of a microreaction system for polymerization was compared with that of a conventional batchwise system by analyzing the properties of the obtained polymers. In linear polymer products, the M_w/M_n values of the polymers synthesized by the batchwise system obviously increased with increasing concentration of monomer. In contrast, the M_w/M_n values in the microfluidic system remained low with high monomer concentrations [5]. It was demonstrated that the microreactor provided high controllability of polymerization even at concentrations that produced poor control of molecular weight distribution in the case of the batch reaction. The controllability of molecular weight distribution is governed by several factors. The first factor is the mixing efficiency of reactants. In the batchwise system, an increase in reagent concentration tends to decrease the mixing efficiency of reagents, and leads to generation of local concentration gradients of the reagents. In addition, the viscosity rise observed for highly concentrated monomer solutions will cause a decrease in the efficiency of mixing based on turbulent flow in the batchwise system. Consequently, it is assumed that such a decrease in mixing efficiency induces a broadening of the molecular weight distribution. In contrast, it is hypothesized that effective mixing of reactants by the attached micromixer in the microfluidic system enables high control of molecular weight distribution. Not only was linear polymer synthesis performed in the microfluidic reactor, but also synthesis of dendrimer molecules. Although still in their infancy, microfluidic systems open the use of microreactors for branched polymers. Overall, the usefulness of microreactors in controlling the reaction of linear and branched polymer synthesis has been demonstrated. For polymer particle synthesis, microfluidic reaction systems show several



Polymer Synthesis within Microfluidic Reactor, Figure 6 Comparisons of polymer properties in batchwise (circle) and microfluidic (triangle) systems at various monomer concentrations. (**a**) ►number average molecular weight (M_n) and (**b**) polydispersity (M_w/M_n) of the obtained polymers against concentrations of NCA. Polymerizations were carried out for 200 min. Reproduced from [5]

advantages over the conventional reaction systems. These benefits arise from the small dimensions of microdevices which provide predictable thermal and mass transportation properties and unique control over the fluid structure. Enhanced transport characteristics of microreactors allow more precise synthesis of polymers compared to traditional batch reactors. Perhaps most importantly, extreme fluid controllability in a laminar flow system enables synthesis of particles with unique shapes not accessible by other methods. Core–shell type polymers and nonspherical polymers were prepared by controlling the fluidic behavior in microchannels. Also, solid, hollow, and multicored asymmetric and irregularly shaped polymer microparticles as well as membranes and fibers can all be produced with microfluidic devices. These particles are generally monodispersed, and the sizes may be tuned from a few micrometers to hundreds of micrometers, depending on the specific device geometry and flow parameters. The design of fluidic systems therefore becomes quite important. Numerical simulation is useful in designing microreaction devices. Likewise, reproducibility of these particles is quite high when performing the reaction using the same microreaction apparatus because of the simple operation of the reactor and strict control of the reaction conditions provided by the system. The reaction does not require special techniques as in batchwise synthesis. This feature is quite advantageous for production of polymer particles by numbering-up. Utilizing the principle of shape control by fluidic behavior, the elegant technique was applied to control the shape of polymers. Microscope projection photolithographic synthesis of particles is a novel particle formation method [8, 9]. This method enables continuous-flow synthesis of particles with complicated shapes. Polymerization was also carried out across laminar, co-flowing streams to generate Janus particles containing different chemistries, whose relative proportions could be easily tuned. This new high-throughput technique offers unprecedented control over particle size, shape, and anisotropy.

To summarize, polymer synthesis in microfluidic reactors, although in its initial stage, holds a promising future. Many efforts are now in progress in many laboratories to develop generally applicable microreactors for polymer synthesis.

Future Directions for Research

Microreactors will represent an indispensable tool for synthesizing polymers with controlled properties. Microreaction in microfluidic systems will find its way in the shift from conventional batchwise reaction to microreaction strategy. In future, microfluidic devices will find broad applications particularly in linear polymer production aimed at obtaining polymers of desired average molecular weight with narrower molecular weight distribution. In addition, the prospect of making novel polymer particles with unique shapes can be realized by microreaction system via control of specific device geometry and flow parameters. The process of rapid prototyping and the emergence of simple, homemade devices that take only minutes or hours to construct have enabled many groups to explore this exciting field. More and more applications of microfluidic reaction systems for polymer synthesis are required to develop a generally applicable microreactor for polymerization reactions. In addition to simple reactions, an aspect of polymer synthesis that may offer great research opportunity is synthesis of novel particles with unique shapes, and thus the development of microscope

projection photolithography will be necessary. In addition, theoretical studies such as numerical simulations are also required to obtain a generally applicable microreactor. Matching of experimental achievements and theoretical studies may accelerate development of microreactors for polymerization reactions. Still, this field is in its initial stage and has much room for development.

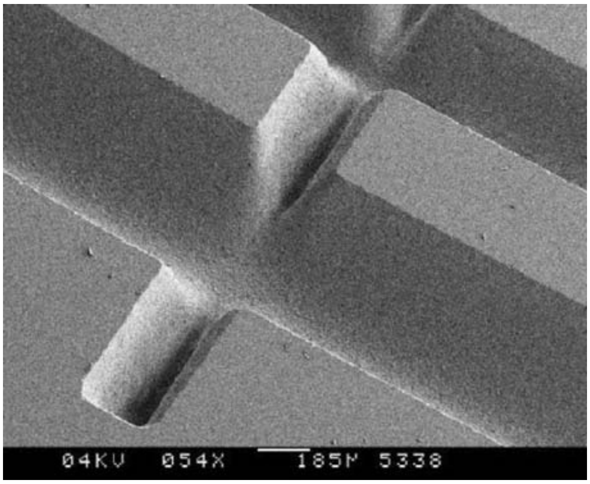
Sand blasting; Micropowder blasting

Definition

Powder blasting is a micromachining technique which uses a high-velocity air jet containing microparticles to impinge on and erode material from a surface.



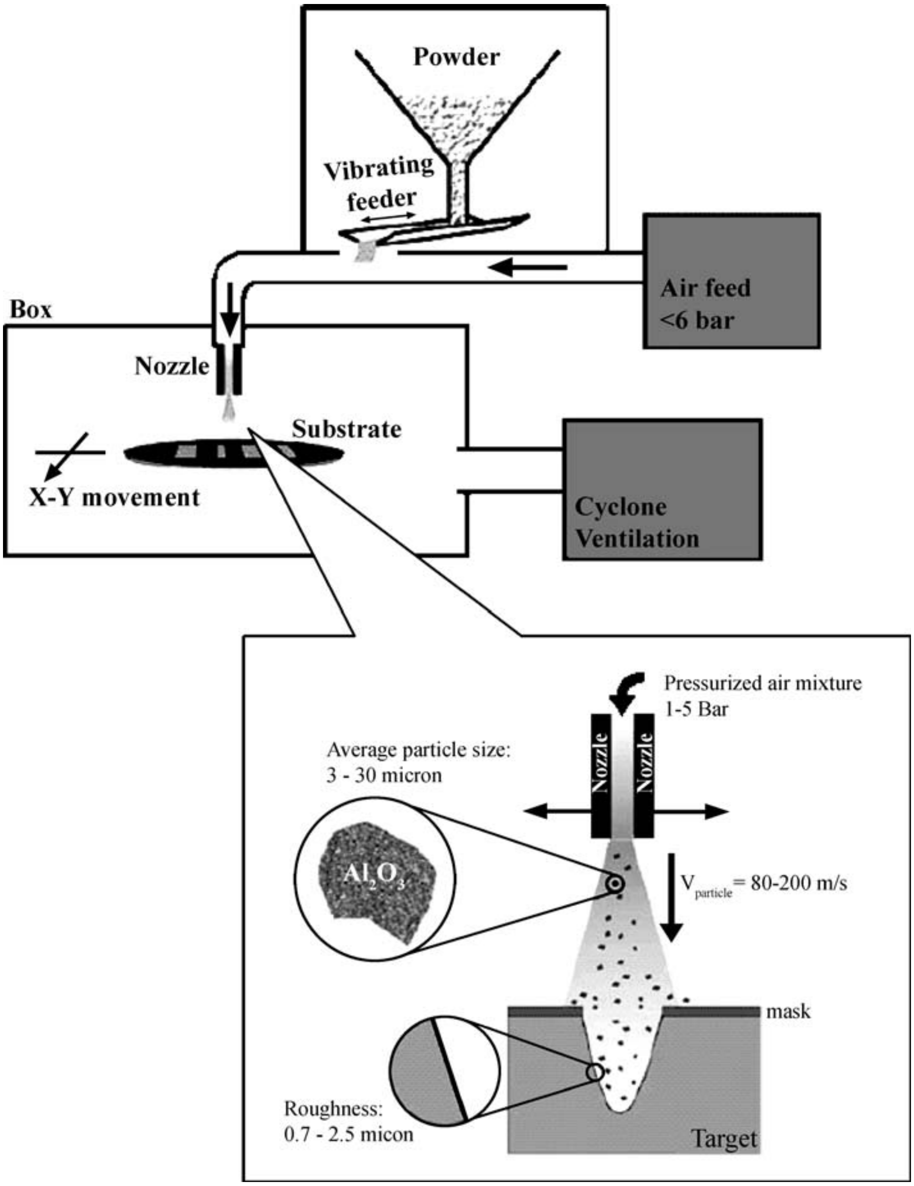
Powder Blasting, Figure 1 Typical etch profile of powder blasting in glass

Overview

Sand blasting is a traditional mechanical processing technique which can be found in a mechanical workshop. Sand blasting has been used commonly for removing rusty surface, dry paints or contaminants from a metal work piece. From the mid-1990s, sand blasting was used to machine large arrays of holes in glass panels for large-area flat panel display devices. Thousands of holes could be machined in the glass at once, which was highly efficient and low cost [1]. Sand blasting was introduced as a microstructuring technique in early 2000, with the name of powder blasting because much smaller particles were used [2]. The principle of power blasting micromachining is that when a powder particle indents the surface of a brittle material such as glass or silicon it generates cracks and a plastic zone around the impact point. There are two types of cracks: lateral and radial. The lateral cracks play a major role in the erosion process because they can reach the surface and remove upper material zone. The radial cracks have no significant contribution in the erosion process, but they weaken the material. The length of such cracks depends on a few parameters like the substrate's Young's modulus and hardness and the indentation volume. These parameters then depend on the kinetic energy of the particle and its shape. Powder blasting has the following features [3]:

- It is only suitable for machining brittle materials, such as glass, silicon and ceramics; it is not suitable for ductile materials, such as metals and polymers. Ductile materials can serve as masking material in powder blasting machining.
- The mask materials for powder blasting are required not only to be ductile but also thick enough. Because high-speed particles inevitably consume the masking layer, even though at a lower rate, when the masking layer reaches a certain thinness the particles with high kinetic energy can penetrate through the mask and damage the work piece surface. The best way of making the mask is to pattern it directly on the work piece surface. For example, a copper layer is deposited by electroplating on the substrate surface and then photolithographically patterned. The selectivity of powder blasting Pyrex glass to copper is 65:1 [4]. Some rubber-like polymers, which are also photon sensitive, can also be used as masking materials.
- Powder blasting is a pure mechanical processing technique. The particle beam from a nozzle is always of the highest speed in the centre, as a result of which the etched profile always has a sloped sidewall. Figure 1 shows typical structure profiles etched by powder blasting [4].
- The resolution of powder blasting is normally above 50 μm. This is mainly attributed to the particle sizes which are around 30 μm. The resolution may increase if smaller particles are used. However, the kinetic energy of particles also reduces for smaller sized particles.
- The roughness of an eroded surface produced by high-speed powder is around the micrometre scale, which is related to the size of the particles.

Powder blasting is not a high-tech machining method. It is for this reason that the technique is less expensive. Powder blasting is particularly useful for making patterns in glass. For micromachining of glass there are no other better techniques apart from wet etching by HF acid. It is well known that HF acid is a hazardous chemical and wet etching by HF is isotropic. Powder blasting is a much better suited



Powder Blasting, Figure 2 Schematic representation of a powder blasting system

method to process glass materials. The structures encountered in microfluidic and biochip systems are normally above a few tens of micrometres, which can be adequately resolved by powder blasting machining [5]. For drilling holes in glass chips, the conventional method is mechanical drilling with a diamond bit. Mechanical drilling can produce chippings on the edge and it becomes extremely difficult to drill thin glass. Powder blasting can machine a large number of holes in glass at once and the quality of the holes is much better than that produced by mechanical drilling.

Basic Methodology

A schematic representation of a powder blasting system is shown in Fig. 2. The microparticles used for powder blasting are not sands, but Al_2O_3 or SiC particles in the size range $20-30\,\mu m$. These are injected from a vibrating feeder into a pressured air flow stream. The pressured particle jet flows through a nozzle and impinge at high velocity normal to the surface of a work piece. The velocity at which the particles impinge on a solid surface is in the range $80-200\,m/s$. These particles with high kinetic

energy can crack and erode the solid surface locally, with etching rate of a few tens to a few hundreds of micrometers per minute, and in extreme cases can be as high as 1 mm/min [2]. The etching rate is directly proportional to the air pressure and the gap distance between the nozzle and surface of the work piece. However, the etching rate becomes saturated when the air pressure is too high and the speed of the air stream approaches the speed of sound. An array of nozzles can be used to etch a large area of surface. The substrate to be blasted is normally mounted on a rotating table, while the nozzle array is fixed. By rotating the table, uniform erosion over a large area of substrate or a number of substrates can be achieved. While the powder jet impinges the substrate, a cyclone ventilation system collects the powders and reuses them. Although small particles can improve the surface roughness of powder blasting, particles smaller than 5 μm cannot be recycled, which is another reason for not using too small powder particles. After powder blasting and removal of the masking layer, the etched surface can be washed clean by water.

There are no commercial powder blasting systems available because there is not such a market. Only a few places worldwide have utilised this technique. There are companies that can make custom designed powder blasting systems. They only make to order. However, there are some companies, such as Micronit in the Netherlands, which provide powder blast micromachining services.

Key Research Findings

Much of the research in powder blasting has been focused on improving resolution and selectivity of masking materials. Currently the resolution of powder blasting is above 50 μm. This is mainly attributed to the particle sizes which are around 30 μm. Using smaller particles can improve resolution and give smaller pattern dimensions. However, there is a limit to the particle size that can be used for powder blasting. As mentioned earlier, there is the sound barrier which limits the velocity of microparticles not to exceed 335 m/s. There is also a threshold kinetic energy above which a particle can crack an eroding material. For powder blasting of soda lime glass with alumina (Al_2O_3) particles, the threshold energy is 25 nJ, from which the minimum size of alumina particles can be estimated to be 6 μm in order to acquire the threshold kinetic energy at the speed of sound [6]. For safety reasons 10 μm alumina particles were used with a velocity of 156 m/s, which helped to achieve a minimum feature size of 30 μm in soda lime glass. However, smaller particles resulted in much less efficiency. Experimental comparison demonstrated that a 10 μm particle is 50 times less efficient than a 30 μm particle in powder blasting. The etch rate is also limited by the mask feature size. The smaller the mask feature size compared to the particle size, the lower the etch rate.

Various photosensitive polymers, as well as metal films, have been used as masking materials. In general, depending on their erosion behaviour, materials can be divided into two classes: one class comprising all materials showing maximum erosion rate at normal impact of particles, and the other class of materials having a maximum erosion rate at a glancing impact angle. Glass belongs to the first class of materials, while metals belong to the second class. Due to their high erosion resistance at normal impact, metals therefore have been used as a masking material. Metallic contact masks can be made by laser ablation or electroplating using a photoresist as a mould. Recent development has shown that elastomers such as polydimethylsiloxane (PDMS) can be used as masking materials [6]. A PDMS mask can be made by casting into a patterned SU-8 mould. The PDMS mask has selectivity of 5000:1 to soda lime glass in powder blasting [7].

Future Directions for Research

Powder blasting as an alterative technique has been increasingly adopted for making microstructures in glass, ceramics or graphite, which are not easy to make by other techniques. Future research will be aimed at improving etching efficiency and resolution by trying out different masking materials or parameters of microparticles and air jet flow.

stephane.colin@insa-toulouse.fr

Synonyms

Poiseuille single phase gas flows

Definition

A pressure-driven gas flow is generated by applying a pressure difference between the inlet and the outlet of a fluidic system, for example a channel. Due to very small hydraulic diameters, pressure-driven gas flows in microchannels are laminar. Gas microflows are distinct from gas macroflows by rarefaction effects which appear as soon as the mean free path of the molecules is no longer negligible compared with the hydraulic diameter of the microchannel. For such rarefied flows, the classic Poiseuille model is no longer valid, and other models should be used, according to the rarefaction level, which is quantified by the Knudsen number.

Overview

Rarefaction Effects and Gas Flow Regimes

Usually, the regime of gas flow in a macrochannel refers to viscous and compressibility effects, respectively quantified by the Reynolds number Re and the Mach number Ma. For low Reynolds numbers (typically for $\mathrm{Re} < 2000$), the flow is laminar and it becomes turbulent for higher values of Re. For $\mathrm{Ma} < 1$, the flow is subsonic and for $\mathrm{Ma} > 1$, it is supersonic. Generally, if $\mathrm{Ma} > 0.3$, compressibility effects should be taken into account.

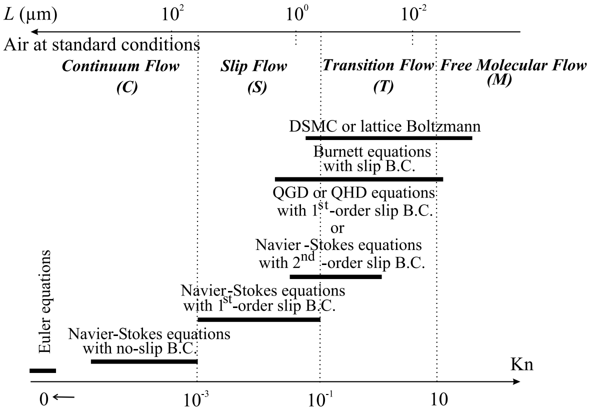
On the other hand, for gas microflows, the main microeffect that results from shrinking down the devices size is rarefaction. Actually, there is a strong – although not complete – analogy between microflows and low pressure flows. Rarefaction, which implies a local thermodynamic disequilibrium, occurs as soon as the mean free path of the gas molecules is no longer negligible compared with a characteristic length of the system.

Thus, it is convenient to differentiate the flow regimes in function of the Knudsen number

$$\mathrm{Kn} = \frac{\lambda}{L}, \tag{1}$$

ratio of the mean free path of the molecules λ over this characteristic length L, and the following classification is usually accepted:

- For $\mathrm{Kn} < 10^{-3}$, the flow is a *continuum flow* **(C)** and it is accurately modeled by the compressible Navier–Stokes equations with classical no-slip boundary conditions.
- For $10^{-3} < \mathrm{Kn} < 10^{-1}$, the flow is a *slip flow* **(S)** and the Navier–Stokes equations remain applicable, provided a velocity slip and a temperature jump are taken into account at the walls. These new boundary conditions point out that rarefaction effects become sensitive at the wall first.



Pressure-Driven Single Phase Gas Flows, Figure 1 Gas flow regimes and main models according to the Knudsen number

- For $10^{-1} < \mathrm{Kn} < 10$, the flow is a *transition flow* **(T)** and the continuum approach of the Navier–Stokes equations is no longer valid. However, the intermolecular collisions are not yet negligible and should be taken into account.
- For $\mathrm{Kn} > 10$, the flow is a *free molecular flow* **(M)** and the occurrence of intermolecular collisions is negligible compared with the one of collisions between the gas molecules and the walls.

The limits of these different regimes are only indicative and could vary from one case to another, partly because the choice of the characteristic length L is rarely unique. For flows in microchannels, L is generally the hydraulic diameter or the depth of the channel. In complex geometrical configurations, it could be preferable to define L from local gradients (for example of the density ρ: $L = 1/|\nabla\rho/\rho|$) rather than from simple geometrical considerations [1]; the Knudsen number based on this characteristic length is the so-called local rarefaction number. The upper axis of Fig. 1 locates these different regimes for air in standard conditions, as a function of a characteristic length, for example a microchannel hydraulic diameter. The lower axis shows the corresponding values of the Knudsen number.

Mean Free Path and Knudsen Number Calculation

Calculating the mean free path requires assumptions about intermolecular collisions. First, the gas is assumed to be a dilute gas, i.e. a gas for which the mean molecular diameter of the molecules is small compared with the mean molecular spacing. This condition is verified with a good precision for all usual gases under standard pressure and temperature conditions. It involves binary collisions between molecules and the mean free path may be expressed as $\lambda = c'/\nu = \sqrt{8RT/\pi}/\nu$, ratio of the mean

P

thermal velocity c' to the collision rate ν. The mean thermal velocity depends on the temperature T and on the specific gas constant R.
For classic collision models, based on an inverse power law (IPL) interaction scheme which only takes into account the repulsion part of the force between two molecules, the expression of ν leads to the general form of the mean free path:

$$\lambda = \frac{k_2 \mu}{\rho \sqrt{RT}} . \tag{2}$$

The mean free path is a function of the temperature T, the density ρ and the dynamic viscosity μ of the gas which itself depends on the temperature as

$$\mu_{(T)} = \mu_{0(T_0)} \left(\frac{T}{T_0} \right)^{\omega} , \tag{3}$$

T_0 being a reference temperature for which the viscosity μ_0 is known.
The values of the dimensionless parameters k_2 and ω for the most classic collision models are given in Table 1. The Maxwell Molecules (MM) model assumes a linear relationship between viscosity and temperature, although for the Hard Sphere (HS) model, the viscosity is proportional to the square root of the temperature. These models could be roughly considered as limits for the real behavior of gases, and the Variable Hard Sphere (VHS) model proposed by Bird [2] is much more accurate. Another sophistication has been proposed by Koura and Matsumoto who developed the Variable Soft Sphere (VSS) model, which introduces via an adjustment parameter α limited corrections – less than 3% – to the evaluation of the mean free path deduced from the VHS model, assuming soft collisions between the molecules. For $\alpha = 1$, the VSS model reduces to the VHS model.
Experimentally deduced values of ω and α are available for different gases (Table 2).

Pressure-Driven Single Phase Gas Flows, Table 1 Mean free path and dynamic viscosity for classic IPL collision models

Model	$\mu \propto T^{\omega}$	$\lambda = k_2 \frac{\mu}{\rho\sqrt{RT}}$
	ω	k_2
Maxwell Molecules (MM)	1	$\sqrt{2/\pi} \approx 0.798$
Hard Spheres (HS)	$\frac{1}{2}$	$\frac{16}{5\sqrt{2\pi}} \approx 1.277$ (sometimes proposed as $\sqrt{\pi/2} \approx 1.253$)
Variable Hard Spheres (VHS)	$\omega = \frac{\eta+3}{2(\eta-1)}$	$\frac{2(7-2\omega)(5-2\omega)}{15\sqrt{2\pi}}$
Variable Soft Spheres (VSS)	$\omega = \frac{\eta+3}{2(\eta-1)}$	$\frac{4\alpha(7-2\omega)(5-2\omega)}{5(\alpha+1)(\alpha+2)\sqrt{2\pi}}$

Ideal Gas Assumption

For a dilute gas in thermodynamic equilibrium, the classic ideal gas equation of state

$$p = \rho RT = nk_{\mathrm{B}} T \tag{4}$$

is valid. If the thermodynamic equilibrium is not verified, Eq. (4) remains valid, providing the thermodynamic temperature T is replaced with the translational kinetic temperature T_{tr}, which measures the mean translational kinetic energy of the molecules. Here, p is the pressure and $\rho = mn$ is the density, $k_{\mathrm{B}} = R'/N = (M/N)(R'/M) = mR = 1.381 \times 10^{-23}\,\mathrm{J\,K^{-1}}$ is the Boltzmann constant, $R' = 8.315\,\mathrm{J\,mol^{-1}\,K^{-1}}$ being the universal gas constant, $N = 6.022 \times 10^{23}\,\mathrm{mol^{-1}}$ the Avogadro's number and M the molecular weight.
As a consequence, for an ideal gas and an IPL collision model, the Knudsen number can be written as

$$\mathrm{Kn} = \frac{k_2 \mu_{(T)} \sqrt{RT}}{pL} , \tag{5}$$

with the value of k_2 given in Table 1.

Modeling Gas Flow in Microchannels

It can be shown from Eq. (5) that for an ideal gas and an IPL collision model,

$$\mathrm{Re} = k_2 \sqrt{\gamma} \mathrm{Ma}/\mathrm{Kn} , \tag{6}$$

since $\mathrm{Re} = \rho u L/\mu$ and $\mathrm{Ma} = u/\sqrt{\gamma RT}$, noting γ the ratio of the specific heats of the gas. As k_2 is of the order of unity (Table 1), the result is that for subsonic microflows, viscous effects are predominant and the flows are laminar.
It can be seen from Fig. 1 that gas flows in micron size channels are typically relevant to the slip flow regime, at any rate for usual pressure and temperature conditions. For lower sizes, i. e. for Knudsen numbers higher than 10^{-1}, the slip flow regime could remain valid, provided that classical velocity slip and temperature jump boundary conditions are modified (taking into account higher order terms as explained below) and/or that Navier–Stokes equations are extended to more general sets of conservation equations, such as the Quasi-Gasodynamic (QGD), the Quasi-Hydrodynamic (QHD) or the Burnett equations [3].
However, for Knudsen numbers higher than unity, as it could be the case in nanochannels (▶ gas flow in nanochannels) or in low-pressure flows in microchannels,

Pressure-Driven Single Phase Gas Flows, Table 2 Molecular weight and dynamic viscosity under standard conditions ($p_0 = 101{,}325$ Pa and $T_0 = 273.15$ K) estimated from a VHS or a VSS model (data from Bird [2]) with corresponding values of ω and α

the continuum approach is not longer valid, and molecular methods such as the Direct Simulation Monte Carlo – DSMC – (► Monte Carlo method) or the Lattice Boltzmann methods (► Lattice Boltzmann method) should be used.

Basic Methodology

For moderate pressure levels, and Knudsen numbers up to 0.5 or so, pressure-driven gas microflows can be modeled with the compressible Navier–Stokes equations, slip velocity and temperature jump boundary conditions, considering the gas as an ideal gas.

Compressible Navier–Stokes Equations

The compressible Navier–Stokes equations are the governing conservation laws for mass, momentum and energy. These laws are written assuming that the fluid is Newtonian and follows the Fourier law of diffusion, so that the stress tensor is a linear function of the velocity gradients and the heat flux vector is proportional to the temperature gradient. Adding Stokes' hypothesis, which expresses that the changes of volume do not involve viscosity, the compressible Navier–Stokes equations may be written as:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{u}) = 0 \tag{7}$$

$$\frac{\partial (\rho \boldsymbol{u})}{\partial t} + \nabla \cdot \left(\rho \boldsymbol{u} \otimes \boldsymbol{u} - \mu \left[\nabla \otimes \boldsymbol{u} + (\nabla \otimes \boldsymbol{u})^{\mathrm{T}} - \frac{2}{3} (\nabla \cdot \boldsymbol{u}) \mathbf{I} \right] \right) + \nabla p = \boldsymbol{f} \tag{8}$$

$$\frac{\partial E}{\partial t} + \nabla \cdot \left((E + p) \boldsymbol{u} - \mu \left[\nabla \otimes \boldsymbol{u} + (\nabla \otimes \boldsymbol{u})^{\mathrm{T}} - \frac{2}{3} (\nabla \cdot \boldsymbol{u}) \mathbf{I} \right] \cdot \boldsymbol{u} - k \nabla T \right) = \boldsymbol{f} \cdot \boldsymbol{u} \tag{9}$$

where $\boldsymbol{u}$ is the velocity vector, $\mathbf{I}$ the unit tensor, t the time and k the thermal conductivity. The total energy per unit volume $E = \rho(e + \boldsymbol{u} \cdot \boldsymbol{u}/2)$ is a function of the internal specific energy e that may be written $e = p/[\rho(\gamma - 1)]$ for an ideal gas.

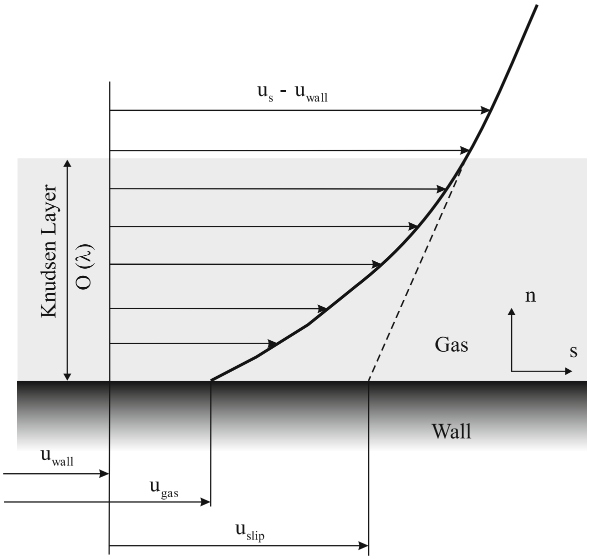
The external volume forces $\boldsymbol{f}$ (gravitational forces, magnetic forces, etc.) are generally negligible in gas flow. It is even more the case in gas microflows, since the volume over surface ratio decreases with the characteristic length L and consequently, in microscale geometries, volume effects may be neglected when compared to surface effects.

P

Knudsen Layer

The Knudsen layer plays a fundamental role in the slip flow regime. This thin layer, between one and two molecular mean free paths in thickness, is a region of local non-equilibrium which is observed in any gas flow near a surface. In non rarefied flows, the Knudsen layer is too thin for having any significant influence, but in the slip flow regime, it should be taken into account.

Although the Navier–Stokes equations are not valid in the Knudsen layer, due to a nonlinear stress/strain-rate behavior in this small layer [4], their use with appropriate boundary velocity slip and temperature jump conditions proved to be accurate for predicting mass flow rates [5] (► methods for flow rate measurements) and velocity profiles out of the Knudsen layer. Classically, the real flow is not simulated within the Knudsen layer, but the influence of the Knudsen layer on the flow outside this non-equilibrium layer is taken into account, replacing the no-slip condition at the wall with a slip-flow condition. For that purpose, a fictitious slip velocity u_{slip} is introduced (Fig. 2). Real slip at the wall, $u_{\mathrm{gas}} - u_{\mathrm{wall}}$, is due to the fact that gas molecules very close to the wall have actually a mean



Pressure-Driven Single Phase Gas Flows, Figure 2 Gas flow regimes and main models according to the Knudsen number

tangential momentum partly due to the non zero momentum of molecules coming from the flow and to the momentum of the molecules reflected by the wall. These reflected molecules keep all their tangential momentum if the reflection is specular, loose all their tangential momentum if the reflection is diffuse or more generally keep only a part of it.

Velocity Slip in the Slip-Flow Regime

The classic slip-flow condition, deduced from a momentum balance at the wall, was first proposed by Maxwell and is generally presented in the form

$$u_{\text{slip}} = \frac{2-\sigma}{\sigma}\lambda \left.\frac{\partial u_s}{\partial n}\right|_w + \frac{3}{4}\frac{\mu}{\rho T}\left.\frac{\partial T}{\partial s}\right|_w . \quad (10)$$

In this equation, σ is the tangential momentum accommodation coefficient, equal to unity for perfectly diffuse molecular reflection and zero for purely specular reflection. In Maxwell's model, u_{slip} overestimates the real velocity at the wall but leads to a rather good prediction of the velocity out of the Knudsen layer, as represented in Fig. 2. After non-dimensionalization with the characteristic length L, a reference velocity u_0 and a reference temperature T_0, Eq. (10) is written as follows:

$$u^*_{\text{slip}} = \frac{2-\sigma}{\sigma}\text{Kn}\left.\frac{\partial u^*_s}{\partial n^*}\right|_w + \frac{3}{4\gamma k_2^2}\frac{\text{Kn}^2\text{Re}_0}{\text{Ma}_0^2}\left.\frac{\partial T^*}{\partial s^*}\right|_w , \quad (11)$$

with $u^*_s = u_s/u_0$, $T^* = T/T_0$, $n^* = n/L$ and $s^* = s/L$. Note that this non-dimensionalization is valid only if the reference lengths are the same in the s and n directions, which is generally not the case for a flow in a microchannel. In that case, it is preferable to keep the dimensional form of Eq. (10). The second term on the right-hand side, which is proportional to the square of the Knudsen number, involves the Reynolds number $\text{Re}_0 = \rho u_0 L/\mu$ and the Mach number $\text{Ma}_0 = u_0/\sqrt{\gamma R T_0}$ defined at the reference conditions. This second term is associated with the thermal creep, or transpiration phenomenon. It shows that a flow can be induced by the sole presence of a tangential temperature gradient, without any pressure gradient. In that case, the gas experiences a slip velocity and moves from the colder toward the warmer region. This can also result in a pressure variation inside a microchannel only submitted to tangential temperature gradients. Given that we consider here pressure driven flows, we assume that there is no thermal creep and that the only cause of flow is a pressure gradient. As a consequence, the first-order slip flow boundary condition is written

$$u^*_{\text{slip}} = \beta_u \frac{2-\sigma}{\sigma}\text{Kn}\left.\frac{\partial u^*_s}{\partial n^*}\right|_w = A_1 \text{Kn}\left.\frac{\partial u^*_s}{\partial n^*}\right|_w . \quad (12)$$

A corrective coefficient β_u has been calculated by different authors [6] who have shown that a better prediction of the flow out of the Knudsen layer would be obtained with this corrective coefficient slightly different from unity, unlike as initially proposed by Maxwell. Its value depends on the collision model: for example, $\beta_u = 1.11$ for a HS model [7]. Equation (12) is called first-order slip boundary condition, because it involves the Knudsen number ($\vartheta(\text{Kn})$) and the first derivative $(\partial u^*_s/\partial n^*)_w$.

For $\text{Kn} > 0.1$, experimental [5] or numerical studies with the DSMC method show significant deviations with models based on first-order boundary conditions. Therefore, since 1947, several authors have proposed second-order boundary conditions, hoping to extend the validity of the slip flow regime to higher Knudsen numbers. Second-order boundary conditions take more or less complicated forms, which are difficult to group together in a sole equation. Actually, according to the assumptions, the second-order terms ($\vartheta(\text{Kn}^2)$) may be dependent of σ [8, 9] or involve streamwise second derivatives $(\partial^2 u^*/\partial s^{*2})_w$, in addition to spanwise second derivatives $(\partial^2 u^*/\partial n^{*2})_w$ [10]. For a developed flow between plane plates or in a circular microtube, the tangential second derivatives are zero and one may compare most of the second-order models that take the generic form

$$u^*_{\text{slip}} = A_1 \text{Kn}\frac{\partial u^*_s}{\partial n^*} + A_2 \text{Kn}^2 \frac{\partial^2 u^*_s}{\partial n^{*2}} . \quad (13)$$

Pressure-Driven Single Phase Gas Flows, Table 3 Coefficients of some second-order boundary conditions proposed in the literature, for $\sigma = 1$

Author, Year	A_1	A_2

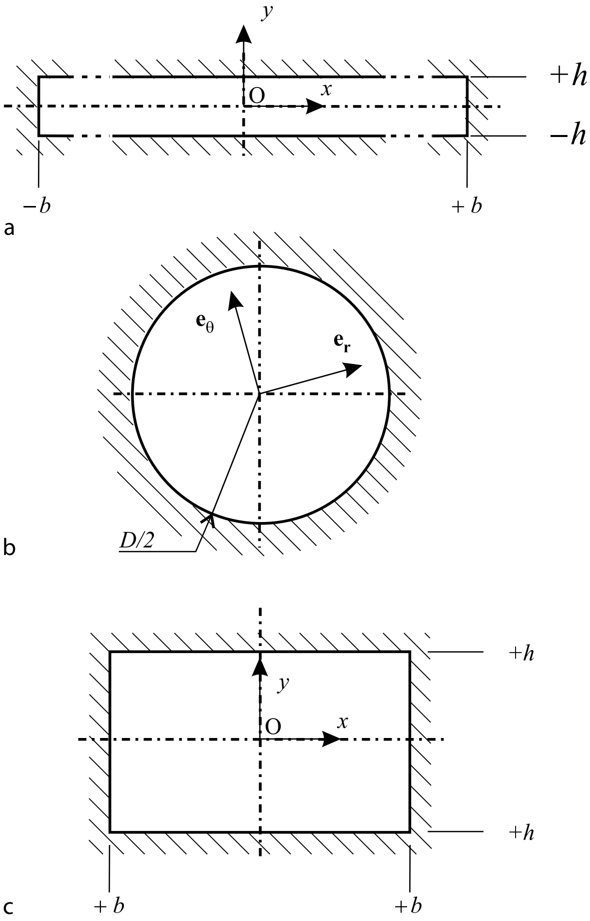
In the particular case of a fully diffuse reflection ($\sigma = 1$), some A_1 and A_2 coefficients proposed in the literature are compared in Table 3. We note significant differences, essentially for the second-order term. Recent experimental flow rate data and molecular numerical simulations show that the second order coefficient A_2 should be negative, which corresponds to a slip velocity higher than that predicted by a first-order slip boundary condition.

Pressure Driven Isothermal Flows in Microchannels

We consider here the flow of an ideal gas through different microchannels in the slip-flow regime. The flow is steady, isothermal and the volume forces are neglected. The flow is also assumed to be locally fully developed: the velocity profile in a section is the same as the one obtained for a fully developed incompressible flow, but the density is recalculated in each cross-section and depends on the pressure and the temperature via the equation of state (4). This assumption is no longer valid if the Mach number is greater than 0.3. The main kinds of sections of interest are the rectangular and the circular sections. Microchannels with rectangular cross-sections are easily etched in silicon wafers, for example by reactive ion etching (RIE) or by deep reactive ion etching (DRIE). If the aspect ratio of the section is small enough, the flow may be considered as a plane flow between parallel plates and the modeling is much simpler. Gas flows in circular microtubes are also frequently encountered, for example in chromatography applications. Fused silica microtubes are proposed by different suppliers with a variety of internal diameters, from one micrometer to hundreds of micrometers. Due to their low cost, they are an interesting solution as connecting lines for a number of microfluidics devices or prototypes.



Pressure-Driven Single Phase Gas Flows, Figure 3 Different microchannel sections; **a** plane channel limited by parallel plates ($b \gg h$), **b** circular duct, **c** rectangular channel

The streamwise coordinate is z and the cross-section is in the (x, y) plane. The different considered sections are represented in Fig. 3.

Two different Knudsen numbers are usually defined for microchannel flows:

$$\mathrm{Kn} = \frac{\lambda}{D_{\mathrm{H}}} = \frac{\lambda}{4A/P} \tag{14}$$

is defined from the hydraulic diameter D_{H} as a reference length. The section area is noted A and the wetted perimeter is noted P. On the other hand,

$$\mathrm{Kn}' = \frac{\lambda}{L_{\min}} \tag{15}$$

is defined from the minimal representative length of the section.

Key Research Findings

Pressure Driven Flows Between Parallel Plates

In the case of a plane flow (Fig. 3a), $h/b \to 0$ and the velocity only depends on the transverse coordinate y. With the previous assumptions, the momentum Eq. (8) reduces to

$$\frac{\mathrm{d}^2 u_z}{\mathrm{d}y^2} = \frac{1}{\mu}\frac{\mathrm{d}p}{\mathrm{d}z}\,. \tag{16}$$

The first-order boundary condition (12) for a fixed wall and an isothermal flow is $u_s|_w = A_1\lambda\,(\partial u_s/\partial n)_w$, i.e. for a flow between parallel plates:

$$u_z|_{y=h} = -A_1\lambda \left.\frac{\partial u_z}{\partial y}\right|_{y=h}, \tag{17}$$

to be associated with the condition of symmetry (cf. Fig. 3)

$$\left.\frac{\mathrm{d}u_z}{\mathrm{d}y}\right|_{y=0} = 0\,. \tag{18}$$

The solution of this set of equations is

$$u_z = \frac{1}{\mu}\frac{\mathrm{d}p}{\mathrm{d}z}\left(\frac{y^2-h^2}{2} - A_1\lambda h\right). \tag{19}$$

In a dimensionless form, the velocity distribution can be written as

$$u_z^* = 1 - y^{*2} + 8A_1\mathrm{Kn} = 1 - y^{*2} + 4A_1\mathrm{Kn}'\,, \tag{20}$$

where $y^* = y/h$, $u_z^* = u_z/u_{z0}$ and $u_{z0} = u_{z\,(y=0,\mathrm{Kn}=0)} = -\left(h^2/[2\mu]\right)\left(\mathrm{d}p/\mathrm{d}z\right)$ represents the velocity at the center of the section when rarefaction is not taken into account.
The integration of the velocity distribution given by Eq. (20) over the cross-section leads to the mean velocity

$$\overline{u_z^*} = \frac{1}{2}\int_{-1}^{1} u_z^*\,\mathrm{d}y^* = \frac{\overline{u_z}}{u_{z0}} = \frac{2}{3} + 8A_1\mathrm{Kn} = \frac{2}{3} + 4A_1\mathrm{Kn}'\,. \tag{21}$$

Considering a long microchannel of length l with a pressure p_i at the inlet and a pressure p_o at the outlet and neglecting the entrance effects, we can deduce from Eq. (21) the mass flow rate $\dot{m} = \rho\overline{u_z}A = p\overline{u_z}A/(RT)$, which is independent of z. According to Eq. (5), the quantity ($\mathrm{Kn}p$) is constant for an isothermal flow and it can be written as a function of the outlet conditions: $\mathrm{Kn}p = \mathrm{Kn_o}p_o$. Therefore, the integration of Eq. (21) yields

$$\int_{p_i}^{p_o}\left(\frac{2}{3}p + 8A_1\mathrm{Kn_o}p_o\right)\mathrm{d}p = -\frac{2\mu\dot{m}RTl}{h^2A}\,, \tag{22}$$

which leads to

$$\dot{m}_{\mathrm{NS1,plan}} = \frac{2bh^3p_o^2}{\mu RTl}\left[\frac{\Pi^2-1}{3} + 8A_1\mathrm{Kn_o}\,(\Pi-1)\right], \tag{23}$$

where $\Pi = p_i/p_o$ is the ratio of the inlet over outlet pressures and $\mathrm{Kn_o}$ is the outlet Knudsen number. The subscript NS1 refers to the Navier–Stokes equations with first-order slip boundary conditions. In a dimensionless form that compares the actual mass flow rate $\dot{m}$ with the mass flow rate $\dot{m}_{ns}$ obtained from a no-slip hypothesis, Eq. (23) becomes:

$$\dot{m}^*_{\mathrm{NS1,plan}} = \frac{\dot{m}_{\mathrm{NS1,plan}}}{\dot{m}_{ns,\mathrm{plan}}} = 1 + 24A_1\frac{\mathrm{Kn_o}}{\Pi+1} = 1 + 12A_1\frac{\mathrm{Kn'_o}}{\Pi+1}\,. \tag{24}$$

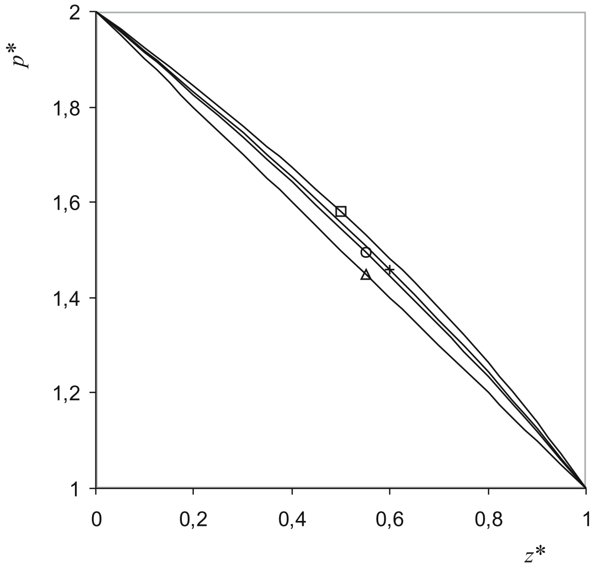
The pressure distribution along the z-axis can be found by expressing the conservation of mass flow rate through the channel, notably between any section defined by z and the outlet section:

$$\dot{m}_{\mathrm{NS1,plan}} = \frac{2bh^3p_o^2}{\mu RT\,(l-z)} \times \left[\frac{(p/p_o)^2-1}{3} + 8A_1\mathrm{Kn_o}\,(p/p_o-1)\right]. \tag{25}$$

Equation (25) shows that the pressure $p^* = p/p_o$ is the solution of the polynomial

$$p^{*2} + \alpha_1 p^* + \alpha_2 + \alpha_3 z^* = 0\,, \tag{26}$$

where $z^* = z/l$ and $\alpha_1 = 24A_1\mathrm{Kn_o}$, $\alpha_2 = -\Pi(\Pi+\alpha_1)$, $\alpha_3 = (\Pi-1)(\Pi+1+\alpha_1)$.
The solution of Eq. (26) is plotted in Fig. 4, for an inlet over outlet pressure ratio $\Pi = 2$. This figure shows that rarefaction and compressibility have opposite effects on the pressure distribution. Rarefaction effects (characterized by Kn) reduce the curvature in pressure distribution due to compressibility effects (characterized by Ma).
Therefore, the previous model can be improved to remain accurate for higher Knudsen numbers. For this purpose,



Pressure-Driven Single Phase Gas Flows, Figure 4 Pressure distribution along a plane microchannel, for $\Pi = 2$.
(△): incompressible flow; (□): $\mathrm{Kn_o} = 0$; (+): $\mathrm{Kn_o} = 0.05$; (○): $\mathrm{Kn_o} = 0.1$

second-order – $\vartheta(\mathrm{Kn}^2)$ – models, based on second-order boundary conditions, may be used.

It is easy to verify that the mass flow rate is consequently corrected as:

$$\begin{aligned}\dot{m}^*_{\mathrm{NS2,plan}} &= \frac{\dot{m}_{\mathrm{NS2,plan}}}{\dot{m}_{ns,\mathrm{plan}}} \\ &= 1 + 24A_1\frac{\mathrm{Kn_o}}{\Pi+1} - 96A_2\mathrm{Kn_o^2}\frac{\ln\Pi}{\Pi^2-1} \\ &= 1 + 12A_1\frac{\mathrm{Kn'_o}}{\Pi+1} - 24A_2\mathrm{Kn'_o}^2\frac{\ln\Pi}{\Pi^2-1}\,. \end{aligned} \quad (27)$$

Pressure Driven Flows in Circular Microtubes

With the same general assumptions than in the previous section, the momentum Eq. (8) in polar coordinates reduces to

$$\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left(r\frac{\mathrm{d}u_z}{\mathrm{d}r}\right) = \frac{1}{\mu}\frac{\mathrm{d}p}{\mathrm{d}z}\,. \quad (28)$$

The first-order boundary condition (12) for a non-moving wall and an isothermal flow is now (cf. Fig. 3b):

$$u_z|_{r=D/2} = -A_1\lambda\left.\frac{\partial u_z}{\partial r}\right|_{r=D/2}, \quad (29)$$

which leads to the dimensionless velocity profile

$$u_z^* = 1 - r^{*2} + 4A_1\mathrm{Kn} \quad (30)$$

where the Knudsen number $\mathrm{Kn} = \lambda/D_\mathrm{H} = \lambda/D = \mathrm{Kn}' = \lambda/L_\mathrm{min}$ is defined from a characteristic length $L = D$. Here, $r^* = 2r/D$ and $u_z^* = u_z/u_{z0}$ with $u_{z0} = -\left(D^2/[16\mu]\right)(\mathrm{d}p/\mathrm{d}z)$. The integration of the velocity within a section and along the microtube leads to

$$\dot{m}_{\mathrm{NS1,circ}} = \frac{\pi D^2 p_\mathrm{o}^2}{16\mu RTl}\left[\frac{\Pi^2-1}{4} + 4A_1\mathrm{Kn_o}(\Pi-1)\right] \quad (31)$$

for a long microtube, neglecting entrance effects and

$$\dot{m}^*_{\mathrm{NS1,circ}} = \frac{\dot{m}_{\mathrm{NS1,circ}}}{\dot{m}_{ns,\mathrm{circ}}} = 1 + 16A_1\frac{\mathrm{Kn_o}}{\Pi+1}\,. \quad (32)$$

The pressure distribution $p^* = p/p_\mathrm{o}$ along the microtube is the solution of the polynomial

$$p^{*2} + \beta_1 p^* + \beta_2 + \beta_3 z^* = 0\,, \quad (33)$$

where $\beta_1 = 16A_1\mathrm{Kn_o}$, $\beta_3 = (\Pi-1)(\Pi+1+\beta_1)$ and $\beta_2 = -1-\beta_1-\beta_3$, which qualitatively leads to the same conclusions as for a plane flow.

The first-order solution can easily be extended to second-order boundary conditions, following the same reasoning as in the previous section. We find

$$\begin{aligned}\dot{m}^*_{\mathrm{NS2,circ}} &= \frac{\dot{m}_{\mathrm{NS2,circ}}}{\dot{m}_{ns,\mathrm{circ}}} \\ &= 1 + 16A_1\frac{\mathrm{Kn_o}}{\Pi+1} - 32A_2\frac{\mathrm{Kn_o^2}\ln\Pi}{\Pi^2-1}\,. \end{aligned} \quad (34)$$

Pressure Driven Flows in Rectangular Microchannels

A rectangular section is characterized by its aspect ratio $a^* = h/b$, with $0 < a^* \le 1$, assuming $h \le b$ (Fig. 3c). Actually, calculation of the mass flow rate in a rectangular microchannel using the plane flow solution (24) or (27) is inaccurate as soon as the aspect ratio of the section a^* is higher than 10^{-2}, due to non-negligible friction on the side walls of equations $x = \pm b$. Typically, the overestimation $[(\dot{m}_\mathrm{plan} - \dot{m}_\mathrm{rect})/\dot{m}_\mathrm{rect}]_\mathrm{NS2}$ is about 0.5% for an aspect ratio $a^* = 0.01$, it rises to 5.3% for an aspect ratio $a^* = 0.1$ and reaches 112% for a square cross-section for which $a^* = 1$! As a consequence, a real 3D model is required. With the general assumptions of previous sections, the momentum equation takes the dimensionless form

$$a^{*2}\frac{\mathrm{d}^2u_z^*}{\mathrm{d}x^{*2}} + \frac{\mathrm{d}^2u_z^*}{\mathrm{d}y^{*2}} = -1\,, \quad (35)$$

with $x^* = x/b$, $y^* = y/h$ and $u_z^* = -\mu u_z/(h^2(\mathrm{d}p/\mathrm{d}z))$.

P

The first-order boundary conditions are

$$u_z^*\big|_{y^*=1} = -2A_1\text{Kn}' \left.\frac{\partial u_z^*}{\partial y^*}\right|_{y^*=1} , \tag{36}$$

$$u_z^*\big|_{x^*=1} = -2a^*A_1\text{Kn}' \left.\frac{\partial u_z^*}{\partial x^*}\right|_{x^*=1} , \tag{37}$$

with $\text{Kn}' = \lambda/(2h)$ and the conditions of symmetry are $\left(\text{d}u_z^*/\text{d}y^*\right)_{y^*=0} = 0$ and $(\text{d}u_z^*/\text{d}x^*)_{x^*=0} = 0$. The solution of Eqs. (35) to (37), compatible with the conditions of symmetry can be written as

$$u_z^* = -\sum_{i=1}^{\infty} \Psi_i\left(x^*\right)\cos\left(\delta_i y^*\right) , \tag{38}$$

where the eigenvalues δ_i must verify

$$\delta_i \tan\delta_i = \frac{A_1}{2\text{Kn}'} \tag{39}$$

in order to be compatible with the boundary condition (36) without leading to a trivial velocity solution. The x^* dependent Ψ_i functions are found by expanding the right-hand side of Eq. (35), i. e. unity, in terms of the orthogonal functions $\cos\left(\delta_i y^*\right)$:

$$\begin{aligned} -1 &= -\sum_{i=1}^{\infty} \frac{2\sin\delta_i}{\delta_i + \sin\delta_i\cos\delta_i}\cos\left(\delta_i y^*\right) \\ &= -\sum_{i=1}^{\infty} \Omega_i\cos\left(\delta_i y^*\right) . \end{aligned} \tag{40}$$

Therefore, to verify the momentum Eq. (35), the functions Ψ_i must obey

$$\frac{d^2\Psi_i}{dx^{*2}} - \left(\frac{\delta_i}{a^*}\right)^2 \Psi_i - \frac{\Omega_i}{a^{*2}} = 0 . \tag{41}$$

The solution of Eq. (41), with the boundary and symmetry conditions and using Eq. (39), is

$$\Psi_i = -\frac{\Omega_i}{\alpha_i^2}\left(1 - \frac{\cosh\left(\frac{\alpha_i x^*}{a^*}\right)}{\cosh\left(\frac{\alpha_i}{a^*}\right) + 2A_1\text{Kn}'\alpha_i\sinh\left(\frac{\alpha_i}{a^*}\right)}\right) . \tag{42}$$

Consequently, the velocity distribution is given by Eq. (38), where Ψ_i and δ_i are obtained from Eqs. (40) and (42). This solution is given as a function of a Knudsen number $\text{Kn}' = \lambda/(2h)$ based on the channel depth, but it can also be expressed as a function of the Knudsen number $\text{Kn} = \lambda/D_\text{H}$ based on the hydraulic diameter, using the relation $2\text{Kn} = \text{Kn}'\left(1 + a^*\right)$.

The solution of the problem with Deissler [10] second-order boundary conditions is detailed in [3]. These boundary conditions may be written in a dimensionless form as

$$\begin{aligned} u_z^*\big|_{y^*=1} &= -2A_1\text{Kn}' \left.\frac{\partial u_z^*}{\partial y^*}\right|_{y^*=1} \\ &\quad - \frac{9}{4}\text{Kn}'^2\left(\left.\frac{\partial^2 u_z^*}{\partial y^{*2}}\right|_{y^*=1} - 1\right) \end{aligned} \tag{43}$$

and

$$\begin{aligned} u_z^*\big|_{x^*=1} &= -2A_1a^*\text{Kn}' \left.\frac{\partial u_z^*}{\partial x^*}\right|_{x^*=1} \\ &\quad - \frac{9}{4}\text{Kn}'^2\left(a^{*2}\left.\frac{\partial^2 u_z^*}{\partial x^{*2}}\right|_{x^*=1} - 1\right) . \end{aligned} \tag{44}$$

for a locally fully developed flow in a rectangular section. A semi-analytical solution for the mass flow is found as [3]:

$$\dot{m}_{\text{NS2,rect}} = -\frac{4ph^4}{a^*RT\mu}\frac{\text{d}p}{\text{d}z}\left[a_1 + a_2\text{Kn}' + a_3\text{Kn}'^2\right] . \tag{45}$$

Values of a_1, a_2 and a_3 coefficients are given in Table 4, for different aspect ratios and values of A_1.

Temperature Jump and Heat Transfer

As for the velocity, it can be shown that the temperature experiences a jump at the wall, which can be written

$$\begin{aligned} T^* - T^*_\text{wall} &= \beta_T\frac{2-\sigma_T}{\sigma_T}\frac{2\gamma}{\gamma+1}\frac{\text{Kn}}{\text{Pr}}\left.\frac{\partial T^*}{\partial n^*}\right|_w \\ &= B_1\frac{2\gamma}{\gamma+1}\frac{\text{Kn}}{\text{Pr}}\left.\frac{\partial T^*}{\partial n^*}\right|_w , \end{aligned} \tag{46}$$

where Pr is the Prandtl number and σ_T is the energy accommodation coefficient; β_T is a corrective coefficient introduced by Cercignani to improve the original formula proposed by Smoluchowski. This temperature jump must be taken into account as well as the velocity slip if the flow is not isothermal and if heat transfer is considered (►convective heat transfer in microchannels). For example, for a hydrodynamically and thermally developed flow in a plane microchannel (Fig. 3a) with a lower adiabatic

wall and an upper wall with constant heat flux, the Nusselt number Nu can be calculated and is given by

$$\mathrm{Nu}^{-1} = \frac{\varsigma^*}{4} + \frac{26 + 147\xi^* + 210\xi^{*2}}{140\,(1 + 3\xi^*)^2}\,, \qquad (47)$$

where $\xi^* = 4A_1\mathrm{Kn}$ and $\varsigma^* = (8\gamma)/(\gamma+1)B_1(\mathrm{Kn}/\mathrm{Pr})$ are the dimensionless slip and temperature jump coefficients. This Nusselt number reduces to the classic value 70/13 when $\mathrm{Kn} = 0$.

Future Directions for Research

Theoretical knowledge on pressure-driven gas microflows is currently well advanced, especially in the slip-flow regime. However, there is yet a need for accurate experimental data, both for steady or unsteady gas microflows, with or without heat transfer. For example, in order to definitely validate the choice of the best boundary conditions in the slip flow regime, we need to isolate the influence of the accommodation coefficients, as it remains an open issue. Relationships between their values, the nature of the substrate and the micro fabrication processes involved are currently not available. There are also few data about flows of gas mixtures in microchannels.

Pressure-Driven Single Phase Liquid Flows

Gian Luca Morini
DIENCA, Università di Bologna, Bologna, Italy
gianluca.morini@mail.ing.unibo.it

Definition

The forced mass movement of single phase liquids through microchannels with a hydraulic diameter less than 1 mm induced by a pressure gradient imposed at the ends of the microchannel is called pressure-driven single phase liquid flow.

Overview

Investigation of the flow phenomena in pipes and channels is the most important subject of hydraulics. In the middle of the nineteenth century an exact solution of the hydrodynamic equations was derived for the flow of a fluid through straight tubes of circular cross-section by Hagen [1] and Poiseuille [2] independently. It is interesting to highlight that the original experimental work of Poiseuille was conducted by testing water through glass capillary tubes having an internal diameter down to 15 μm. This work can be considered the first experimental test of pressure-driven single phase liquid flows in microchannels.

Basic Methodology

The behavior of isothermal pressure-driven single phase fluid flows in microchannels can be studied by determining the velocity distribution in the fluid region with the aid of the mass conservation principle (*continuity equation*) and the equations of conservation of fluid momentum [3]:

$$
\begin{aligned}
-\frac{1}{\rho}\frac{D\rho}{Dt} &= \nabla \cdot \boldsymbol{v} \\
\rho\frac{D\boldsymbol{v}}{Dt} &= -\nabla p + \rho \boldsymbol{g} - \nabla \cdot \boldsymbol{\tau}
\end{aligned}
\qquad (1)
$$

in which $\boldsymbol{v}$ is the velocity vector, ρ is the fluid density, t is the time, p is the pressure, D/Dt is the total derivative and $\boldsymbol{\tau}$ is the viscous tensor.

In Table 1 the components of the viscous tensor for Newtonian fluids are reported for Cartesian, cylindrical and spherical coordinates.

In order to solve the continuity and momentum balance equations (Eq. (1)) the following *constitutive laws* have to be taken into account:

$$
\begin{cases}
\rho = \rho(p, T) \\
\mu = \mu(p, T)
\end{cases}
\qquad (2)
$$

Pressure-Driven Single Phase Liquid Flows, Table 1 Components of the viscous tensor for Cartesian, cylindrical and spherical coordinates

Cartesian coordinates (x, y, z)	$\tau_{xx} = -\mu\left[2\frac{\partial v_x}{\partial x} - \frac{2}{3}(\nabla \cdot \boldsymbol{v})\right]$
	$\tau_{yy} = -\mu\left[2\frac{\partial v_y}{\partial y} - \frac{2}{3}(\nabla \cdot \boldsymbol{v})\right]$
	$\tau_{zz} = -\mu\left[2\frac{\partial v_z}{\partial z} - \frac{2}{3}(\nabla \cdot \boldsymbol{v})\right]$
	$\tau_{xy} = \tau_{yx} = -\mu\left[\frac{\partial v_x}{\partial y} + \frac{\partial v_y}{\partial x}\right]$
	$\tau_{yz} = \tau_{zy} = -\mu\left[\frac{\partial v_y}{\partial z} + \frac{\partial v_z}{\partial y}\right]$
	$\tau_{zx} = \tau_{xz} = -\mu\left[\frac{\partial v_z}{\partial x} + \frac{\partial v_x}{\partial z}\right]$
Cylindrical Coordinates (r, θ, z)	$\tau_{rr} = -\mu\left[2\frac{\partial v_r}{\partial r} - \frac{2}{3}(\nabla \cdot \boldsymbol{v})\right]$
	$\tau_{\theta\theta} = -\mu\left[2\left(\frac{1}{r}\frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r}\right) - \frac{2}{3}(\nabla \cdot \boldsymbol{v})\right]$
	$\tau_{zz} = -\mu\left[2\frac{\partial v_z}{\partial z} - \frac{2}{3}(\nabla \cdot \boldsymbol{v})\right]$
	$\tau_{r\theta} = \tau_{\theta r} = -\mu\left[r\frac{\partial}{\partial y}\left(\frac{v_\theta}{r}\right) + \frac{1}{r}\frac{\partial v_r}{\partial \theta}\right]$
	$\tau_{\theta z} = \tau_{z\theta} = -\mu\left[\frac{\partial v_\theta}{\partial z} + \frac{1}{r}\frac{\partial v_z}{\partial \theta}\right]$
	$\tau_{zr} = \tau_{rz} = -\mu\left[\frac{\partial v_z}{\partial r} + \frac{\partial v_r}{\partial z}\right]$
Spherical coordinates (r, θ, ϕ)	$\tau_{rr} = -\mu\left[\frac{\partial v_r}{\partial r} - \frac{2}{3}(\nabla \cdot \boldsymbol{v})\right]$
	$\tau_{\theta\theta} = -\mu\left[2\left(\frac{1}{r}\frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r}\right) - \frac{2}{3}(\nabla \cdot \boldsymbol{v})\right]$
	$\tau_{\phi\phi} = -\mu\left[2\left(\frac{1}{r\sin\theta}\frac{\partial v_\phi}{\partial \phi} + \frac{v_r}{r} + \frac{v_\theta \cot\theta}{r}\right) - \frac{2}{3}(\nabla \cdot \boldsymbol{v})\right]$
	$\tau_{r\theta} = \tau_{\theta r} = -\mu\left[r\frac{\partial}{\partial y}\left(\frac{v_\theta}{r}\right) + \frac{1}{r}\frac{\partial v_r}{\partial \theta}\right]$
	$\tau_{\theta\phi} = \tau_{\phi\theta} = -\mu\left[\frac{\sin\theta}{r}\frac{\partial}{\partial \theta}\left(\frac{v_\phi}{\sin\theta}\right) + \frac{1}{r\sin\theta}\frac{\partial v_\theta}{\partial \phi}\right]$
	$\tau_{\phi r} = \tau_{r\phi} = -\mu\left[\frac{1}{r\sin\theta}\frac{\partial v_r}{\partial \phi} + r\frac{\partial}{\partial r}\left(\frac{v_\phi}{r}\right)\right]$

If the flow is isothermal, Eqs. (1) and (2) allow the calculation of the pressure field and of the velocity vector $(p, \boldsymbol{v})$ in the fluid region.

It is possible to demonstrate that, for Newtonian fluids with constant viscosity μ, the following equality is satisfied:

$$
(\nabla \cdot \boldsymbol{\tau})_i = -\mu\left[\nabla^2 v_i + \frac{1}{3}\frac{\partial}{\partial i}(\nabla \cdot \boldsymbol{v})\right] \qquad (3)
$$

where $i = x, y, z$ for Cartesian coordinates.

Combining Eq. (3) and the momentum equation one obtains

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = -\nabla p + \rho \boldsymbol{g} + \mu \left[\nabla^2 \boldsymbol{v} + \frac{1}{3} \nabla (\nabla \cdot \boldsymbol{v}) \right] \tag{4}$$

This version of the momentum equation is known as the *Navier–Stokes equation*.

For an incompressible ($\rho = \text{const}$) and Newtonian fluid with constant viscosity ($\mu = \text{const}$) the continuity and the momentum balance equations can be written as follows:

$$\nabla \cdot \boldsymbol{v} = 0$$

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = -\nabla p + \rho \boldsymbol{g} + \mu \nabla^2 \boldsymbol{v} \tag{5}$$

The momentum balance equation can be simplified in the case of very slow fluid motion. In this case the total derivative of the velocity and the acceleration due to the gravity can be neglected in the *Navier–Stokes equation*:

$$\mu \nabla^2 \boldsymbol{v} = \nabla p \tag{6}$$

Equation (6) applies to the analysis of fluid behavior in tribology and microchannel flows: this kind of flow is called *Stokes flow*. In this case, the velocities are free of macroscopic fluctuations at any point in the flow field and the flow is defined as *laminar*.

For a laminar flow through a straight microchannel the fluid particles move in definite paths called streamlines and there are no components of fluid velocity normal to the duct axis. The projection of Eq. (6) along the axial direction (z) gives

$$\mu \nabla^2 v_z = \frac{\mathrm{d}p}{\mathrm{d}z} \tag{7}$$

Equations (6) and (7) are valid only far from the inlet section of the microchannel (see ► developing flows and ► entrance region) where the velocity profile can be considered hydrodynamically fully developed. Laminar flow is designated as hydrodynamically fully developed when the fluid velocity distribution at a cross-section is of an invariant form independent of the axial distance z.

Laminar Regime

Let us consider a liquid flowing through a straight microchannel having an axially unchanging and uniform cross-section with an area equal to Ω and the perimeter equal to Γ. It is possible to define the *hydraulic diameter* of the microchannel as follows:

$$D_\mathrm{h} = \frac{4\Omega}{\Gamma} \tag{8}$$

and the *mean fluid velocity* as the integrated average axial velocity over the flow area Ω:

$$W = \frac{1}{\Omega} \int_\Omega v_z d\Omega = \frac{\dot{m}}{\rho \Omega} \tag{9}$$

in which the link with measurable quantities, like the mass flow rate, is highlighted.

It is suitable to introduce the dimensionless quantities

$$\Omega^* = \frac{\Omega}{D_\mathrm{h}^2}; \quad \Gamma^* = \frac{\Gamma}{D_\mathrm{h}}; \quad \nabla^* = D_\mathrm{h} \nabla;$$

$$V_z = \frac{v_z}{W}; \quad c_1 = -\frac{D_\mathrm{h}^2}{\mu W} \frac{\mathrm{d}p}{\mathrm{d}z} \tag{10}$$

Consequently, the dimensionless momentum balance equation is readily obtained in the following form:

$$\nabla^{*2} V_z + c_1 = 0 \tag{11}$$

In order to characterize a liquid flow through microchannels under an imposed pressure gradient Eq. (11) can be used together with the appropriate boundary condition that, for Newtonian liquids, is the no-slip boundary condition at the walls:

$$V_z|_{\Gamma^*} = 0 \tag{12}$$

For a Newtonian liquid flow, this assumption is justified if the microchannel has a hydraulic diameter larger than 1 μm. In fact, for liquids the typical mean free path λ of molecules under ambient conditions is 0.1 – 1 nm. Since the fluid velocity tends to evidence a slip at the microchannel walls for Knudsen numbers, defined as $\mathrm{Kn} = \lambda / D_\mathrm{h}$, larger than 0.001, the no-slip boundary condition has to be abandoned only when the hydraulic diameter of the microchannel becomes less than 1 μm.

On the contrary, for non-Newtonian liquids, like polymer solutions and surfactants, a slip velocity at the walls can be observed even for microchannels having a hydraulic diameter greater than 1 μm.

The solution of Eqs. (11) and (12) yields the velocity distribution inside the microchannel in the laminar regime for fully developed flow. The analytical solution of this differential problem is available only for very simple geometries.

From the velocity distribution obtained by the solution of Eqs. (11) and (12) it is possible to calculate the value assumed by the main flow parameters which can be useful during the design stage of a microfluidic device:

- the *ratio between the maximum and the mean value of the velocity* (V_max):

P

$$V_{\max} = \frac{v_{z,\max}}{W} \quad (13)$$

- the asymptotic value of the *momentum flux correction factor* K_d defined as:

$$K_d = \frac{1}{\Omega^*} \int_{\Omega^*} V_z^2 \, d\Omega^* \quad (14)$$

- the asymptotic *kinetic energy correction factor* K_e defined as:

$$K_e = \frac{1}{\Omega^*} \int_{\Omega^*} V_z^3 \, d\Omega^* \quad (15)$$

- the asymptotic *incremental pressure drop number* $K(\infty)$:

$$K(\infty) = \frac{2}{\Omega^*} \int_{\Omega^*} \left[\left(V_z^3 - V_z^2 \right) \right] d\Omega^* = 2\,(K_e - K_d) \quad (16)$$

- the *Poiseuille number* defined as the product of the Fanning friction factor for fully developed flow (f) and the Reynolds number ($\mathrm{Re} = \rho W D_h / \mu$):

$$(f\mathrm{Re})_{fd} = -\frac{1}{2\Omega^*} \int_{\Gamma^*} \left. \frac{\partial V_z}{\partial n^*} \right|_{\Gamma^*} d\Gamma^* = \frac{c_1}{2} \quad (17)$$

where n^* is the normal direction to the walls.

For Newtonian laminar flows these parameters depend on the geometry of the microchannel cross-section only.

Circular Cross-Section

For a channel with a circular cross-section it is possible to demonstrate that the velocity distribution, written in dimensionless form, is

$$V_z(r^*) = 2(1 - 4r^{*2}) \quad (18)$$

in which r^* is the dimensionless radius defined as r/D_h with D_h being the inner diameter.

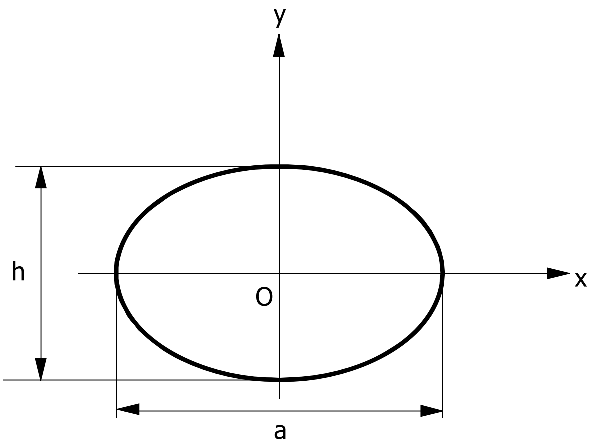
In Table 2 the values assumed by $V_{\max}$, K_d, K_e, $K(\infty)$ and $f\mathrm{Re}_{fd}$ are quoted for this geometry.

Elliptical Cross-Section

Microtubes with elliptical cross-section in which fully developed laminar flow occurs are geometrically characterized by the value of the aspect ratio β defined as ratio between the minor (h) and the major (a) axes (see Fig. 1).

Pressure-Driven Single Phase Liquid Flows, Table 2 Analytical laminar fully developed values of $V_{\max}$, K_d, K_e, $K(\infty)$ and of the Poiseuille number ($f\mathrm{Re}_{fd}$) for circular microtubes

$V_{\max}$	K_d	K_e	$K(\infty)$	$f\mathrm{Re}_{fd}$
2	4/3	2	4/3	16



Pressure-Driven Single Phase Liquid Flows, Figure 1 Schematic of the elliptical cross-section and of the Cartesian coordinate system

The fully developed laminar velocity profile is

$$V_z(x^*, y^*) = 8\left(\frac{1}{4} - x^{*2} - y^{*2}\right) \quad (19)$$

in which x^* and y^* are dimensionless coordinates defined as x/a and y/h respectively and the Cartesian coordinate system has its origin at the center of the channel (see Fig. 1).

It is possible to demonstrate by using Eq. (19) that $V_{\max}$, K_d, K_e and $K(\infty)$ assume the same values as those for circular cross-section (see Table 2) for any β.

The fully developed Poiseuille number can be calculated analytically by means of the following relation:

$$f\mathrm{Re}_{fd} = 2\pi^2 \left(1 + \beta^2\right) \left[\frac{1}{E(1 - \beta^2)}\right]^2 \quad (20)$$

where E denotes the complete elliptical integral of the second kind.

In Table 3 the value of the fully developed Poiseuille number is quoted as a function of the aspect ratio β of the elliptical cross-section.

Concentric Annular Cross-Section

The solution of Eq. (11) with the no-slip boundary condition (Eq. (12)) through an annular channel with an inner radius equal to r_i and an outer radius equal to r_o (see Fig. 2) can be written as follows:

$$V_z(r^*) = \frac{2}{\left[1 + \beta^2 - 2r_m^{*2}\right]} \left(1 - r^{*2} + 2r_m^{*2} \ln(r^*)\right) \quad (21)$$

in which β is the aspect ratio of the annuli defined as r_i/r_o, r^* is the dimensionless radius defined as r/r_o and r_m^* is given by

$$r_m^* = \left[\frac{1-\beta^2}{2\ln(\frac{1}{\beta})}\right]^{\frac{1}{2}} \quad (22)$$

and designates the dimensionless radius corresponding to the maximum value of the velocity.

For this geometry a closed form solution for V_{max} and the Poiseuille number is known:

$$\begin{aligned} V_{max} &= 2\frac{\left(1-r_m^{*2}+2r_m^{*2}\ln(r_m^*)\right)}{1+\beta^2-2r_m^{*2}} \\ f_i\mathrm{Re}_{fd} &= 16\frac{(1-\beta)}{\beta\left(1+\beta^2-2r_m^{*2}\right)}\left(r_m^{*2}-\beta^2\right) \\ f_o\mathrm{Re}_{fd} &= 16\frac{(1-\beta)}{\left(1+\beta^2-2r_m^{*2}\right)}\left(1-r_m^{*2}\right) \\ f\mathrm{Re}_{fd} &= \frac{16}{\left(1+\beta^2-2r_m^{*2}\right)}\left(1-r_m^{*2}\right) \end{aligned} \quad (23)$$

where f_i and f_o designate the Fanning friction factors at the inner and outer walls respectively and $f\mathrm{Re}_{fd}$ is the perimeter average Poiseuille number:

$$f\mathrm{Re}_{fd} = \frac{\beta f_i\mathrm{Re} + \beta f_o\mathrm{Re}}{1+\beta} \quad (24)$$

In Table 4 the value assumed by V_{max}, K_d, K_e and $f\mathrm{Re}_{fd}$ are quoted for this geometry as a function of the aspect ratio β. It is evident that, the circular geometry can be considered as the limit case for $\beta = 0$ and the parallel plate geometry for $\beta = 1$.

Rectangular Cross-Section

For a rectangular channel with an aspect ratio $\beta = h/a$ (see Fig. 3a), for which a Cartesian system of coordinates x, y, z is assumed, with its origin in the left bottom corner of the inlet rectangular cross-section (y along the side with length h and z perpendicular to the cross-section), the analytical solution of Eqs. (11) and (12) gives the following velocity distribution:

$$\begin{aligned} V_z(x^*, y^*) = &\sum_{n=1,\mathrm{odd}}^{\infty}\sum_{m=1,\mathrm{odd}}^{\infty} v_{n,m}\sin\left(n\pi\frac{2\beta}{1+\beta}x^*\right) \\ &\times \sin\left(m\pi\frac{2}{1+\beta}y^*\right) \end{aligned} \quad (25)$$

0.75	0.872	1.501	1.200	1.546	25.295	22.971	23.967
0.8	0.898	1.501	1.200	1.544	24.978	23.182	23.980
0.9	0.950	1.500	1.200	1.543	24.440	23.596	23.996

in which the series coefficients $v_{n,m}$ are defined as

$$v_{n,m} = \frac{\pi^2}{4mn\left(\beta^2 n^2 + m^2\right)} \frac{1}{\sum\limits_{i=1,\mathrm{odd}}^{\infty} \sum\limits_{j=1,\mathrm{odd}}^{\infty} \frac{1}{i^2 j^2 (\beta^2 i^2 + j^2)}} \tag{26}$$

and x^* and y^* are the dimensionless coordinates defined as x/D_h and y/D_h respectively.
It is easy to demonstrate that for a rectangular cross-section the hydraulic diameter D_h, the aspect ratio β and the length of the sides (a, h) are correlated:

$$a = \frac{1+\beta}{2\beta} D_h; \quad h = \frac{1+\beta}{2} D_h \tag{27}$$

Since Eq. (25) involves considerable computational complexity, a simple approximation in the following form, validated for $\beta \le 0.5$, can be suggested:

$$V_z(x^*, y^*) = \left(\frac{w+1}{w}\right)\left(\frac{k+1}{k}\right)\left[1 - \left(\frac{4}{1+\beta} y^*\right)^w\right] \times \left[1 - \left(\frac{4\beta}{1+\beta} x^*\right)^k\right] \tag{28}$$

but in this case the origin of the Cartesian system of coordinates x, y, z is assumed at the center of the cross-section ($a/2$, $h/2$) (see Fig. 3b).

The exponents w and k can be calculated by means of the following empirical correlations:

$$k = 1.7 + 0.5\beta^{-1.4}$$
$$w = \begin{cases} 2 & \text{for } \beta \le \frac{1}{3} \\ 2 + 0.3\left(\beta - \frac{1}{3}\right) & \text{for } \beta > \frac{1}{3} \end{cases} \tag{29}$$

In Table 5 the values assumed by V_{max}, K_d, K_e, $K(\infty)$ and $f\mathrm{Re}_{fd}$ are quoted for this geometry as a function of the microchannel aspect ratio β. It is evident that, owing to the symmetry of the cross-section, for microchannels having β greater than 1, one can use $1/\beta$ in order to calculate the integral parameters from Table 5.

Parallel Plates

Very shallow rectangular microchannels with $h \ll a$ (or, for symmetry, in the case that $h \gg a$) are characterized by low values of the aspect ratio ($\beta = 0$); in this case the rectangular microchannel can be modeled as two parallel plates. It is possible to demonstrate that for parallel plates with a plate spacing equal to h, the fully developed laminar velocity profile can be written as follows:

$$V_z(y^*) = \frac{3}{2}\left[1 - 16\left(y^*\right)^2\right] \tag{30}$$

in which y^* is the dimensionless coordinate defined as y/D_h with $D_h = 2h$, as obtained by Eq. (27) for $\beta = 0$. As depicted in Fig. 4, in this case the origin of the Cartesian coordinate system is assumed as placed at the center of the channel.

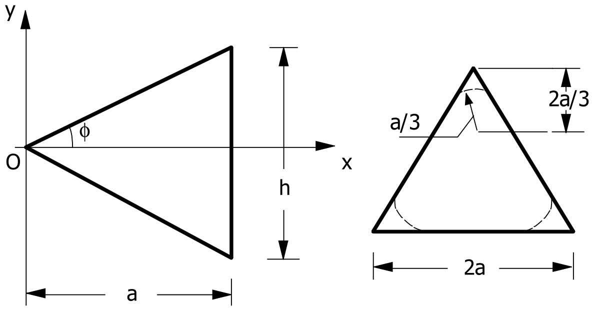
The values assumed by V_{max}, K_d, K_e, $K(\infty)$ and $f\mathrm{Re}_{fd}$ are given in Table 5 for $\beta = 0$.

Triangular Channels

The fully developed laminar velocity profile for isosceles triangular ducts (see Fig. 5a) can be in general determined by solving numerically Eq. (11) with Eq. (12). Shah and London [4] reported the following approximate closed-form solution for the velocity profile for isosceles triangular channels:

$$V_z(x^*, y^*) = \frac{3(B+2)}{(B-2)}\left[4y^{*2} - x^{*2}\right]\left[x^{*B-2} - 1\right]$$
$$B = \left[4 + \frac{5}{2}\left(\frac{1}{\tan^2\phi} - 1\right)\right]^{\frac{1}{2}} \quad (31)$$



Pressure-Driven Single Phase Liquid Flows, Figure 5 Schematic of (**a**) the isosceles triangular cross-section and (**b**) an equilateral triangular microchannel with rounded corners

where x^* and y^* are dimensionless coordinates defined as x/a and y/h (see Fig. 5a). For the isosceles triangular ducts the hydraulic diameter can be calculated by means of the following equation:

$$D_h = \frac{a\sin\phi}{1+\sin\phi} = \frac{h\cos\phi}{1+\sin\phi} \quad (32)$$

It can be demonstrated that the maximum value of the velocity occurs at $y^* = 0$ (for the symmetry) and

$$x_m^* = \sqrt[B-2]{\frac{2}{B}} \quad (33)$$

The fully developed Poiseuille number can be calculated by means of the following equation:

$$f\mathrm{Re}_{fd} = \frac{12(B+2)(1-\tan^2\phi)}{(B-2)\left[\tan^2\phi + (1+\tan^2\phi)^{\frac{1}{2}}\right]^2} \quad (34)$$

The numerical results obtained by Shah and London [4] for V_{max}, K_d, K_e, $K(\infty)$ and $f\mathrm{Re}_{fd}$ for this geometry are quoted in Table 6.

Because the manufacturing processes employed sometimes produces microchannels of triangular cross-section with one, two or three rounded corners instead of sharp corners, in Table 7 the numerical results obtained by Shah and London [4] for an equilateral triangular microchannel with rounded corners in terms of V_{max}, K_d, K_e, $K(\infty)$ and $f\mathrm{Re}_{fd}$ are quoted. The radius of each rounded corner is considered as $a/3$, as shown in Fig. 5b, with $2a$ as the side length of the base triangle.

Trapezoidal Channels

It is well known that with a photolithographic-based process one can obtain microchannels having a cross-section fixed by the orientation of the wafer crystal planes; for example, the microchannels etched in ⟨100⟩ silicon using

Pressure-Driven Single Phase Liquid Flows, Figure 6 (**a**) KOH-etched trapezoidal cross-section and (**b**) KOH-etched double-trapezoidal cross-section

a KOH solution have a trapezoidal cross-section with an apex angle of 54.74° imposed by the crystallographic morphology of the ⟨100⟩ silicon. By gluing together two KOH-etched trapezoidal silicon microchannels one can obtain microchannels having a double-trapezoidal cross-section (see Fig. 6). These cross-sectional geometries are investigated in this section.

Only numerical solutions of Eq. (11) have appeared in the open literature for this kind of geometry.

In Tables 8 and 9 the numerical results for KOH-etched trapezoidal and KOH-etched double trapezoidal microchannels respectively in terms of V_{max}, K_d, K_e, $K(\infty)$ and fRe_{fd} are given.

Two different definitions of the aspect ratio are used in the literature for trapezoidal channels ($\beta = h/a$ or $\gamma = h/b$ with reference to the symbols quoted in Fig. 6a). In Table 8, both β and γ are quoted in order to simplify the use of the data. For a ⟨100⟩ silicon microchannel the aspect ratio β cannot exceed the value of $\tan(\phi)/2$ (equal to 0.707 for $\phi = 54.74°$) corresponding to the degeneration of the channel cross-section to the triangular geometry ($\gamma = \infty$). The aspect ratio β of a double-trapezoidal channel is defined as the ratio between the height (h) and the maximum width (a); β can assume all the values between 0, the parallel plate configuration, and 1.414, the rhombic configuration.

Comparison Among Microchannel Cross-Sections

The data illustrated in the above sections can be used in order to minimize the pressure drop in a microfluidic

device with microchannels. In Fig. 7 a comparison among rectangular, KOH-etched trapezoidal microchannels and KOH-etched double-trapezoidal microchannels in terms of friction factor as a function of the aspect ratio β is shown. It is evident that, for a fixed value of the aspect ratio, the trapezoidal geometry allows the achievement of lower friction factors than the other cross-sections. The differences among the cross-sections in terms of friction factors decrease when the aspect ratio decreases.

A fifth-order polynomial approximation for calculating $f\mathrm{Re}_{fd}$, K_d and K_e as a function of the channel aspect ratio (β) is given with the aim of offering a very simple but accurate tool for technicians and designers involved in microfluidic applications:

$$f\mathrm{Re}_{fd} \text{ or } K_d \text{ or } K_e = \sum_{n=0}^{5} g_i \beta^n \qquad (35)$$

The values of the constants g_i are listed in Table 10 for microchannels having rectangular, trapezoidal and double-trapezoidal cross-sections;, the maximum relative differ-

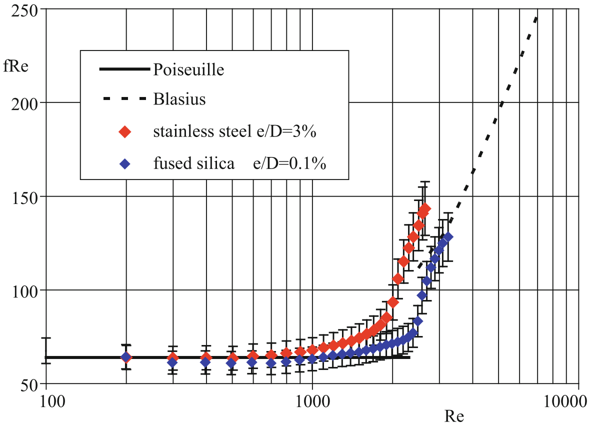
ence Δ quoted in Table 10 is positive when Eq. (35) gives values greater than the rigorous calculation.

Laminar-to-Turbulent Transition

The laminar regime in a channel holds until the Reynolds number reaches a critical value above which the laminar motion becomes unstable and a transition to a turbulent flow will generally occur. It has been demonstrated experimentally that for a microchannel the critical value of the Reynolds number depends on the entrance conditions, on the cross-section geometry and on the wall roughness. The effect of the roughness on the laminar-to-turbulent transition is very important and it can be evidenced by observing Fig. 8 in which the experimental values of the Poiseuille number ($f\mathrm{Re}$) are shown as a function of the Reynolds number for two microtubes made in stainless steel and in fused silica. The stainless steel microtube has an internal diameter of 133 μm and a relative roughness (e/D) equal to 3%, while the tube made in fused silica is characterized by an internal diameter equal to 100 μm and a relative roughness equal to 0.1%. The agreement with the Poiseuille law is confirmed for low values of the Reynolds number ($\mathrm{Re} < 1600$). The stainless steel microtube exhibits an earlier deviation from the Poiseuille law at Re equal to 1600. On the contrary, for the smoother microtube in fused silica the Poiseuille law holds up to Re equal to 2300. In general, for smooth microtubes the critical Reynolds number is about 2000 – 2300, in agreement with the behavior of macrotubes. On the contrary, for rough microtubes it can be concluded that higher relative roughness tends to anticipate the transition and thus decreases the value of the critical Reynolds number down to 1700 – 1800.



Pressure-Driven Single Phase Liquid Flows, Figure 8 Effect of the relative roughness on the laminar-to-turbulent transition in a microtube

Turbulent Regime

For Reynolds numbers larger than the critical Reynolds number the flow becomes turbulent and the fluid velocity at a point can be defined as the mean value of the velocity at this point with respect to time by taking a time interval t_0 larger than the typical time of one turbulent fluctuation and shorter than the typical time of pressure variations. Since mass and momentum must be conserved in turbulent as well as in laminar flow, the conservation equations (Eq. (1)) hold equally for turbulent flow, provided the velocities and pressures in these equations are interpreted as instantaneous velocities and pressures of the turbulent field. From a practical standpoint such equations are of little value because there is no interest in knowing the complete and complex history of instantaneous velocities and pressures but only their time-mean values that can be measured and observed (see also ▶turbulence in microchannels). In microchannels with hydraulic diameters less than 500 μm the maximum value that the Reynolds number can assume drops to between 10,000 and 30,000. In fact, in order to reach these values of the Reynolds number a very large pressure difference has to be imposed at the ends of the microchannels. For this reason, the analysis of the turbulence in microchannels is bounded to Reynolds numbers less than 30,000.

Circular Cross-Section

The time-mean value of the dimensionless velocity $\langle V_z \rangle$ can be written in fully developed turbulent flow in a micro-

tube as follows:

$$\langle V_z \rangle = (1 - 2r^*)^{\frac{1}{m}}$$

$$m = \begin{cases} 6 & 4000 < \mathrm{Re} < 110{,}000 \\ 7 & 110{,}000 \le \mathrm{Re} < 3{,}200{,}000 \\ 10 & \mathrm{Re} > 3{,}200{,}000 \end{cases} \tag{36}$$

in which the following dimensionless quantities are used:

$$\langle V_z \rangle = \frac{\langle v_z \rangle}{\langle W \rangle}; \quad r^* = \frac{r}{D} \tag{37}$$

The ratio $\langle V_{\max} \rangle$ can be computed by using the following equation:

$$\langle V_{\max} \rangle = \frac{\langle v_{z,\max} \rangle}{\langle W \rangle} = \frac{(m+1)(2m+1)}{2m^2} \tag{38}$$

Parallel Plate Cross-Section

For shallow rectangular microchannels, having a low value of the aspect ratio β, the rectangular cross-section can be modeled as a parallel plate geometry (see Fig. 4). In this case one obtains that the velocity distribution for fully developed turbulent flows becomes the following:

$$\frac{\langle v_z \rangle}{v^*} = \frac{1}{k}\left[\ln\left(1 - \sqrt{4y^*}\right) + \sqrt{4y^*}\right] + \frac{\langle v_{z,\max} \rangle}{v^*} \quad \left(0 \le y^* \le \frac{1}{4}\right) \tag{39}$$

in which $y^* = y/D_h$ with $D_h = 2h$, ($\boldsymbol{\tau}_0$ is the wall shear stress) and $k = 0.36$.

Friction Factor

For Newtonian fluids, the Fanning friction factor f is defined in terms of the wall shear stress as

$$f = \frac{\boldsymbol{\tau}_0}{\frac{\rho W^2}{2}} \tag{40}$$

For turbulent fully developed flow ($\mathrm{Re} > 10{,}000$) in a *smooth* microtube, the Fanning friction factor can be calculated from the *Karman–Nikuradse relation*:

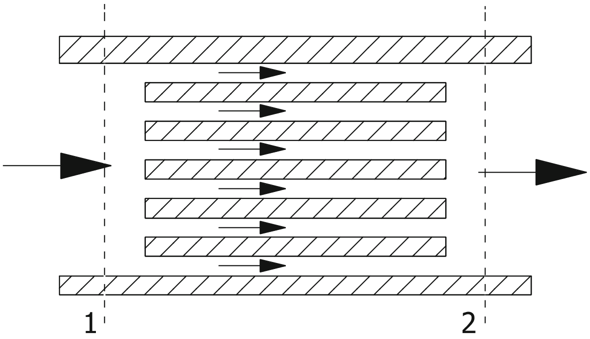
$$\frac{1}{\sqrt{4f_{\mathrm{fd}}}} = -0.8 + 0.87 \ln\left(\mathrm{Re}\sqrt{4f_{\mathrm{fd}}}\right) \tag{41}$$

In the range $5000 < \mathrm{Re} < 30{,}000$, in which in general microtubes could work, the *Blasius equation* may be used instead of Eq. (41) for smooth tubes:

$$f_{\mathrm{fd}} = \frac{0.079}{\mathrm{Re}^{0.25}} \tag{42}$$

In *rough* microtubes, like metallic microtubes, the effect of the inner roughness e on the friction factor cannot be neglected and the friction factor can be calculated by using the *Colebrook correlation*:

$$\frac{1}{\sqrt{4f_{\mathrm{fd}}}} = -2.0 \log\left[\frac{\frac{e}{D_h}}{3.7} + \frac{2.51}{\mathrm{Re}\sqrt{4f_{\mathrm{fd}}}}\right] \tag{43}$$



Pressure-Driven Single Phase Liquid Flows, Figure 9 Model for pressure drop analysis of multiple microchannel systems

Since the *Colebrook correlation* is awkward to use, an approximate explicit relation for the friction factor was published by *Haaland*:

$$\frac{1}{\sqrt{4f_{\text{fd}}}} = -1.8\log\left[\left(\frac{\frac{e}{D_{\text{h}}}}{3.7}\right)^{1.11} + \frac{6.9}{\text{Re}}\right] \quad (44)$$

This relation gives values within 2% of the *Colebrook correlation*.

Typical values of the relative roughness defined as the ratio e/D_{h} in microchannels vary between 0.0001 (glass microtubes) and 0.1 (stainless steel microtubes).

Pressure Drop Calculation

Pressure drop evaluation for flow through both single-microchannel and multiple-microchannel systems is very important in the design of microfluidic devices.

The model for the pressure drop analysis is depicted in Fig. 9 in which multiple microchannels with an abrupt entrance and exit are shown. The equations to be presented in this section apply to this model and are not restricted to a particular geometry of the microchannel cross-section.

They are applicable to single-microchannel flow by reducing the appropriate terms. The general relation for flow-stream pressure drop calculations is the following:

$$\Delta p = \frac{\rho_1 W_1^2}{2}\left[\left(K_{\text{c}} + 1 - \sigma^2\right) + 2\left(\frac{\rho_1}{\rho_2} - 1\right) + 4f\frac{L}{D_{\text{h}}}\frac{\rho_1}{\rho} - \left(1 - \sigma^2 - K_{\text{ex}}\right)\frac{\rho_1}{\rho_2}\right] \quad (45)$$

in which L is the microchannel length, W_1 is the average velocity defined by Eq. (9) and based on the minimum free flow area, σ is the free flow/frontal area ratio ($\sigma = 1$ for a single microchannel), K_{c} and K_{ex} represent entrance and exit loss coefficients and ρ is given by

$$\frac{1}{\rho} = \frac{1}{L}\int_0^L \frac{1}{\rho}\,\text{d}z \quad (46)$$

The terms involved in Eq. (45) in order to calculate the total pressure drop represent:

- the entrance effects (see ►developing flow and ►entrance region);
- the flow acceleration effect for a compressible fluid;
- the usual friction pressure drop;
- the exit effects.

In order to investigate only the entrance pressure drop Eq. (45) can be reduced as follows:

$$\Delta p_{\text{inlet}} = \frac{\rho_1 W_1^2}{2}\left(1 - \sigma^2\right) + K_{\text{c}}\frac{\rho_1 W_1^2}{2} \quad (47)$$

in which the first term is the pressure drop which would occur due to a change in the cross-section alone, without friction, and the second term represents the loss due to irreversible free expansion that follows the abrupt contraction. The irreversible component of the pressure drop is contained in the abrupt contraction or entrance coefficient K_{c}. The exit pressure rise is similarly broken into two parts:

$$\Delta p_{\text{exit}} = \frac{\rho_1 W_1^2}{2}\left(1 - \sigma^2\right) - K_{\text{ex}}\frac{\rho_1 W_1^2}{2} \quad (48)$$

The first is the pressure rise which occurs due to the area change alone, without friction, and is identical to the corresponding term in the entrance pressure drop. The second term is the pressure loss associated with the irreversible free expansion following an abrupt expansion and this term in the present case subtracts from the other.

The values of K_{c} and K_{ex} have been established analytically for a number of simple entrance and exit geometries and are quoted in many textbooks [9]. These coefficients have been evaluated on the assumption of essentially uniform velocity in the manifolds linked to the microchannels but by considering a fully established velocity profile in the microchannels (that means $L \gg D_{\text{h}}$). These assumptions can be considered verified for long microchannels for which $L > 100D_{\text{h}}$.

In applying the data related to the values of K_{c} and K_{ex} it should be remembered that these coefficients already include the pressure change associated with change in velocity profile.

Thus the friction factor used in Eq. (45) to evaluate the overall pressure drop should be defined on the basis of the mean wall shear stress after the entrance region and not on the basis of the overall pressure drop.

For liquids for which the incompressible model holds Eq. (45) can be simplified as follows:

$$\Delta p = \frac{\rho_1 W_1^2}{2}\left[K_c + 4f\frac{L}{D_h} + K_{ex}\right] \quad (49)$$

where f is the friction factor based on the mean wall shear stress after the entrance region.

For long microchannels for which $L \gg D_h$ (this condition is very common in microchannels) one can use the fully developed value of the friction factor in the calculation of the pressure drop:

$$\Delta p = \frac{\rho_1 W_1^2}{2}\left[K_c + 4f\mathrm{Re}_{fd}\frac{L}{\mathrm{Re}D_h} + K_{ex}\right] \quad (50)$$

To eliminate the uncertainties caused by estimation of minor losses (K_{ex}, K_c) many authors have suggested performing tests with microchannels of different lengths; in this manner it is possible to even out the inlet and outlet minor losses by subtracting the pressure drop of the shorter tube from that of the longer one for a fixed value of the average Reynolds number. By following this method, the value of the friction factor would be calculated as follows:

$$f_{fd} = \frac{\rho}{2\mu^2}\left(\frac{\Delta p(L_1) - \Delta p(L_2)}{L_1 - L_2}\right)\frac{D_h^3}{\mathrm{Re}^2} \quad (51)$$

where L_1 and L_2 are the lengths of the longer and shorter tube respectively.

It is important to observe that this method is in general valid for liquid flows in microchannels but becomes unsuitable for gaseous flows when the effects of compressibility are strong, as the values of the minor losses at the inlet and at the outlet, even for a fixed average value of the Reynolds number, can be very different.

When the initial velocity profile is uniform and there are no abrupt contraction ($K_c = 0$) and expansion ($K_{ex} = 0$) one can take into account the effects of momentum change in the entrance region by using $K(\infty)$ which includes the increased wall shear in the entrance region but separates out the downstream fully developed flow pressure drop due to wall shear to give

$$\Delta p = \frac{\rho_1 W_1^2}{2}\left[4f\mathrm{Re}_{fd}\frac{L}{\mathrm{Re}D_h} + K(\infty)\right] \quad (52)$$

Experimental Results

As mentioned above, the first experimental work in which water through glass microtubes with an inner diameter down to 15 μm was tested was due to Poiseuille in 1840 [2]. The experimental data obtained by Poiseuille were used to state the famous *Poiseuille law* for laminar flows through circular tubes, according to which for Stokes flows the product of the friction factor times the Reynolds number is a constant (equal to 16 for circular tubes) that depends on the cross-section geometry only.

On the contrary, as evidenced in [10], many experimental works published in the last decade seem to be partially in disagreement with the conventional theory and if these results are used in order to establish the validity of the conventional theory for microchannels in laminar and turbulent regime the answer obtained is not unequivocal. In fact, some authors found that the predictions of the conventional theory agree with the experimental results on the friction factor; however, for the same range of hydraulic diameters, some other authors found the opposite result.

It is possible to sum up the main results quoted in the open literature on the friction factor in microchannels highlighting the peculiarities, proposed by different authors, with respect to the conventional macrochannels:

- the friction factor for laminar fully developed flow is found to be smaller or larger than the conventional value;
- the Poiseuille number for laminar fully developed flow depends on the Reynolds number;
- the fully developed turbulent friction factor seems to be in disagreement with the *Blasius equation* for smooth microchannels and with the *Colebrook correlation* for rough microchannels;
- the friction factor depends on the material of the microchannel walls (metals, semi-conductors and so on) and/or on the test liquid (polar fluid or not), thus evidencing the importance of electro-osmotic phenomena at microscales;
- the friction factor depends on the relative roughness of the walls of the microchannels also in the laminar regime.

However, from a chronological analysis of the experimental results of the literature it is possible to extrapolate how the deviations of the behavior of fluid flow through microchannels from that through large-sized channels are decreasing. This fact can be explained by taking into account the dramatic improvement of the techniques of microfabrication with the consequent reduction of the issues of surface roughness of the microchannels and a more appropriate control of the channel cross-sections; for this reason the results of the older studies may not provide useful comparisons. Another possible explanation of the decrease of the observed deviations is related to the increase of the reliability/accuracy of the more recent experimental data quoted in literature. This seems to be confirmed by the increasing number of experimental results on the friction factor of the last few years, which confirm the success of conventional correlations in pre-

dicting pressure drop for Newtonian liquids in microchannels having inner hydraulic diameters down to 10 μm.

Future Directions for Research

The analysis of the behavior of single phase Newtonian liquid flow through microchannels in laminar and turbulent regime evidenced that the conventional theory validated for large channels holds for hydraulic diameters down to 10 μm. Further investigations are required for non-Newtonian flows, like polymer solutions and surfactants, for which slip velocity at the walls has been observed even for microchannels having a hydraulic diameter greater than 1 μm. In addition, an accurate analysis of the critical Reynolds numbers for which the laminar-to-turbulent transition occurs in microchannels of different cross-sectional geometry (for Newtonian and non-Newtonian liquids) could be important to improve the understanding of the rules of the development of turbulence at the microscale.

Two-phase flow driven by pressure

Definition

Pressure-driven ▶ two phase flows are flows of two immiscible fluids in the same micro- or nanofluidic conduit driven by a pressure gradient. The fluids can be of different chemical compositions – liquid/liquid, or in different physical states – gas/liquid.

Overview and Theory

In the past decade, micro- and nanofluidics has been studied in great detail because of the increasing availability of methods for fabricating complicated flow configurations and measuring transport phenomena on the micro and nanoscales. The micro- and nanofluidic channel systems with integrated pumps, valves, and detectors, are known as ▶ Lab-on-a-Chip (LOC) or ▶ micro total analysis system (μTAS) [1]. Ideally, each process – e. g., sampling, sample pretreatment, reaction, separation, detection and analysis in an analytical system – is realized on one integrated device. Fluid mechanics studies in these processes therefore are indispensable for the design and fabrication of LOC and μTAS.

Fluids that are of interest in nature, biotechnology and chemistry, are rarely simple single-phase fluids. Most compartmental chemistry, interfacial phenomena and applications employ two-phase flows. It is therefore not surprising that recently a surge of interest has arisen in two-phase microfluidic manipulation.

Compared to single-phase flow systems, when discussing two-phase flow in micro- and nanosystems, there are many questions that arise even in a simple configuration. When two phases flow in the same conduit or channel, the flow patterns change between droplet-base flows and stratified flows depending on the physicochemical properties of fluids and channel surfaces. At the same time, in two-phase flow systems, several flow phenomena, such as film flow, corner flow and slip flow play increasingly important roles with reduction of the dimensions. Both advantages and disadvantages originate from the reduction in dimension

and the coexistence of two phases. In all these phenomena, the fluid manipulation is no doubt the most important factor.

Manipulating fluids in a two-phase flow system is much more complicated than in single-phase systems. Fluid flows can be actuated spontaneously, non-mechanically or mechanically. The most frequently used flow actuation method, till now, is still pressure-driven pumps due to their availability and versatility. Especially, for a two-phase flow system, the naturally existing inhomogeneity makes other methods much more difficult to be applied. Electroosmosis for instance, resulting from the force exerted on a space-charge region in the liquid by an electric field, will not work if the conductivity continuum in the fluid is interrupted by an entrapped dielectric liquid droplet or gas bubble.

Fluid flow in channels of constant cross-sectional shape can be simply described by Poiseuille's law:

$$Q = \int v_i \, dA \approx \frac{\Delta P}{R_{hy}} \tag{1}$$

where Q ($m^3 s^{-1}$) is the volume flow rate, v_i ($m s^{-1}$) is the flow velocity at the position i, A (m^2) is the area of cross section. The hydrodynamic resistance, R_{hy}, can be approximately expressed as:

$$R_{hy} \approx \eta l C^2 A^{-3} \tag{2}$$

where η (Pa s) is the fluid viscosity, l (m) is the channel length, and C (m) is the perimeter of the cross section. ΔP (Pa) is the pressure difference between two ends of the fluid, which is the total pressure acting on the fluids. It is the sum of externally applied pressure ($P_{ex.}$) and the internal (capillary) pressure ($P_{cap.}$):

$$\Delta P = P_{ex.} \mp P_{cap.} \tag{3}$$

If there is a positive capillary pressure in a channel, the externally applied pressure has to exceed it to pump fluid, and inversely fluid can be automatically imbibed in a microchannel if there exists a negative capillary pressure (capillary action). Therefore, pressure-driven flows can be manipulated not only by externally applied pressure but also by the internally generated capillary pressure.

The dynamical response of two-phase flows can be commonly characterized successfully in terms of the dimensionless numbers [2]. Table 1 lists some force-related dimensionless numbers. These dimensionless numbers demonstrate competing phenomena of forces: buoyancy, gravitational, inertial, viscous and interfacial forces. The Grashof number (buoyancy to viscous forces), the Bond number (gravitational to interfacial forces) and the Reynolds number (inertial to viscous forces) scale with the third, the second and the first power of flow dimensions, respectively. The relative importance of the different forces that act on fluids therefore dramatically changes on downscaling. With downscaling, the buoyancy, gravitational and inertial forces become less and less important and viscous and interfacial forces become more and more predominant. In micro-systems, the relative importance of forces, calculated for a water/oxygen two-phase flow, is given by the following order: buoyancy forces < inertial forces < gravitational forces < viscous forces < interfacial forces.

Of these dimensionless numbers, the Reynolds number is the most frequently used number to describe microfluidics. It expresses the ratio of inertial forces to viscous forces:

$$\mathrm{Re} = \frac{\rho v L}{\eta} \tag{4}$$

where ρ ($kg\,cm^{-3}$) is the effective density, v ($m s^{-1}$) is the average flow velocity, L (m) is the characteristic flow dimension, and η (Pa s) is the effective viscosity. In a straight channel, the value of $\mathrm{Re} \approx 10^3$ is accepted as a limit for the transition from a laminar flow to a turbulent flow. In a straight micro- or nanochannel with diameters between 100 nm and 100 μm, where $\eta(H_2O) = 1.025 \times 10^{-3}$ Pa s, $\rho(H_2O) = 10^3\ kg\,m^{-3}$ and $v = 1\ mm\,s^{-1}$, the calculated Reynolds number lies between 10^{-1} and 10^{-4}. For a gas, oxygen for instance, $\eta(O_2) = 20.317 \times 10^{-6}$ Pa s and $\rho(O_2) = 1.429\ kg\,m^{-3}$, the Reynolds number at these channel dimensions ranges from 10^{-5} to 10^{-2}. Therefore, inertial forces are over-

whelmed by viscous forces in microfluidic devices. Laminar flows are thus expected in micro- and nanochannels for both gas and liquid, and not turbulent or random flows. The forces acting on two-phase fluids can be divided into tangential and normal components. On the micro- and nanoscales, as shown in Table 1, a pair of competitive forces – the viscous force and the interfacial force – become dominant. The viscous forces mainly act tangential to the interface elongating it, whereas the interfacial forces act normal to the interface inducing droplet or bubble formation (minimizing the interfacial area). The capillary number is the ratio of these two competitive forces, and can be expressed as:

$$\mathrm{Ca} = \frac{\eta v}{G\sigma} \tag{5}$$

where η (Pa s) is the viscosity of continuous phase, G is a geometrical constant, and σ ($\mathrm{N\,m^{-1}}$) is the interfacial tension. The capillary number is independent of flow dimensions, and can be controlled by the properties of fluids and channels and the interactions between them. It is the most useful dimensionless number to describe two-phase microfluidic flow phenomena including flow formation, sizing, coalescing, mixing and splitting.

Keeping in mind that two-phase flows include both liquid-liquid systems, and gas-liquid systems, the different behavior of a gas and liquid must be emphasized before discussing two-phase flows. The average distance between molecules in a gas phase is one order of magnitude higher than the diameter of its molecules, while it approaches the molecular diameter in a liquid phase. Therefore, in some microdevices the gas is compressed when the pressure strongly changes. The Mach number Ma is a dynamic measure of fluid compressibility, and is defined as the ratio of flow velocity (v) to sound speed (a):

$$\mathrm{Ma} = \frac{v}{a} \tag{6}$$

The flow of a compressible fluid like air can be treated as incompressible if the local Mach number is less than 0.3. Ma is very small in microfluidic systems due to the low flow velocity. Compression however might still occur in the case of density gradients, for instance by high local pressure changes, wall heating or cooling. In that case, equations for compressible flow must be applied [3]

Basic Methodology

Channel Geometries

Two-phase flows can be easily generated by combining flow of different phases in certain channel geometries. The basic channel configurations used to generate multiphase flows are T, Y or cross junctions (Fig. 1).

Pumping by Externally Applied Pressure

In micro- and nanofluidic devices, a pressure is normally externally applied by syringe pumps or vacuum pumps. The pressure difference, generated at two ends of fluids, pushes or pulls fluid to move, and the resulting volume flow rate is expressed by Eq. (1).

The advantage of syringe or vacuum pumping is its versatility. It can be applied to drive all kinds of fluids (gas, liquid or gas-liquid two-phase fluids), and theoretically, it can also be used on all scales as long as the pressure is high enough to overcome the flow resistance. However, the hydrodynamic resistance in a channel is proportional to flow distance and inversely proportional to the fourth power of the channel size, and therefore, very high pressure is necessary to drive flows in smaller channels. For example, without capillary pressure, calculated from Eq. (1), to have water flow with $1\,\mathrm{cm\,s^{-1}}$, in a $10\,\mu\mathrm{m}$ diameter channel of 1 mm length 10^3 Pa is needed, however, 10^7 Pa has to be applied for the same flow in a 100 nm diameter channel.

Syringe pumping and vacuum pumping remain predominant in microfluidic flows. Fluid flows driven by capillarity become more efficient on downscaling due to its favorable scaling behavior.

Pumping by Capillary Pressure

A hydrophilic liquid, water for instance, *pulls* itself into or through a hydrophilic micro- or nanochannel by capillary action which is induced by interfacial tensions (Fig. 2a). The capillarity-induced pressure pulling the liquid along the channel (Fig. 2a and 2b) is expressed by Young–Laplace's equation:

$$P_{\mathrm{cap.}} = G\sigma_{\mathrm{lg}} \cos\theta\, d^{-1} \tag{7}$$

where G is a geometrical constant, d (m) is the characteristic diameter, σ_{lg} ($\mathrm{N\,m^{-1}}$) is the liquid-gas interfacial tension, and θ (degree) is the contact angle which is set up when a liquid droplet contacts both a solid and a gas (or a solid and a second immiscible liquid) (Fig. 2c and 2d). The liquid curvature of the droplet is caused by the differences among interfacial tensions. The force balance is described by Young's equation:

$$\sigma_{\mathrm{sg}} = \sigma_{\mathrm{sl}} + \sigma_{\mathrm{lg}} \cos\theta \tag{8}$$

where σ_{sg} and σ_{sl} ($\mathrm{N\,m^{-1}}$) indicate the interfacial tensions of solid-gas and solid-liquid, respectively. Fluids,

therefore, can be spontaneously propelled by a capillarity-induced pressure gradient.

In a channel, the motion of a fluid segment can result from the capillarity-induced pressure difference between the front and a rear of the fluid column. Such a pressure difference (ΔP) is described by:

$$\Delta P = P_{\mathrm{cap.2}} - P_{\mathrm{cap.1}} = G\sigma_{\mathrm{lg}} \left(\frac{\cos\theta_2}{d_2} - \frac{\cos\theta_1}{d_1} \right) \quad (9)$$

According to the equation, the pressure difference can be obtained by changing the channel diameter (d), the interfacial tension (σ) or the contact angle (θ). Therefore, self-propelling slugs can be realized by careful design, material selection, microfabrication, and surface control and processing. For example, a slug will move from the wide part to the narrow part when the channel diameter changes (Fig. 3a). The movement can also be realized by using different channel materials (Fig. 3b) or fluids (Fig. 3c) with different interfacial energy. Similar phenomena happen for two or more juxtaposed phases (Fig. 3d). The motion can even be inverted by juxtaposing a liquid of low surface tension.

Furthermore, interfacial tensions can be tuned electrically (Fig. 4a), thermally (Fig. 4b), optically (Fig. 4c), chemically (Fig. 4d), or by combinations of them such as optic-electrically.

Flow Phenomena

Flow patterns

Two-phase flow in microfluidic systems is broadly categorized into ► segmented (droplet-based) flow and ► parallel (stratified) flow architectures. Gas-liquid two-phase flows in microchannels have been studied in detail for heat-exchanger applications. Between segmented flows and stratified flows there can be several other flow patterns – bubbly flow, ring flow, lump flow and annular flow (Fig. 5a) [4]. The flow of immiscible liquids has been successfully manipulated to study chemical reactions and for biotechnology purposes. The two-phase microchannel flows change from the droplet-based flows to stratified flows depending on the flow rate and fluid composition, in a manner ultimately dependent on the capillary number (Eq. (5), Fig. 5b) [5].

Immiscible gas-liquid and liquid-liquid mixtures form droplet-based flows over a wide range of flow conditions and channel dimensions without additional control due to interfacial forces. Vice versa, two immiscible streams would flow alongside one-another if there were no interfacial forces between them. Theoretically, a stable elongated interface between two phases only occurs when tangential forces (viscous shear forces) are equal to or greater than normal forces (interfacial forces), i.e, at higher capillary number. Figure 5c shows a typical example of a two-phase flow transition according to the capillary number [6]. Two streams of water are added to a carrier liquid in a cross configuration. The two streams of water coalesce to form a big droplet-based flow at extremely small Ca (~ 0.0004). By increasing Ca, alternating droplet-based flow is generated with decreased droplet size. Droplet size (R) in a two-phase flow depends on the channel size (h) and the capillary number: $R \sim h/\mathrm{Ca}$ [7]. Finally, stratified flow is obtained for $\mathrm{Ca} > 0.15$ at a water fraction of 0.2.

Based on the definition of the capillary number, the two-phase flow patterns in microchannels can be influenced by interfacial forces (σ), fluid viscosity (η), flow velocity (v) and geometric features (G). The interfacial forces can be modulated by adding surfactants, surface coating and patterning techniques, but also by electrical, thermal or optical modulations of the interfacial tensions (see previous section). The fluid viscosity will be changed by changing temperature or adding polymers. The flow velocity is mainly tuned by actuation forces and geometrical tailoring. The geometric features include designing smart geometries and adding microtextures inside micro- and nanofluidic devices.

When two immiscible phases come into contact at a junction, an approximately parabolic flow profile can be obtained for a two-phase stratified flow in a common pressure-driven microfluidic system. On the other hand, in a droplet-based flow, stimulated by the shear between the stationary fluid at the channel wall and the slug axis, there exists internal recirculation in both continuous and dispersed phases [8]. Complex flow patterns may appear under different conditions, depending on the forces acting on the fluids.

Whether a stable two-phase flow can be obtained in a fluidic system depends on both fluid dynamic conditions and surface chemistries. The aim is to open the way to control the flow and to achieve versatility and reproducibility in on-chip flow management. The design will require smart network topologies and interplay of multiple physical and chemical effects.

Slip Flow

Traditional *non-slip* assumptions have been doubted for a long time in microfluidic systems. Recently, the results from molecular dynamics simulations and experiments on micro- and nanoscales strongly indicate the existence of slip flow. Theoretically, fluids will slip when the attraction between fluids molecules is stronger than the wall/fluid molecule attraction. The amount of slip is described as the slip length which is the notional distance inside the surface at which the velocity equals to zero (Fig. 6a).

Molecular dynamics (MD) simulations have shown that slip can occur only when a critical surface shear stress is reached, and that there exists a general relationship (linear or nonlinear given by different results) between the slip length and the local shear rate at a solid surface. Significant slip has been experimentally demonstrated by driving different fluids through micro- and nanochannels. Slip length depends on the interactional parameters between solid and fluid: shear stress, wetting properties, fluid properties (e. g., viscosity and density) and interfacial roughness.

Different fluids have different interactions with each other or with solid surfaces. The fluid/fluid intermolecular interactions can be stronger or weaker than those of fluid/solid surfaces. Therefore, in two-phase flows, boundary conditions are much more complicated. As diagnostic techniques improve our ability to probe the fluid surface at the molecular scale, it is expected that slip flows can be investigated by direct measurement of fluid velocity or the movement of contact lines.

Film Flow

When droplet-based multiphase flow is considered, there are two possible configurations. In the first, a drop forms a distinct contact line with the walls of the channel. In the other, a drop is separated from the boundaries by a thin wetting film. Because of the affinity of fluids and surfaces,

Reprinted from [6] with permission of the American Chemical Society

hydrophilic fluids prefer to flow along hydrophilic channel surfaces, and hydrophobic fluids like to flow along hydrophobic surfaces. As hydrophilic liquids are imbibed into hydrophilic channels by capillary force, hydrophobic fluids flow into hydrophobic channels much more easily.

When fluid slugs flow forward in a channel, the trail left by the previous slug act as a lubricant for the following one (Fig. 6b). The film thickness can be theoretically calculated from the ratio of the loss of the fluid volume to the surface area traveled by the fluid. The thickness of a lubricating film experimentally depends on viscosity of neighboring slugs, fluid velocities and surface properties. Viscosity causes the deposition while capillary forces oppose the formation of a film. The film thickness (h_∞) deposited behind a wetting meniscus is therefore a function of Ca. At $10^{-5} < \mathrm{Ca} < 10^{-2}$ it can be expressed by: [9]

$$h_\infty = nR\mathrm{Ca}^{2/3} \qquad (10)$$

where n is a prefactor determined by fluid properties, and R is the channel radius. Although the thickness decreases with flow dimension, the percentage of film flow will still increase with downscaling due to both the decrease of fluid amount and the increase of specific interfacial areas. The greater the capillary number, the larger the film thickness according to Eq. (10), which allows more liquid flow through the film. A stable thin liquid film between the tube wall and gas slugs can appear at high velocities on carefully treated clean surfaces, and vice versa, so that thin films can be decreased in thickness or eliminated by sur-

face modification of the channel walls by changing the wetting properties.

Corner Flow

As we know, liquid surface tension is prone to minimize the liquid surface area to minimize the surface energy. Most of the channels fabricated on the micro- or nanoscale possess rectangular or slit-like cross sections. To satisfy the contact angle wetting condition the fluid will curve along the perimeter of the interface, thus minimizing interfacial area, and achieving a lower energy state (Fig. 6c). The polymorphism of the wetting liquid depends on two parameters: the channel geometry, and the interaction between substrate materials and liquids. The corner flow velocity is influenced by a flow resistance coefficient and geometric factors: the corner half-angle and the contact angle [10].

In a two-phase flow system, the different affinity of the two fluids for the wall makes one fluid preferentially flow along corners due to the capillarity. As the number of the polygon sides decreases and the corners sharpen, the cross-sectional area of fluids held in corners increases, and corner flow becomes more important. Therefore, corner flow must be considered carefully in such processes as evaporation and drying of micro- and nanochannels with small angular polygonal cross sections.

Key Research Findings

Applications

Two-phase systems are more complex than their single-phase counterparts, but are ubiquitous in process applications. Both the immiscible individual fluids separated by interfaces and the interfaces themselves provide us with mediums that are very suitable to study microreactions and interfacial phenomena.

Droplet-based Flows

Immiscible gas-liquid and liquid-liquid mixtures form droplet-based flows over a wide range of flow conditions and microchannel dimensions without additional control. There are several advantages for droplet-based flows to be applied in different fields. Specific interfacial areas as large as $9000-50{,}000\,\text{m}^{-1}$ have been obtained by decreasing channel dimensions and droplet (bubble) sizes down to $50\,\mu\text{m}$, which is 100 times larger than generally obtained in macroscopic channels. Thermal and mass transfer is therefore rapid due to the large specific interfacial area and consequently small molecular diffusion distance. Moreover, the process controllability is wide in droplet-based flows. The size, the number, and the composition of droplets can be controlled at each step of the process. By varying the initial composition of droplets, one can assess its effect on reaction yield and kinetics, providing a useful operational research tool for laboratories. Furthermore, in a droplet-based multiphase flow, droplets are separated from channel walls by a thin layer of immiscible (carrier) fluid, therefore the internal compositions of the droplets can not change due to contact with the channel walls, and the internal recirculation inside the droplets makes components mix efficiently in a very short time. This supplies us with more flexibility to employ each droplet as a separate microreactor.

Droplet-based two-phase flows offer controlled picoliter or femtoliter volumes of droplets (Fig. 7a) which are almost ideal chemical reactors and therefore have been utilized in emulsification and encapsulation, microreaction, synthesis, mixing, and bioassay [7].

Stratified Flows

In a multiphase stratified flow, the interfaces between immiscible fluids have several characteristics. Firstly, the specific interfacial area can be very large just as droplet-based flow. It can for example be about 10,000 m^{-1} in a microchannel compared with only 100 m^{-1} for conventional reactors used in chemical processes. Secondly, the mass transfer coefficient can be very high because of the small transfer distance and high specific interfacial area. It is more than 100 times larger than that achieved in typical industrial gas-liquid reactors. Thirdly, the interfaces of a stratified microchannel flow can be treated as nano-spaces. Simulation results show that the width of the interfaces of a stratified flow is in nanometers, and that diffusion-based mixing occurs at the interface. The interface width can be experimentally adjusted by adding surfactants. Finally, reactants only contact and react with each other at the interface. Therefore, the interfaces supply us with mediums to study interfacial phenomena, diffusion-controlled interfacial reactions and extraction.

The ideal 2D "nano-reactors" of the interfaces between immiscible fluids in stratified flows (Fig. 7b) have been used for chemical synthesis, triphase hydrogenation and biological enzymatic degradation, for extraction and separation, and for kinetic studies.

Future Directions for Research

Two-phase flows for a long time have been propelled by externally applied pressure, due to the inhomogeneity of two confined phases in the same system. High external pressure is needed to maintain flow in small devices due to the hydrodynamic resistance which increases with downscaling. This makes syringe pumping and vacuum pumping less suitable at smaller length scales. However, the capillarity-induced flow shows its importance at small flow dimensions. The capillary pressure is induced by interfacial forces which increase with downscaling. Moreover, more and more means have been found to modulate different interfacial forces of gas-liquid, gas-solid, liquid-liquid and liquid-solid. As device size decreases, the capillary pressure-driven flow therefore gains importance and may increasingly be used for systems where externally applied pressure would have to be extremely high.

Definition

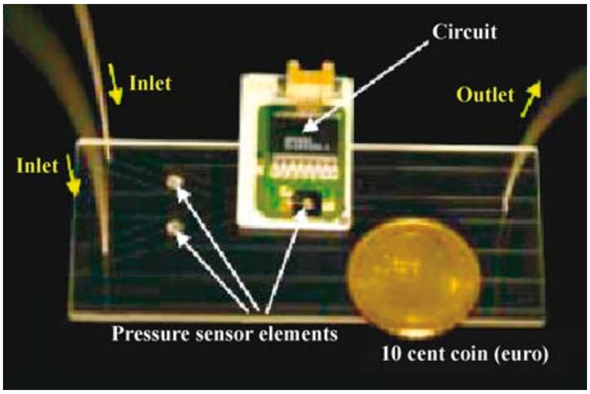
Experimentation and novel measurement techniques are crucial for the further development of microfluidic devices. Pressure is one of the basic parameters involved in microfluidic experiments. However, it is not realistic to apply conventional pressure measurement techniques to microsystems, since the characteristic dimensions of these measurement instruments are already comparable to those of the microdevices used. Therefore, novel pressure methods are needed for pressure measurement on the microscale.

Overview

It is not practical to measure pressures inside microchannels and nanochannels by use of conventional sensors, since it is very difficult or impossible to implement these sensors in microsystems without disturbing the flow field. Therefore, some novel methods are required for pressure measurement on the microscale.

The common practice for measuring the pressure drop along a microchannel is to use pressure transducers in the inlet and exit reservoirs, which gives overall information about the pressure rather than the pressure distribution along the channel. This approach is used in many studies related to fluid flow in microchannels [1–4].

Sekimori et al. [5] have developed a pressure sensor for use in Lab-on-a-Chip (LOC) devices. It has an embedded miniaturized structure and high chemical resistance, and causes no interference in the microflow during the measurement. This pressure sensor element has a volume of 1 mm^3 and was fabricated by using MEMS technology. The pressure sensor element was installed in an LOC without any dead volume or disturbance to the microflow, and the pressure inside the microchannel was measured (see Fig. 1).



Pressure Measurements, Methods, Figure 1 Installation of the pressure sensor to a microchip. Reprinted from [5] with permission from Dr. Kitamori

Wu et al. [6] proposed the use of single-walled carbon nanotubes (SWNTs) as nanoscale electromechanical pressure sensors. These authors demonstrated computationally a reversible pressure-induced shape transition in armchair SWNTs, which in turn induced a reversible electrical transition from metal to semiconductor. They also discussed the potential long lifetime of this pressure sensor due to the excellent mechanical durability of carbon nanotubes.

Li and Chou [7, 8] proposed the use of SWNTs as mechanical sensors to measure also mass, strain, and temperature, as well as pressure. The principle of sensing was based on the shift of the resonant frequency of a carbon nanotube resonator when it is subjected to changes in attached mass, external loading, or temperature. Li and Chou discussed the feasibility of such a sensor, with the aid of computer simulation using atomistic modeling together with molecular structural mechanics. They concluded that the sensing capability of this nanoscale sensor was superior to that of current microsensors, and that the sensitivity could be further enhanced by using smaller-sized carbon nanotubes.

Kim and Daniel [9] have recently suggested the use of atomic force microscopy (AFM) for measuring pressure profiles in micro/nanochannels. The method is based on measurement of the deflection of a thin plate over the channel surface by topographic imaging of the plate using AFM. Kim and Daniel verified this measurement technique numerically with artificially generated topographic data. Since the topographic imaging takes quite a long time, this technique is only applicable to steady-state processes. Moreover, special attention needs to be paid to providing vibration-free surroundings, since vibrations transmitted via the fluid can cause noise in the data, leading to loss of accuracy.

Matsuda et al. [10] have proposed the use of a pressure-sensitive paint (PSP) technique, which is based on the interaction of atoms or molecules with photons, to measure the pressure inside micro/nanochannels. This technique is limited to gaseous flow, and has drawbacks for high-pressure and low-speed applications. Moreover, the surface where the pressure is to be measured must be visible to the detector. The temperature sensitivity of the PSP technique must also be considered during the calibration.

In conclusion, although several techniques have been suggested by many researchers, the development of measurement techniques for use on the microscale is a challenging topic, and this topic seems likely to remain open-ended in the near future.

Definition

Protein microarrays are small chips made of glass, plastic or silicon that enable the study of protein–protein, protein–antibody and protein–drug interactions in a miniaturized, automated fashion.

Overview

Protein microarrays are chips made of glass, plastic or silicon spotted with an array of known antibodies or peptides onto which a biological sample of immobilized proteins is applied and binding determined (Fig. 1). These microarrays are used for identifying interactions between molecules fixed onto the surface (i. e. antibodies) and proteins in a solution. In a single experiment, these microarrays enable the simultaneous analysis of thousands of molecular parameters [1]. Typical applications of protein microarrays include determining protein–protein, enzyme–substrate, antibody–protein and drug–protein interactions, and determination of protein expression levels. In general, protein microarrays are classified under two broad categories: *analytical protein microarrays* for identifying the contents of an analyte and *functional protein microarrays* for studying the interaction between the protein of interest and other molecules [2]. Analytical protein microarrays often have microfluidic channels where a solution containing the proteins being investigated is pumped into a flow cell containing the microarrays. These types of protein microarrays are mainly used for basic molecular biology research, disease marker identification, toxicological response profiling and pharmaceutical target screening [3]. In contrast, functional protein microarrays have the proteins being investigated attached to the chip itself.

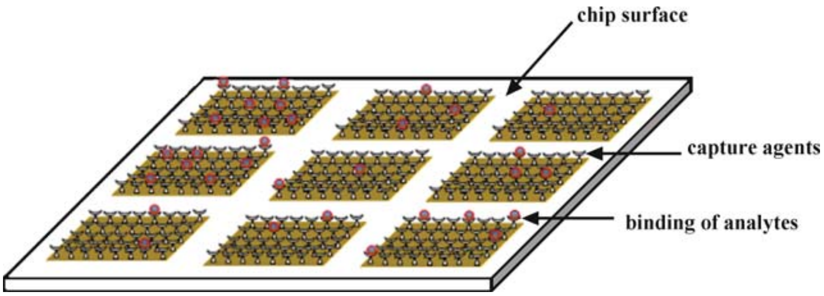
Protein microarrays are very similar to DNA microarrays; however, they are much more difficult to design [4]. DNA is an unstructured linear polymer that hybridizes due to information contained in the nucleic acid sequence. Proteins, however, are much more complex and possess a wide degree of secondary, tertiary and quaternary structures. In addition, protein function is highly dependant on protein structure. As a consequence, protein microarrays must be synthesized in a way that prevents denaturing of the molecule. Maintaining proteins in buffers at appropriate temperatures and pH is crucial in preserving protein shape. In manufacturing protein microarrays several sources of proteins and peptide have been arrayed onto a solid support including synthetic peptides, recombinant proteins, monoclonal antibodies and polyclonal antibodies. Out of these sources, antibody microarrays have been the most developed due to their good biochemical stability.

Basic Methodology

The design and fabrication of a protein microarray parallels that of a DNA microarray. Using a solid support that exhibits low non-specific binding is quite important in the design of a protein microarray. As shown in Fig. 1, typically glass and in some cases silicon and polymer are used as the support for protein microarrays. To increase signal-to-noise ratios, coating with nitrocellulose polymers can be used [4]. Some of the common protein microarray fabrication methods include robotic contact printing, ink-jetting, piezoelectric spotting and photolithography. A microfluidics system for automated sample incubation with arrays on glass slides and washing has also been developed.

In terms of attachment chemistry, covalent bond formation between the protein and the glass slide or affinity interactions are exploited as the means of attaching a protein to the solid support. In the covalent bond formation method, random regions of the protein are used as linkages to bind to the solid support resulting in different sides of the protein being exposed for probing interactions. In the affinity interaction method, the proteins to be plated are expressed as recombinant His-tagged proteins. The tagging of the protein enables the uniform placement of the protein onto the solid support, which can result in a more uniform signal. However, it has been suggested that the tag can artificially enhance some protein–protein interactions. Tagging both N- and C-terminals and comparing the results can resolve this problem.

Several companies have explored different means of attaching an array of proteins onto a solid surface. Schlei-



Protein Microarrays, Figure 1 A protein microarray with capture agents spotted on a chip surface. Typically glass and in some cases silicon and polymer are used as the support. Robotic contact printing is often used for spotting the agents on the surface. A microfluidics system for automated sample incubation with arrays on glass slides and washing is included. The analytes of interest are retained by selective binding to the capture agents. Specific binding is monitored by fluorescence or mass spectroscopy.

cher & Schuell and the Pall Corporation have used nitrocellulose-coated FAST and Vivid slides using simple random adsorption. The sensitivity for their antibody microarray has been reported in the range of 1 pg/mL. Xenopore, NoAb, BioDiscoveries, Microsurfaces and TeleChem International have products with surface-reactive groups that can minimize protein denaturation. Perkin Elmer and Biocept have commercially available glass slides coated with a hydrogel that increases the protein loading capacity.

Protein Microarray Applications

Protein microarrays find several uses such as in gene expression, detection of signal transduction, genome mismatch scanning, inflammation, cancer, cell cycle, DNA replication, oxidative stress, hormone action, apoptosis, neurodegenerative disease, infectious disease and cytoskeleton [4]. In broad terms, protein microarrays have found unique and superior advantage in the following areas: expression profiling, protein-protein interactions, drug discovery, and diagnostics.

- *Expression Profiling.* This is one of the main application areas for protein microarrays. The microarrays essentially help in identifying proteins in a sample or mixture. This requires good binding specificity and good binding affinity. In other words, the interactions between antibody and protein must be very specific and strong. Today, this is not done quantitatively, rather qualitatively. As a result, we get a relative difference in expression rather than a quantitative amount. This difficulty in quantifying binding efficiency accurately is due to high non-specific binding such as antibodies binding to proteins at varying degrees. Typically, quantification is done with standard calibration curves on the array for calibration.
- *Protein–protein interactions.* This is another area of protein microarray applications where proteins come to contact with other elements in the cell by binding interactions. These interactions influence the behavior of those elements with which they come in contact (i. e. signal transduction). Studying protein–protein interactions allows deeper understanding of the functionality of cells. Protein microarrays offer a means of directly studying these interactions, unlike DNA microarrays which are indirect in that – for protein expression – extrapolation of genetic sequencing or gene expression is used.
- *Drug discovery.* Drugs are often small molecules and interact with proteins. These proteins become activated or repressed due to the drug–protein interaction. Microarrays are being used to gain more understanding of cross reactivity and toxicity due to a given drug–protein interaction. Microarrays can be used as a means to optimize drug targets and avoid toxicity or side effects from activation of unwanted receptors.
- *Diagnostics.* Two diagnostic formats are generally available. One involves antigens printed onto the microarray with the purpose of identifying antibodies in patients. The other format involves antibodies printed onto the microarray with the intent of identifying proteins expressed as a result of genetic defects or disease.

P

Major Protein Microarrays in the Market

Many microarrays are available on the market, one of which is Clonetech's AB Microarray 500 [5]. This microarray is comprised of over 500 antibodies immobilized onto a glass surface at a high density. This device allows for direct comparison of protein expression in two biological samples. The device uses a fluorescence-based analysis which determines the relative measure of pro-

tein abundance in one sample compared to another. The device is typically used as a screening tool to identify proteins involved in physiological or pathological processes. For example, it can be used to detect proteins involved in signal transduction, cell-cycle regulation and apoptosis. Applications range from toxicity testing, to disease investigation and drug discovery [5].
Several companies are involved in developing protein microarrays for expression profiling and diagnostics. Examples include Zyomyx (Hayward, CA), Axcell Biosciences (Newtown, PA), BioSite (San Diego, CA), LumiCyte (Fremont, CA), Phylos (Lexington, MA) and ProteinOne (Bethesda, MD). Other players in the protein microarray market include BD Biosciences and Invitrogen who actually have leading positions in the market. Other chips on the market address the need for probing for a specific group of proteins rather than a diverse range. Zyomyx (Hayward, CA), for example, has developed a chip specific for human cytokines.

Key Findings and Future Directions for Research

Significant research and product development efforts in protein microarrays are being carried out in the following key areas: development of capture agents, surface attachment chemistry, and better detection methods.

- *Development of capture agents.* Monoclonal antibodies take a long time to develop and are labor intensive. Among some of the ongoing research in improving capture agents is the use of phage display methods that can be used to isolate high-affinity binding agents against protein targets [6]. Phage display is a system in which a protein is displayed on the surface of a phage as a fusion with one of the coat proteins of the virus.
- *Surface substrates and attachment.* The quality of data obtained from protein microarray experiments is severely affected by the nature of the surface substrate and attachment chemistry [7]. The immobilization of biotinylated proteins onto streptavidin surfaces has been demonstrated to lead to an increase in sensitivity over random attachment in a microarray assay. Poly(ethylene glycol) derivates used as coatings have also proved successful in increasing sensitivity.
- *Detection methods.* There are several detection methods currently under development. These include laser scanning, ELISA, phosphorimaging, atomic force microscopy, nanoparticles and rolling circle amplification. Currently, research efforts continue in improving detecting binding events. One promising area is the use of sandwich immunoassay with labeled detection antibodies. For ELISA-based assays that have certain restrictions, a highly sensitive detection strategy that uses rolling circle amplification (RCA) has been introduced [8].

Protein Profiling

► Lab-on-Chip Devices for Protein Analysis

Proteolysis

Synonyms

Enzymatic or chemical digestion

Definition

Proteolysis is the process of cleaving protein molecules into smaller pieces (peptides) via chemical or enzymatic reactions. Living systems carry out proteolysis to obtain amino acids from protein substrates or as part of the construction of new proteins. In proteomic analyses, it is often

necessary to perform proteolysis in order to facilitate identification of a protein of interest, as digest peptides form a characteristic "fingerprint" of the parent protein.

Definition

Proteomics is the study of the collection of proteins (the proteome) expressed in a given system. The field of proteomics can be divided into three subtypes:

- *profiling* – identification and quantification of the proteins in a sample and drawing comparisons between samples,
- *functional* – the study of the behavior of specific proteins, and
- *structural* – the study of protein folding and the complexes it forms.

Microfluidics is characterized by devices that contain channels or features with dimensions measured in microns, and are capable of transporting and analyzing sample volumes in the nanoliter range.

Overview

Proteomics is a field that first gained prominence in the mid 1990s. The sheer number of proteins as well as the number of variations that comprise the proteome presents a huge challenge for analysis. Serum protein concentrations can vary by several orders of magnitude, and often a single disease will affect both high- and low-abundance proteins to varying degrees. In addition to basic protein structures and sequences, a vast array of post-translational modifications exists that significantly impacts the functionality, structure, and activity of the native proteins. The primary applications of microfluidics in proteomics have been in the profiling and functional subtypes – structural proteomics has not yet been extensively studied on the microscale.

Profiling proteomics is used to identify all of the proteins in a sample or to compare changes in protein expression between several samples. Due to the complexity of the proteome, accurate analysis requires a great deal of sample processing, including proteolytic digestion, followed by multidimensional separations and mass spectrometry. Separations and mass spectrometry are be covered in other chapters of the *Encyclopedia* ►lab-on-chip devices for protein analysis, ►chromatographic chip devices, ►interfaces between microfluidics and mass spectrometry, but chemical processing for profiling proteomics will be discussed here. Readers are encouraged to see Friere and Wheeler [1] for a comprehensive discussion of proteome profiling in microfluidics.

The study of functional proteomics on the microscale comprises an assortment of assays to identify functional groups on proteins and evaluate binding events to determine functional properties of proteins. Functional proteomics is exploited in *enzyme assays* and *immunoassays* to characterize the behavior of a protein within a biological system.

There are a number of ways in which enzymatic studies contribute to the understanding of the proteome. Enzymes are commonly used in proteomics to investigate analytes that are difficult to measure by conventional means. Quantitation of small molecules with enzymatic methods provides insight into the concentration and activity of the proteins associated with those molecules. A great variety of these enzymatic assays have been carried out in microfluidic devices. Another function of enzymatic assays is in kinetics; measurements of properties of enzymes such as the Michaelis–Menten constant (the concentration of substrate when the reaction rate is half the maximum rate) and the turnover number (the number of moles of substrate that are converted to product per catalytic site per unit time) are vital to understanding the mechanics of the proteome, and are used to characterize of the effects of known drugs and discover new ones.

The immunoassay is another widely used technique that has been applied to a diverse set of proteomic applications, including the identification and quantization of protein markers for diagnosis of diseases where laboratory facilities are not readily available. Immunoassays can be

designed to detect very small amounts of antigens and to measure the concentrations quite accurately; in addition, further information about the disease markers, such as the existence of structural changes and posttranslational modifications, can be elucidated. Since immunoassays typically comprise a number of repetitive steps and require expensive reagents, they are a ripe target for adaptation to the microscale format, where sample sizes, reagent quantities, and analysis times are all greatly reduced.

Basic Methodology

The methods used in microscale proteomics applications can be divided into two categories, related to the features of microfluidic devices, and the nature of the analyses and assays themselves.

Features of Microfabricated Proteomic Devices

In proteomics applications, the most important features of microfluidic systems are related to delivery of fluid reagents, immobilization of proteins, mixing and reactions, and geometric microarrays.

Movement of Fluids

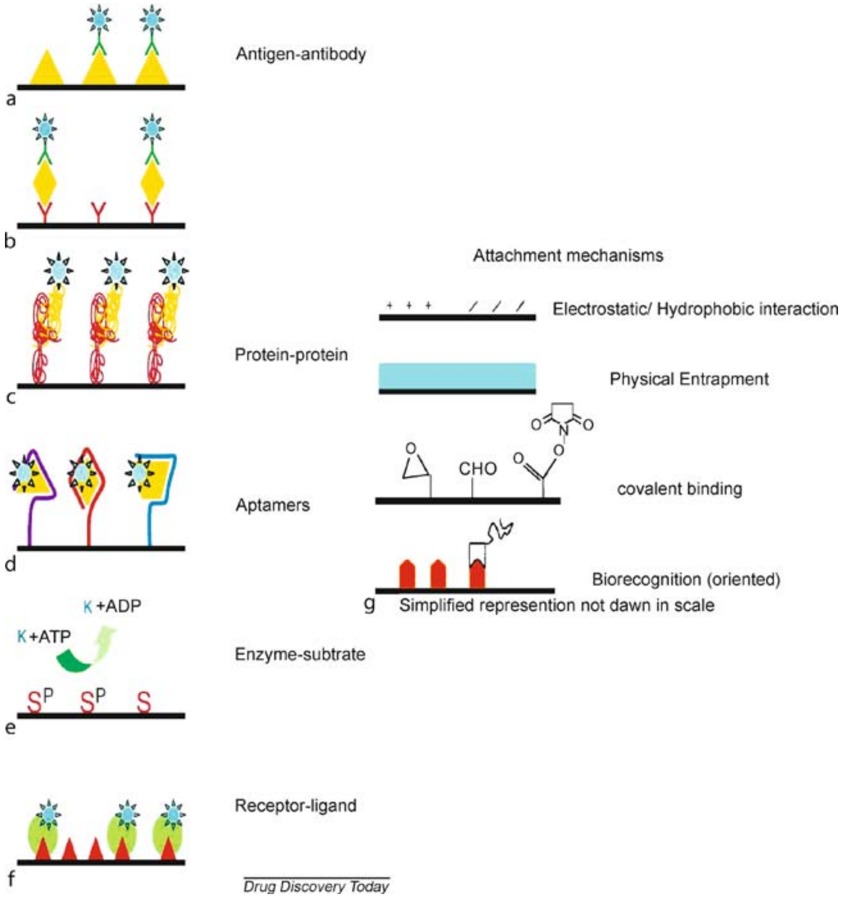
A critical decision for any microfluidic system is how to generate and control the flow of fluid. The most common methods rely on external pumps or electrokinetic flow. Conventional pumps are too large for pumping ~nL volumes of solutions, requiring splitters to isolate a fraction of the pressure to apply to the device. Smaller pumps such as syringe pumps are used frequently, but can be difficult to interface with microchannels in a device. Another common option is using electroosmotic (or electrokinetic) flow (EOF) to move analytes through a chip. This method is advantageous because it doesn't require any pressure to be applied on the sometimes fragile chips, it can move fluids at fast rates (exceeding 33 mL/min), and electrodes can easily be integrated into the chip itself. The magnitude of EOF is a function of the density of charge on microchannel walls (or on the surface of packed media); thus, careful consideration must be made in determining the materials used to fabricate devices. If materials without adequate charge density are used (or if the native EOF is too weak or strong), there are a number of coatings that can be used tune the direction and magnitude of EOF (► electroosmotic flow). Electrokinetic effects can also be used to separate the constituents of solutions; however, this can be one of its biggest disadvantages. Any fluid pumped by this method will have its components at least partially separated from one another, creating an inherent bias in any injected sample plug, and flow rates will vary due to protein adsorption on the interior of the chip or with Joule heating in the device. A final disadvantage is that all solutions must contain buffer ions in a particular concentration range, which is not convenient for all applications.

There are several less common alternatives for controlling fluid flow in microchannels. ► Digital microfluidics (DMF) is an alternative fluid handling method that is beginning to be used in proteomic applications. In DMF, discrete droplets are manipulated on a surface (rather than as streams in enclosed channels) via electrowetting and/or dielectrophoretic forces generated when an electrical potential is sequentially applied to electrodes in an array. This technique can be used with a wide variety of different fluids and can be applied to some aspects of sample preparation and purification. Hydrodynamic pumping, in which flow is driven by siphoning from one fluid reservoir to another, is an option for driving flow that does not introduce a sampling bias. It can, however, be difficult to control; consistency and fine-tuning of flow rate are problematic. Centrifugal pressure flow is another attractive option for fluid movement in protein studies, as it is insensitive to pH, ionic strength, and other characteristics of the fluid that may need to be varied for different assays. Centrifugal pumping is also relatively unaffected by the deposition of analytes onto channel walls (unlike EOF, DMF, etc.); however, it typically relies on single-use valves and therefore flow can only be driven one-time, and in one direction.

Immobilized Proteins

There are two basic formats in which assays are incorporated in microfluidic devices: homogeneous, or solution-based, assays, and heterogeneous, or surface-based, assays. Both approaches significantly reduce sample and reagent consumption relative to their macroscale counterparts, but heterogeneous assays are emerging as the dominant method for proteomics, as they can be adapted to many different types of interactions (Fig. 1a–f) [2].

Heterogeneous assays require proteins or other substrates to be immobilized on surfaces, which allows for conservation and repeated use of the immobilized bed, as well as facilitating the analysis of a sample without need for a separate concentration or mixing step. Also, the binding event or interaction between analytes is not restricted by equilibrium conditions or adequate mixing/diffusion of reagents. Finally, immobilization makes it easier to incorporate more than one reaction-zone in a device, increasing the number of analyzes that can be performed on a sample and taking greater advantage of the benefits of a microfluidic system. Several properties are required for useful surface-immobilized proteins, including: the sur-



Proteomics in Microfluidic Devices, Figure 1 (**a**)–(**f**) Several heterogeneous protein assay formats (reprinted from [2]). A variety of protein binding events can be studied, ranging from antibody/antigen to protein/protein to enzyme/substrate interactions. (**g**) Strategies for the immobilization of proteins on solid supports (reprinted from [4])

face must have a high binding capacity for the capture protein, the immobilized protein must retain its biological activity, the protein must be spatially accessible, and there must be a low level of *non*specific interactions between proteins in solution and the coated surface.

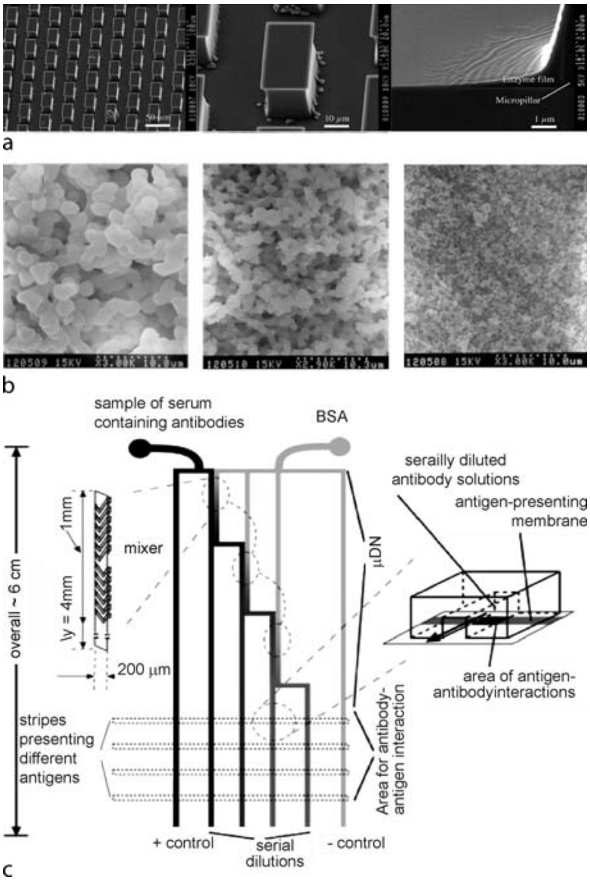
In microfabricated devices, protein immobilization is most often carried out on glass or silicon supports, using a wide variety of surface chemistries [3]. The most common methods for attachment of proteins to surfaces are depicted in Fig. 1g [4], ranging from simple (e. g., adsorption of proteins via electrostatic or hydrophobic interactions with the surface, entrapment in immobilized polymers, etc.) to more sophisticated techniques, relying on covalent bonding and biological recognition (e. g., biotin/streptavidin). In general, the most robust immobilized protein beds are formed by covalent attachment. One popular method requires two steps: a first layer is formed by silane chemistry such that the surface presents a reactive group (e. g., epoxy, amino, thiol, etc.), and a second layer (e. g., the protein to be immobilized or a linker molecule) is covalently attached via the immobilized reactive groups. Other strategies include covalent attachment to functionalized polymer coatings on the interior of the device or linkage to the free end of a self-assembled monolayer (SAM) on a gold surface. Most of these methods result in incomplete coating of the surface, and some reactive groups are left vulnerable to interaction with target proteins during analysis; this phenomenon is called non-specific interaction, and can negatively impact assay performance. A number of strategies exist for blocking surfaces to prevent nonspecific binding of analytes, most of which involve coatings of polymers (e. g., polyethylene glycol) or proteins (e. g., albumin or casein) that will not interact with the sample. However, even with these precautions, interactions between analytes and the surface of the device are very difficult to eliminate.

P

Mixers and Microreactors

In contrast to heterogeneous assays, in homogeneous assays, solutions of an enzyme and a substrate or an *antibody* and antigen are combined in a channel to evaluate the enzyme kinetics or properties of inhibitors, or measure the amount of displaced antigen, which requires thorough mixing. In low Reynold's Number microfluidic channels, turbulent mixing is not possible, and diffusive mixing dominates. Diffusive mixing is a reasonable technique for small molecules; however, enzymes and other large molecules diffuse much too slowly for adequate mixing in many proteomic applications. A number of passive mixing schemes in microfluidic systems have been developed – for example, a network of interconnecting channels of varying lengths and widths is capable of mixing solutions being pumped by electroosmotic flow, while patterned surface grooves enable mixing in a pressure-flow device.

One solution to the challenges of mixing proteins in microfluidic systems is to immobilize proteins in *microreactors* [5]. These systems typically consist of chambers of enzymes immobilized on beads, micropillars [6], or porous polymer monoliths [7] (Fig. 2a–b). Such systems have large surface area-to-volume ratios, which minimizes diffusion time for reactions with solution-phase reagents. Microreactors can be used either for the conversion of an analyte to another form that is more easily detected, or for direct studies of the properties of enzymes and substrates. One of the most common uses is for the digestion of proteins for proteome profiling, but such systems can also be used for the removal of amino acid residues from peptides or proteins or for enzyme kinetic studies.



Proteomics in Microfluidic Devices, Figure 2 (**a**) An enzymatic microreactor containing micropillars that have been coated with trypsin for protein digestion. Reprinted from [6]. (**b**) Porous monolith microreactors of various pore sizes. Pore size is determined by the ratio of monomer to porogen (solvent) during polymerization. Reprinted from [7]. (**c**) A microdilution network (µDN) for the quantitation of multiple antigens. The device uses a series of T-intersections to sequentially dilute a serum sample. Herringbone patterned areas are used as mixers in the dilution channels. Several antibodies have been deposited on a membrane using a microfluidic network, and the membrane is incorporated in the bottom of the µDN device. Reprinted from [12]

Microarrays

Biological microarrays are two-dimensional arrangements of immobilized spots of molecules on a surface. When a microarray is exposed to a solution containing unknown analytes bearing an appropriate label, analytes binding to particular spots on the surface can be rapidly identified. DNA microarrays were introduced in the late 1990s, and have become a widely used tool for high-throughput genomic analysis; however the development of similar tools for proteome analysis has been hampered by the diverse properties of proteins. For example, all DNA molecules inherently possess specific capture properties through complementary base-pairing; proteins do not have such a universal property. Additionally, protein capture *ligand*s tend to be more delicate in structure and function than the relatively robust DNA molecule. Finally, small amounts of DNA can be detected quite easily using amplification techniques such as the polymerase chain reaction (PCR); no such amplification technique exists for proteins.

Despite these disadvantages, the promise of multiplexed detection of analytes has made protein microarrays a popular research topic in microfluidic implementations of proteomic analyses.

The immobilized spots used in protein microarrays may contain protein molecules, or smaller molecules such as inhibitors or ligands with which a protein in solution may interact. Very small spots are advantageous in that higher detection throughput can be achieved with minimal amounts of printed material and sample. Spots are typically deposited either by contact methods, such as printing arrayers that use needles to deposit droplets directly on the

surface, or by non-contact methods, including the use of capillaries or ink jet dispensers to deposit droplets with nanoliter-picoliter volumes.

An alternative to microarrays is the use of arrays of multiple parallel channels. Typically, such structures are used to carry out a number of duplicate assays on one or more samples, to perform a serial dilution of a single sample for quantitation of a given protein, or to detect multiple targets in a single sample. In the latter case, an array of channels may be used in conjunction with a printed array of spots or bands – the channel network is used for fluid delivery to the printed array (Fig. 2c).

Analyses and Assays

Microfluidic devices are used in a variety of profiling and functional proteomics applications; the goal in much of this work is to reduce sample and reagent consumption and increase throughput. The primary application in profiling proteomics is in the preparation of protein samples for separations and mass spectrometry, while the major functional proteomics tools are enzymatic and immunological assays.

Sample Preparation for Profiling Proteomics

The identification of unknown proteins often requires that they be digested (or divided) into a group of constitutive peptides, which are interrogated by mass spectrometry. Comparing the masses of the peptides to genomic databases enables absolute identification by means of peptide mass fingerprinting (PMF). Proteins are digested by exposure to proteolytic enzymes (e. g., trypsin), or other lytic reagents (e. g., cyanogen bromide, CNBr); this is often part of a multistep process requiring 12 – 18 h, including mixing the sample with buffer and denaturant, mixing and incubating the sample with reducing agent to reduce disulfide bonds, mixing and incubating the sample with alkylating agent to prevent disulfide bonds from reforming, and finally, mixing and incubating with lytic reagent. This process is extremely tedious and time-consuming, making it an attractive application for microfluidics.

Several device configurations have been used for proteomic processing in microfluidic devices, including open channels, immobilized beads, and other solid phase media. Open-channel devices for tryptic digestion and reduction of disulfides in proteins are capable of achieving complete tryptic digestion in timeframes ranging from 15 min to 5 s. Immobilized beads increase the surface-to-volume ratio further; for example, a bed of trypsin-modified beads immobilized in a microfluidic chamber can be used very effectively for *proteolysis* of relatively large volumes of flowing sample. An alternative method for increasing the surface area-to-volume ratio in microfluidic devices is to use trypsin-modified monoliths, formed from polymer plugs cured in situ, or from membranes sandwiched between channels. Trypsin and other enzymes can also be copolymerized within hydrogel microstructures – the hydrogel is a biocompatible matrix that reduces the likelihood of damage to the enzyme during and after immobilization.

Microfluidics is promising for developing tools with integrated chemical processing of proteomic analytes, by virtue of fast reaction kinetics. Sample purification and concentration can be carried out on the microscale by methods such as solid phase extraction on hydrophobic surfaces ► lab-on-chip devices for sample extraction or affinity chromatography ► chromatographic chip devices. Immunoassays on magnetic beads have been used not just for detection of antigens (described below), but also as a purification method for the isolation of a target for mass spectrometry. However, to our knowledge, there have been no reports of implementing a fully integrated process, including stepwise reduction, alkylation, and digestion. Microfluidic tools for chemical processing will likely not be widely adopted until this critical benchmark is achieved.

Enzymatic Assays

Traditionally, enzymatic assays are performed in microtitre plates (plastic trays containing arrays of isolated wells), where an enzyme and its substrate are mixed in an individual well, and the substrate turnover is measured to determine the activity of the enzyme. Microfabricated devices that can perform enzymatic studies without interference between individual elements are highly desirable, as the macroscale method consumes a great deal of enzyme. There are three basic applications of enzymatic assays in proteomic studies:

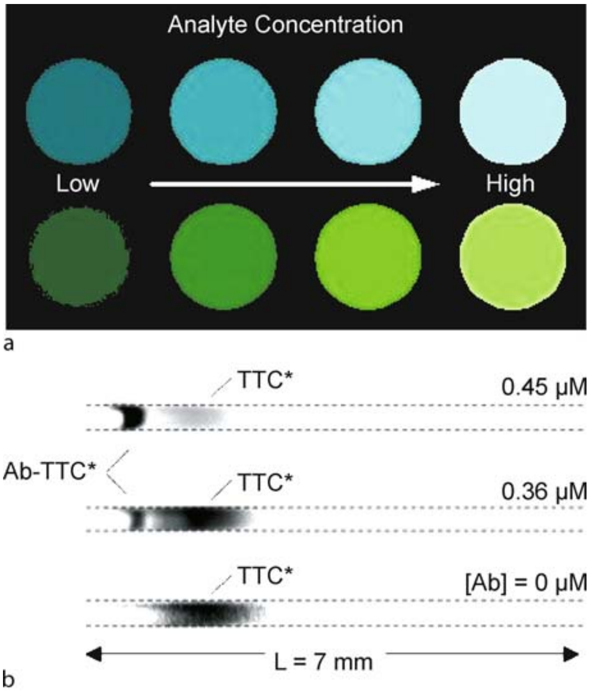
1. small molecule detection or sensing via an enzymatic reaction,
2. studies of enzyme–substrate, protein–ligand, and protein–protein interactions, and
3. kinetic studies.

The first type of enzyme application in microfluidics is chemical sensing. Sensors can be constructed in cases where an enzyme turns over a particular small-molecule substrate to produce a product quantifiable by fluorescence, chemiluminescence, absorbance spectroscopy, or electrochemical detectors. In cases where the substrate is not detectable itself, an enzymatic product can often be coupled to another enzyme that produces a detectable product. For example, there are a wide variety of small

molecules (such as nutrients, amino acids, and sugars) that can be coupled to the chemiluminescent reaction of luminol and peroxide in the presence of horseradish peroxidase. These enzyme-substrate assays were the first to be adapted to microfluidic devices – a great number of small-molecule sensors have been developed based on microfluidic channels with electroosmotic or hydrodynamic flow, and pre-loaded microfluidic cartridges containing nanoliter volumes of reagents have shown great promise as a replacement for 96-well plates for high-throughput screening [8].

The second type of enzyme application in microfluidics is protein interaction studies. In order to study interactions between enzymes and substrates, peptides, or other proteins, an alternative to microtitre plates is the microarray. These arrays are very often used in conjunction with microfluidic sample and reagent delivery systems; alternatively, microchannels can be used to deposit spots in an array. By immobilizing substrates or inhibitors on the array, it is possible to screen large numbers of molecules for their relative abilities to bind a particular enzyme. This is typically accomplished by tagging the enzyme with a fluorescent molecule and using the intensity of the array spots to determine the amount of enzyme bound (Fig. 3a). This is a promising approach for the identification of protein drug targets, or for the evaluation of compound libraries in drug discovery. Peptide fragments of proteins of interest have great potential as capture ligands, as they are easy to synthesize, stable, and able to mimic proteins. However, small molecules such as peptides are difficult to immobilize on a surface such that they are still accessible to the sample. Peptide fragments are also not as specific as complete proteins; for some applications, it is preferable to immobilize an entire protein to characterize its interactions with other proteins or enzymes of interest. Sample delivery to the elements of an array via microfluidics enables hundreds of different analyses to be performed on a single sample while reducing the size of that sample from microliter volumes to nanoliters.

A third type of enzyme application in microfluidics is kinetic studies, which may be carried out in either homogeneous or heterogeneous format. In homogeneous assays, adequate mixing of the enzyme, substrate, and any inhibitors that are being studied is crucial – this is done either via the merging of reagent streams at a T- or Y-shaped junction between channels or by means of a microfabricated mixer to ensure complete homogenization. A microfluidic mixer is advantageous – it ensures complete mixing of the enzyme and substrate and a smaller quantity of enzyme is consumed. Electrophoretically-mediated microanalysis, or EMMA, uses electrokinetic forces as the pumping method, which has the added benefit of separating product from substrate as the analysis proceeds. EMMA was first developed in capillary electrophoresis systems, but was readily adapted to microchannel setups [9]. Since a chip disperses Joule heat much more efficiently than a capillary does, the analysis can be run at higher potentials, increasing the speed of measurement. In most cases, a modified substrate is used that is converted to a fluorescent, chemiluminescent, or colored product by the enzyme, and optical methods are used to calculate factors such as the turnover number and Michaelis constant. Kinetic assays have also been carried out in centrifugal flow microfluidic devices [10], which are applicable for a wide variety of biological samples, including whole blood, plasma, and urine, that are incompatible with electroosmotic flow systems. Centrifugal devices are also easily adapted to perform multiple analyses on a single plastic device, reducing the costs of manufacturing. However, fresh enzyme is required for each determination, making enzyme recovery difficult. Heterogeneous enzyme microreactors eliminate the need for recovery



Proteomics in Microfluidic Devices, Figure 3 Detection of binding of a protein analyte in a heterogeneous (**a**) or homogeneous (**b**) assay. In (**a**), the fluorescence intensity of spots on an array reflects the amount of the target protein in the sample solution. Different analytes are tagged with molecules that fluoresce at different wavelengths to simplify identification. steps and dead time during the measurement. Microfluidic devices containing immobilized enzymes enable the study of kinetics with excellent enzyme recovery and decreased reagent consumption, increasing the overall efficiency of the method and greatly decreasing waste.

Immunoassays

Like enzymatic assays, immunoassays are conventionally implemented in microtitre wells, but they are even more easily adapted to the microscale. Homogeneous immunoassays are typically employed for the study of small molecules, while heterogeneous immunoassays are preferred for large-molecule detection.

A homogeneous assay is carried out by combining an antigenic sample and an antibody by means of electrokinetic flow in a microchannel. After the antigen binds the antibody, the complex can be separated from the remaining free antibody via electrophoresis to determine the amount of antigen present in the sample (Fig. 3b) [11]. On a microfluidic chip, this analysis can easily be multiplexed – a different assay can be performed in different channels on the same sample.

There are two common forms of heterogeneous assays used to detect and quantify disease markers: the direct-labeling method, in which the proteins in a sample are labeled with a detectable tag and isolated from a complex sample by means of a bed of immobilized antibodies, and the indirect-labeling method, in which two antibodies are used for each marker. Sandwich-type immunoassays, such as the enzyme-linked immunosorbent assay (ELISA), require two antibodies: an immobilized antibody used to capture a molecule of interest – a protein, a virus, or a small molecule (e. g., a hormone, pharmaceutical, or environmental pollutant) – and a second antibody in solution that is conjugated to a detectable tag. Immunoassays have also been carried out with detection via surface plasmon resonance microscopy, atomic force microscopy, and electrochemical sensors, eliminating the need for a detectable label. These assays are very useful because the antibody-antigen binding that must occur at each step is highly specific and thus has built-in redundancy – they are very sensitive and capable of quantitation of changes in concentration with a dynamic range of up to 2 – 3 orders of magnitude. As for enzymatic assays, microfluidic channels can be used either to deposit the first antibody onto a surface for immobilization or to direct the sample over the immobilized antibody (concentrating the antigen on the surface in the process) and any subsequent reagents – in some cases, microfluidic systems have been used for both purposes [12]. While basic immunoassays are well-suited for determining the presence of a given molecule in a sample and sometimes the quantity, they do not provide any other information about the target molecule. In recent work, immunoassays have been adapted to provide structural and post-translational modification information on marker proteins, however, these assays have not yet been widely applied to microfluidic devices and are still primarily performed in microtitre wells.

Key Research Findings

In the first report of on-chip proteolytic processing, Gottschlich et al. used open-channel devices for tryptic digestion and reduction of disulfides in proteins, which enabled complete processing in 15 min. More recently, Huang et al. [13] and Liu et al. [14] used surface adsorbed trypsin in channels to enable complete digestion in less than 5 s. In an alternative strategy, Yue et al. used a bed of trypsin-modified agarose beads immobilized in a weir in a glass microfluidic device to digest β-casein [15]. Peterson et al. used the related heterogeneous technique of forming methacrylate plugs cured in situ to increase the surface area-to-volume ratio to achieve tryptic digestion of myoglobin in $\sim$11 s [16]. Sakai-Kato et al. developed similar methods using trypsin immobilized in a sol-gel matrix [17]. Gao et al. reported using a trypsin-modified polyvinylidiene fluoride (PVDF) membrane in a PDMS microfluidic chip, enabling protein digestion in 3 – 10 min [18]. Each of these methods represents a vast improvement over conventional macroscale proteolysis, which typically requires hours-days. One promising approach for sample purification during processing is the use of digital microfluidics to remove hydrophilic impurities from proteomic samples [19].

Hadd et al. performed the first homogeneous assays to determine enzyme kinetics in a microfluidic chip – these assays relied on diffusional mixing of β-galactosidase and resorufin β-D-galactopyranoside (RBG) within a channel electrophoresis system [9]. This assay successfully characterized the kinetics of the enzyme, and reduced reagent consumption by four orders of magnitude over conventional assay methods. The same assay was later modified by Burke et al. by including a passive microfluidic mixer, resulting in a characterization of enzyme kinetics that more closely agreed with that obtained via conventional methods [20]. Puckett et al. developed a centrifugal microfluidic system in which homogeneous protein-ligand binding assays were performed to detect and characterize the binding interaction between phenothiazine antidepressants and calmodulin, a calcium-binding protein known to interact with this class of drugs [21]. This system utilized pre-measured aliquots of reagents,

increasing the speed and reproducibility of the analysis for high-throughput applications. In an effort to integrate multiple analyses on one device, Wang et al. incorporated two homogeneous assays into one microfluidic channel: an enzymatic assay for glucose and an immunoassay for insulin [22]. Electrokinetic effects were used for both fluid movement and separation of the components before detection. Through the use of pre- and post-column reactors and an electrophoretic separation of analytes, two independent measurements were made in the same space.

Perhaps the greatest area of interest in microfluidics for proteomics applications is in multiplexed, heterogeneous assays. Kim et al. used microfluidic PDMS channels to pattern sol–gels on polyvinylacetate-coated glass slides under conditions mild enough to retain protein activity [23]. The use of a microfluidic channel system generated a well-defined, intricate pattern of immobilized protein that simplified data collection. Jiang et al. patterned antigens on a membrane via a microfluidic network, and then positioned the membrane under a microdilution network to carry out serially-diluted immunoassays to detect multiple antigens on the patterned surface (Fig. 2c) [12]. This fluidic network enables the simultaneous quantitation of several molecules that vary widely in concentration – a major challenge in proteomics – in a single submicroliter sample. Brevig et al. developed a hydrodynamic microfluidic system that uses two streams of fluid to focus a sample and perform parallel immunoassays to quantitate levels of C-reactive protein, a well-known marker of inflammation (Fig. 4) [24]. As this method effectively creates a microscale stream within a larger chamber, it conserves sample but can also be carried out on whole blood without risk of clogging very small channels. In recent years, a great number of biochips have been made commercially available that use networks of microfluidic channels to perform analyses of over 100 different proteins using only 0.1 μL of whole blood [25]. These chips are capable of separating plasma from blood cells, and then directing the plasma sample across an ELISA array – the heterogeneous

array format and simplified sample prep are advantageous in terms of both speed of analysis and reduced sample consumption. This is very promising, as the cleanup of whole blood is a major bottleneck to the use of microfluidics in medical applications.

Future Directions for Research

The future of miniaturization in proteomic applications lies in achieving greater sophistication of devices. A variety of arrays have been used to investigate post-translational modifications such as phosphorylation and glycosylation, and it is only a matter of time before these are incorporated into microfluidic systems. Factors such as antibody synthesis currently limit the range of proteins that can be incorporated on an array, and devices that are capable of simultaneous quantitation of a protein and the study of its post-translational modifications, activity, etc., are not yet fully realized. Enzymatic microreactors are evolving in directions that will enable rapid screening of enzyme inhibitors for pharmaceutical purposes, industrial-scale synthesis, and environmental applications such as conversion of used grease to diesel fuel. Tools such as biochips mark the beginning of a shift from central laboratory to point-of-care testing, one of the hallmark aims of microfluidic technology. Together, these innovations will enable the development of a true total analytical system capable of greatly increasing the efficiency and throughput of any number of diagnostic, prognostic, and industrial processes.

Pyroelectric Flow Sensors

HUI YAN, HONGKAI WU
Department of Chemistry, Tsinghua University, Beijing, P. R. China
hkwu@mail.tsinghua.edu.cn

Synonyms

Pyroelectric sensors; Pyroelectric; Thermal flow sensors

Definition

A *pyroelectric* is substance that generates an electrical charge during a temperature change. The *pyroelectric coefficient* is the measured change in the polarization with a variation in the temperature in a single-domain pyroelectric material. *Pyroelectric sensors*, in principle, work as thermal transducers. The pyroelectric sensing element converts a non-quantified thermal flux into an output measurable quantity like charge, voltage or current.

Overview

Pyroelectric Effect

The pyroelectric coefficient (p) of a material under constant stress and electric field is defined by the following expression:

$$p = \left(\frac{\partial P}{\partial T}\right)_{E,\sigma} \tag{1}$$

where P is the polarization, T the temperature, E the electric field and σ ghe elastic stress.

Pyroelectrics can be classified into two main categories:

- non-pyroelectric pyroelectrics, those whose polarization cannot be switched by an application of external electric field (such as some semiconductors and biological materials); and
- pyroelectric pyroelectrics, those whose polarization is obtained by poling and also can be switched by an electric field.

The pyroelectric effect of pyroelectric pyroelectrics usually exists below a certain transition temperature called the *Curie point*, T_c, in proper pyroelectrics and is more temperature dependent than that of the non-pyroelectric pyroelectrics.

Primary and Secondary Pyroelectric Effects

Thermodynamic analysis of the pyroelectric effect yields the expression

$$P_i^\sigma = P_i^\varepsilon + d_{ijk}^T c_{jklm}^{T,E} \alpha_{lm}^\sigma \tag{2}$$

where P_i^σ is the total pyroelectric effect measured at constant stress, and P_i^ε, the pyroelectric effect at constant

strain ε, is called the primary effect. The second term of Eq. (2) is the contribution caused by thermal deformation of the crystal and is known as the secondary pyroelectric effect. Parameters d, c and σ are the piezoelectric, elastic stiffness and thermal expansion coefficients of the crystal, respectively.

In pyroelectric ferroelectrics, generally, the primary effect is large and negative because the spontaneous polarization decreases with increasing temperature. The secondary effect is considerably smaller and may have either sign depending on the values of the constants. And so the experimentally observed pyroelectric coefficients are dominated by the primary effect and are negative in pyroelectric crystals. But in non-ferroelectric pyroelectric crystals there is no simple way to predict the sign and the magnitude of their coefficients. In practice the total pyroelectric effect can be measured and, also, the secondary effect calculated from the constants d, σ and c.

Pyroelectric Currents

Pyroelectric currents are proportional to the time derivative of the temperature and, in case of infrared (IR) detectors, to the changes of IR radiation. In order to assess stationary IR sources as well, a chopper is used to modulate the IR radiation. Signals thus exhibit a well-defined angular chopping frequency ω. The smallest detectable temperature change is limited to the temperature fluctuation of the detector system, the electronics or the intrinsic noise current j_n of the pyroelectric element, given here for a thin film by the expression

$$j_n = \sqrt{\frac{A}{t} 4KT(\sigma + \omega\varepsilon_r\varepsilon_0 \tan\delta \Delta f)} \tag{3}$$

where σ is the leakage conductivity of the pyroelectric thin film (in bulk detectors, the parallel resistor); ω the angular frequency; $\tan\delta$ the loss tangent; Δf the frequency bandwidth; A the surface; and t the thickness of the element.

The crossover frequency $\omega_{el} = \sigma/\varepsilon_r\varepsilon_0 \tan\delta$ between resistor-type noise and dielectric noise is typically $0.1 - 10$Hz. At typical modulation frequencies of 30 Hz, the dielectric noise dominates. The figure of merit of dielectric and pyroelectric material parameters for an optimal detectivity can thus be formulated as

$$F_D = \frac{p}{\sqrt{\varepsilon_0\varepsilon_r \tan\delta}} \tag{4}$$

Essential Materials

Pyroelectrics in Materials with Perovskite Structure

Perovskite oxides have the structural formula ABO in which A may be some large cation, such as Ba^{2+} or Pb^{2+}, and B may be some medium size cation, such as Ti^{4+} or Zr^{4+}. These cations are located in cages formed by the network of the oxygen anions. There is an abundance of perovskites, natural (minerals) and synthetic ones, because of a large number of cations having sizes that can fit into the oxygen cages. Pyroelectric perovskites are a sub-group in the perovskite family.

Lead Zirconate Titanate (PZT)

Because of its high piezoelectric constants, PZT is the most widely used pyroelectric ceramic in sensor applications. PZT is a solid solution of lead titanate and lead zirconate. The substitution of a small fraction ($\sim$1 %) of the PZT cations by other cations can improve the properties. This method is always used to produce PZT that is optimized for different applications. Doping by cations of lower valence, e. g. Fe^{3+} replacing Ti^{4+}, Zr^{4+} and/or Na^{+} for Pb^{2+}, results in oxygen vacancies that stabilize the domain walls. PZT ceramics with dopants of lower valence (acceptors) are very useful for underwater applications and also for high-power and high-voltage applications. Doping with a higher valence than the substituted cations (donors), e. g., Nb^{5+} for Ti^{4+}/Zr^{4+} and/or La^{3+} for Pb^{2+}, increases the concentration of lead vacancies, enhancing the mobility of domain walls. These materials are used for medical transducers and for sensitive pressure sensors. PZT ceramics for pyroelectric applications are rich in titanium. The compositions rich in titanium (e. g., zirconium titanium) have a high pyroelectric coefficient and low permittivity, giving good pyroelectric figure of merit. Additionally, their coercive field is high, reducing the risk of depolarization during use and making this composition useful also in the form of thin films.

Relaxors and Relaxor Pyroelectrics

A large number of lead-containing perovskites, called relaxors, show anomalous characteristics typified by a strong frequency dispersion of the permittivity. Examples are lead magnesium niobate ($PbMg_{1/3}Nb_{2/3}O_3$ or PMN) and lead zinc niobate ($PbZn_{1/3}Nb_{2/3}O_3$ or PZN). These materials have many useful advantages:

- very high permittivity over a wide temperature range,
- large electrostrictive strain and
- strong pyroelectric response under a DC bias field. Solid solutions of relaxors and normal pyroelectrics, which are the subject of much interest, are called relaxor pyroelectrics, such as $PMN - PbTiO_3$ and $PZN - PbTiO_3$.

Layer Perovskites

A large number of pyroelectrics crystallize in the so-called layer perovskite phases. These phases are made of layers of perovskites separated by other layers; a typical example is bismuth oxide. Many pyroelectric layer perovskites have a high T_c, making them interesting for high-temperature piezoelectric applications. In addition, many of them are lead free. A prototype material is bismuth titanate ($Bi_4Ti_3O_{12}$).

Lithium-niobate and Lithium-tantalate

Lithium-niobate (LN) and lithium-tantalate (LT) are uniaxial pyroelectrics, having trigonal structure, with spontaneous polarization arising from asymmetrical displacement of lithium relative to the other ions. These materials' T_c values are 1210 and 620 °C, respectively. They are always produced commercially in single-crystal forms. Both are much used for surface acoustic wave devices (e. g., high-frequency filters), while LT is used for pyroelectric detection due to its large pyroelectric coefficient and low permittivity.

Pyroelectric Polymers

Pyroelectricity is also found in polymers. Polyvinylidenfluoride (PVDF, $(CH_2CF_2)_n$) is used for sensor applications that can benefit from a large sensor area. The pyroelectric polymers have low pyroelectric coefficients d and high coefficients because of the low permittivity. The polymers are light and then have good acoustic impedance matching to water, to organic and biological matter.

Dimensional and Microstructural Aspects of Pyroelectric Materials

Pyroelectric sensors utilize a wide range of material forms: crystals, bulk ceramics, thick layers and thin films. Noteworthy among new compositions with improved performance is the class of relaxor pyroelectrics. Many novel pyroelectric sensors utilize thin and thick films. Bulk pyroelectric ceramics for room temperature, and pyroelectric sensors, are widely available. New compositions with higher permittivity are available now.

Poling of Pyroelectric Materials

After the manufacturing, pyroelectric materials usually do not possess pyroelectric properties, since the pyroelectric domains are randomly oriented. The poling process consists of the application of a DC electric field to align the domains. A remanent polarization persists after the removal of the field and the material is pyroelectrically active. Poling is usually done at elevated temperatures (see below) using fields larger than the coercive field. During use of pyroelectric materials, care should be taken to avoid depolarization under high temperatures, electric fields or stresses.

In summary, pyroelectric materials have found applications in a wide range of fields. For device applications and the convenience of application engineers, several figures of merit criteria are defined. Most of these can be calculated using the thermal, electrical and optical characteristics of the materials available in the literature and various handbooks on the physical constants of materials.

Pyroelectric Flow Sensors

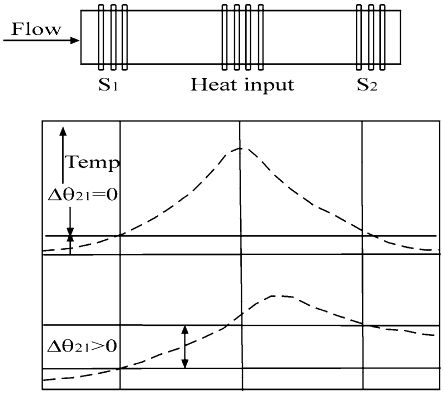
Pyroelectric flow sensors are a kind of thermal flow sensor. They can be classified according to the thermal transfer mechanism, i. e., calorimetric- or boundary-layer-type flow meters and here the latter will be introduced.

Thermal mass-flow meters directly measure the mass-flow rate utilizing the thermal transfer process between a heated element and the flowing mass. According to the thermal transfer mechanism, they can be classified as calorimetric- or boundary-layer-type flow meters. Calorimetric flow meters utilize the simple principle that as the mass flows through the device, power has to maintain the temperature of the incoming mass at a known level. By measuring the supplied power P and the temperature above ambient, ΔT, the mass-flow rate $\dot{M}$ can be calculated as the expression

$$\dot{M} = \frac{1}{c_{pg}} \frac{P}{\Delta T} \tag{5}$$

where c_{pg} is the specific heat of the mass at constant pressure. A typical example of calorimetric flow meters consist of a thin-walled capillary with a heater wire wound around its center. The wire resistor serves both to heat the center section and to provide a measure of the temperature, since the resistance of the heater wire is a function of temperature. Because the capillary has a very small diameter, the mass absorbs heat from the wall and quickly reaches the wall temperature. As the mass follows, additional power has to be supplied to compensate for the energy carried away by the mass. The mass-flow rate may be measured by keeping either the power or the elevated temperature constant.

Another type of capillary flow meter is shown in Fig. 1. A central heater (H) is wound about a thin walled capillary tube. Two resistive sensor elements are mounted on the capillary symmetrically, one upstream (S_1) and the other downstream (S_2) of the heater to monitor the temperature



Pyroelectric Flow Sensors, Figure 1 A capillary flow meter with external heater and transducers is depicted at the top with the corresponding temperature profile along the capillary for zero (upper) and nonzero (lower) gas flow

as depicted in the upper portion of Fig. 1. The difference in temperature between the two sensors

$$\Delta T_{21} = \Delta T\,(\mathrm{S}_2) - \Delta T\,(\mathrm{S}_1) \tag{6}$$

is used to determine the flow rate. In the absence of flow, the temperature profile in the capillary is symmetric with $\Delta T_{21} = 0$ as shown in Fig. 1. As mass flows, heat is transferred from the wall to the moving fluid at the upstream position, thereby lowering $\Delta T(\mathrm{S}_1)$. At the downstream electrode, energy is injected into the wall at S_2 by the heated flowing fluid, thereby increasing the temperature $\Delta T(\mathrm{S}_2)$. The net effect is an asymmetric temperature profile in the tube causing $\Delta T_{21} \neq 0$, as indicated at the bottom of Fig. 1. This differential measurement has the advantage of being directional and providing a zero signal at zero flow.

Basic Methodology

Methods for Determination of Pyroelectric Coefficients

There are several methods for measurement of pyroelectric coefficients, but most can be grouped into two kinds. The objective in the first case is to directly measure the pyroelectric current and at the same time change the temperature. In the second method measurements of polarization or charge can be estimated either by the integration of pyroelectric current during the continuous heating of the sample or recording the hysteresis loop at various temperatures by the Sawyer–Tower technique.

In the first approach the changing temperature can be generated by chopping the incoming radiation source or AC heating (known as the Chynoweth technique) of the sample and the pyroelectric response current i can be expressed as follows:

$$i = \frac{p\eta W T_{\mathrm{r}}}{Ct}$$

where η is the power absorbed by the sample, T_{r} is a transfer function depending on the thermal circuit of the sample and the chopping or modulation frequency, t is the thickness of the sample and C is the thermal capacity of the sample. Often a thin layer of highly absorbing material is applied on the sample in order to achieve $\eta = 1$.

The pyroelectric current $i(T)$ at a temperature T can also be measured by uniformly heating or cooling the sample at a constant rate (generally, 1 to 4 °C/min) and the pyroelectric coefficient, p, can be calculated using the following expression (Byer–Roundy technique):

$$i(T) = \frac{Ap}{(\Delta T/\Delta t)^{-1}}$$

where A is the electroded area of the sample and $\Delta T/\Delta t$ is the heating or cooling rate of the sample. Here, the charge release (in either of the two cases mentioned earlier) at a discrete temperature is determined and the pyroelectric coefficient is obtained graphically or by differentiation.

Methods for Thin-Film Deposition

Thin-film deposition techniques such as sol–gel method, hydrothermal route, sputtering, metalorganic chemical vapor deposition (MOCVD) and pulsed laser deposition have been developed and are being adapted in commercial devices. Table 1 lists some advantages and disadvantages of different film deposition techniques. Three major kinds are sol–gel, physical vapor deposition and chemical vapor deposition. In wet methods, the sol–gel technique uses fine powder in gel forming a liquid-like mixture of metal oxides and organic salts to grow transparent ceramic films. It is low energy consuming process at lower crystalline temperature and allows better control of chemistry by mixing of precursors in the liquid state at the molecular level. Most electroactive ceramics and polymers are amenable to this technique. Physical vapor deposition requires vacuum and uses DC or RF magnetron sputtering and pulse laser deposition to provide high quality, uniformity and stability but low deposition rates of materials. Chemical vapor deposition, i. e., MOCVD, on the other hand, uses volatile chemical precursors, which are vaporized on heated substrates. It is proving suitable for conformational deposition of high-quality three-dimensional structures on bottom electrodes and is characterized by high deposition rates.

Pyroelectric Flow Sensors, Table 1 The advantages and disadvantages of different film deposition techniques

	Deposition technique	Advantages	Disadvantages
1	Sol–gel	Lower crystallization temperature, lower cost, better control of mixing of precursors, quickly produce new materials	Lack of phase and composition control, morphology, reproducibility
2	Physical vapor deposition (i) DC sputtering (ii) Pulsed laser deposition (iii) MBE	Compatibility with IC processing Uniformity and scalability, high quality Rapid sampling of materials, quickly produce new materials Composition control, precise atomic layering, extreme flexibility and scalability	High equipment cost Low deposition rate, high point defect concentration Lack of uniformity, high residual stresses Expensive development stage
3	Chemical vapor deposition	High deposition rate, good stoichiometry control, low point defect concentration, high conformity and scalability	Low precursor stability, expensive

Properties to be Considered of an Appropriate Material

While the pyroelectric, dielectric and thermal properties of pyroelectric materials are clearly fundamental in determining the basic performance of a device, there are many other properties to be considered when making a selection of an appropriate material. These are the following:

- Electrical resistivity. The circuit in Fig. 2 shows a resistor R_G connected across the active element. This serves three functions. First, it fixes the electrical time constant τ_E of the device. Second, it allows the gate leakage current of the FET to bias its operating point. If there was no bias resistor here, the FET amplifier would not be stable and would take a long time to settle. Third, it determines the voltage responsivity.
- Piezoelectric properties. At first sight it seems surprising that piezoelectric properties are important in pyroelectric devices. However, all pyroelectric detectors used in a high-vibration or acoustically noisy environment will produce a piezoelectric microphonic noise signal, mostly through flexure, which can be very significant if steps are not taken to suppress it.
- Manufacturability. The ability to make the selected material in a large area at low cost is a very important consideration. Pyroelectric ceramics have an important advantage here over some of the single-crystal materials that are available, as a consequence of their relative ease of manufacture using a range of techniques and their stability during other subsequent manufacturing processes.

Examples for Sensor Design and Fabrication

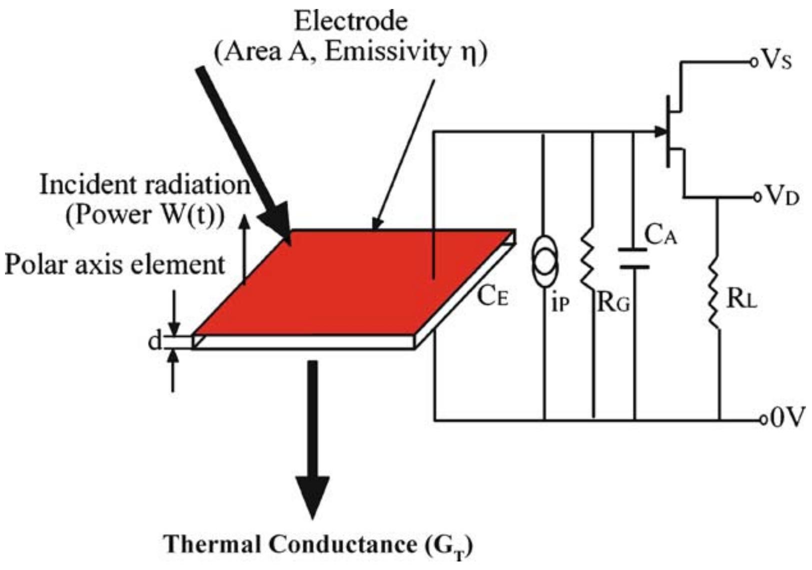
Many studies had demonstrated that pyroelectric anemometers based on single-crystal $LiTaO_3$ have a very wide range and the promise of interesting response characteristics. The following example was well characterized by a conjugate gas-flow–heat-flow model.

A 200 μm thick, 30 mm diameter, Z-cut, single-crystal $LiTaO_3$ wafer, unpolished on both sides, was used to fabricate the pyroelectric flow sensor. The wafer was first degreased by immersing in trichloroethane, acetone and isopropyl alcohol for 10 min each and then it was rinsed in deionized (DI) water and blown dry with nitrogen. After cleaning, nichrome (NiCr) and gold films were sequentially deposited on the front surface of the wafer. This was done in a cryo-pumped electron-beam evaporator at a pressure of about 10^{-5} Pa without breaking vacuum between the NiCr and Au evaporations. The last step minimized contamination of the devices.

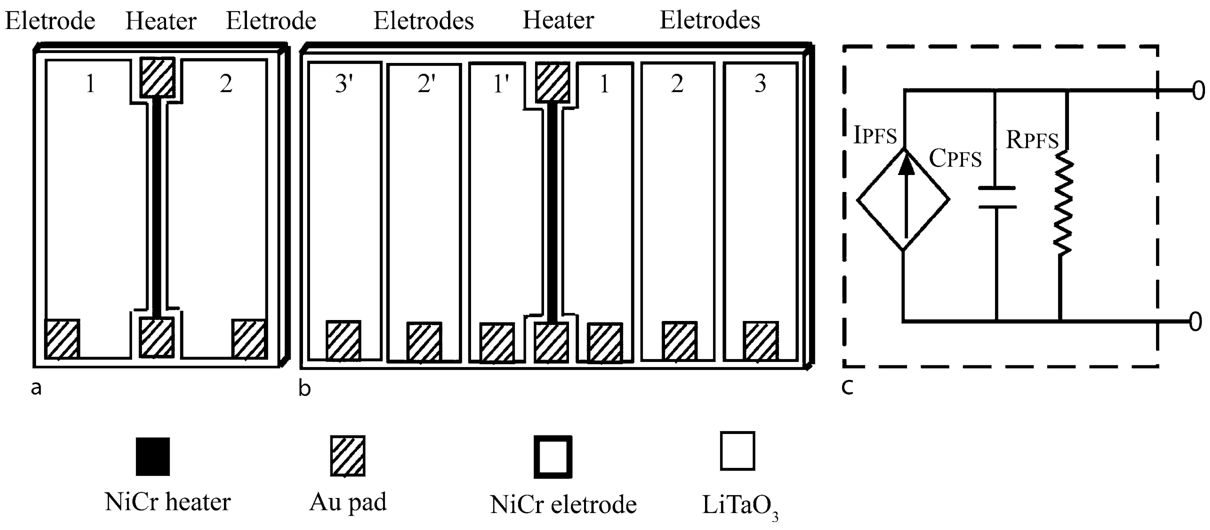
Two masks were prepared to define the nichrome and gold patterns. Using standard photolithography, the Au leads and contact patterns were formed in a photoresist layer. The residual gold was removed with a solution of $4\,g\ KI : 1 g\ I_2 : 40\,mL\ H_2O$. The $KI - I_2$ solution was chosen because it etches the gold film but not the NiCr. The photoresist was then removed using photoresist stripper and rinsed in DI water.

After cleaning and processing, the NiCr pattern was formed in the photoresist by aligning a suitable mask to the Au pattern on the wafer. The NiCr on the wafer was etched using a solution of $310\,g\ (NH_4)_2Ce(NO_3)_6 : 1970\,mL\ H_2O : 120\,mL\ HNO_3$. With the completion of the front side patterning, a 200 nm thick NiCr film was evaporated onto the backside of the wafer. The wafer was then sliced into chips.

The two-electrode element, 3.8 mm × 3.8 mm × 0.2 mm in size, is shown in Fig. 3. The device was mounted on a ceramic carrier with one end of the heater connected to the NiCr common on the other side of the $LiTaO_3$ chip. The assembled unit was then inserted into a standard



Pyroelectric Flow Sensors, Figure 2 Schematic diagram of a pyroelectric detector element



Pyroelectric Flow Sensors, Figure 3 Layer of (**a**) a two-electrode element pyroelectric flow sensor and (**b**) a six-electrode one and (**c**) the equivalent circuit of the pyroelectric electrode

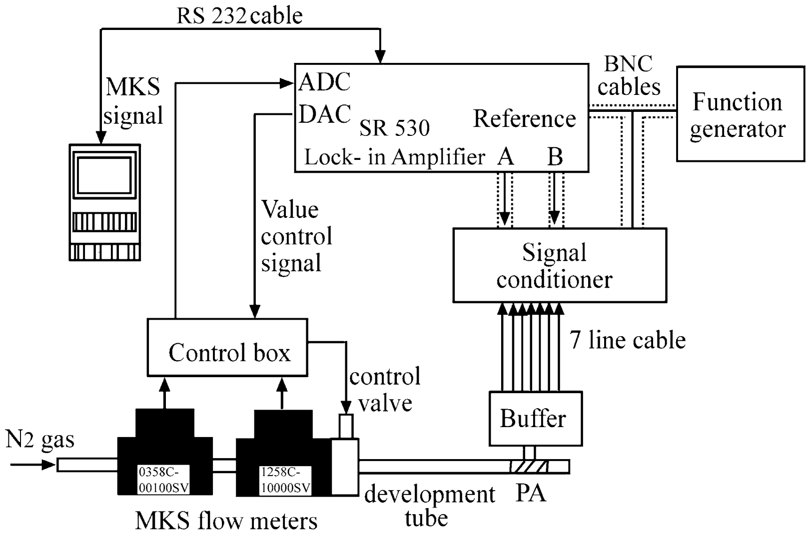
1/4′ Union Tee. For completeness, the equivalent circuit of the pyroelectric flow sensors electrode is shown in Fig. 3. A schematic diagram of the measurement system is shown in Fig. 4. The basic component consists of a function generator that produces the heater current and a computer-controlled two-phase analog lock-in amplifier.

Other parts of the electronic measuring system consisted of a function generator to supply a sinusoidal driving voltage to the heater of the sensor, a buffer, a signal conditioner for the output from the sensor, a two-phase lock-amplifier and a computer. The signals from the two electrodes of the sensor are sent directly to a buffer. The buffer section transforms the high impedance of the sensor signal into a low-impedance signal, which is sent to a signal conditioner through a seven-line cable. Because of the extremely high resistance, R_{PA}, of the sensor chip, the loading by the electronics produces a voltage output signal across the input resistance of the buffer amplifier.

Key Research Findings

Modification of Pyroelectric Materials

As we know, there are many kinds of pyroelectric materials, but all of them have some advantages and disadvan-



Pyroelectric Flow Sensors, Figure 4 Diagram of the measurement system

tages. For example, as a perovskite-type pyroelectric compound desirable for pyroelectric infrared detectors because of its relatively large pyroelectric coefficient and spontaneous polarization, PT has poor mechanical properties due to its large tetragonal strain which makes poling of PT materials difficult. Much attention has been focused on the modification of PT by doping with the purpose of obtaining improved mechanical and electrical properties. The incorporation of off-valent (La^{3+}, Sm^{3+}, Nd^{3+}, Gd^{3+}) and isovalent ions (Ca^{2+}, Ba^{2+}, Sr^{2+}) into PT ceramics is reported to enhance the pyroelectric properties. Substitution of these ions results in the reduction of lattice anisotropy leading to hard and dense ceramics with high mechanical strength. From the standpoint of thermal responsivity, the performance of a pyroelectric detector is enhanced when it is in the form of a thin film. In recent device applications, it has become increasingly necessary to consider the improvement of these films in their performance in addition to the large component area and connection to many circuit elements. Recently, calcium- and lanthanum-doped lead titanate (PCT and PLT) thin films have been studied due to their possible use in optical waveguides, infrared sensors, dynamic random access memories and non-volatile memories. Thin-film optical devices are especially attractive because of their potential for monolithic integration. In addition, thin films offer the potential for increased speeds, reduced operating voltages and enhanced efficiency.

In order to improve mechanical properties for different applications, many pyroelectric polymer composites have been prepared, such as $BaTiO_3$–PVC composites, $(Bi_{0.5}Na_{0.5})_{0.94}Ba_{0.06}TiO_3$/P(VDF-TrFE), 65PMN-35PT/P(VDF-TrFE) and DTGS:PVDF.

Preparation of Thin Films

The use of bulk pyroelectrics in pyroelectric devices inevitably leads to a situation where the material must be cut, lapped and polished to make a thin, thermally sensitive layer. If an array of detectors is required for a thermal goal, this must be metallized on both faces, processed photolithographically and bonded to a silicon read-out circuit to yield a complete hybrid array. Clearly, it would be desirable if the material could be deposited as a thin film, to remove the requirement for lapping and polishing, if possible directly onto a complete wafer of chips, where it could be processed to yield an array of thin, thermally isolated structures. Fortunately, many techniques have been researched for pyroelectric thin-film deposition, mainly for applications to non-volatile memories. These include chemical solution deposition (CSD), metalorganic deposition (MOD), RF magnetron sputtering, pulsed laser ablation (PLD) and metalorganic chemical vapor deposition (MOCVD).

Pyroelectric flow sensors and chips

Pyroelectric sensors have recently been increasingly employed for sensing purposes. Excellent piezoelectric and pyroelectric properties of pyroelectric materials, combined with design flexibility and miniaturization offered by thin-film geometry and also developments in micro- and nanoscale fluids technologies have generated great

interest in pyroelectric thin films. The multisensing chip utilizes the pyroelectric effect in the following sensing devices: gas-flow sensor infrared detector arrays, chemical reaction sensors and charge-coupled device imagers. A multipurpose integrated sensor chip that responds simultaneously to several different physical and chemical variables has been fabricated.

Also, multifunctional pyroelectric flow sensors have also appeared. As we know, any change in the temperature induces charges on the surface of the material, inducing an electric field, which generates transverse strain and bending deformation (see Fig. 3). A typical example is used for flow sensor and valving purposes.

Future Directions for Research

During recent years, the study of micro- and nanoscale fluids has shown significant opportunities for high detectivity of elementary devices with small size. For pyroelectric flow sensors, it is highly desirable to develop theoretical models, experimental methods for pyroelectric element preparation and sensor fabrication, and higher sensitivity with excellent mechanical properties.

Definition

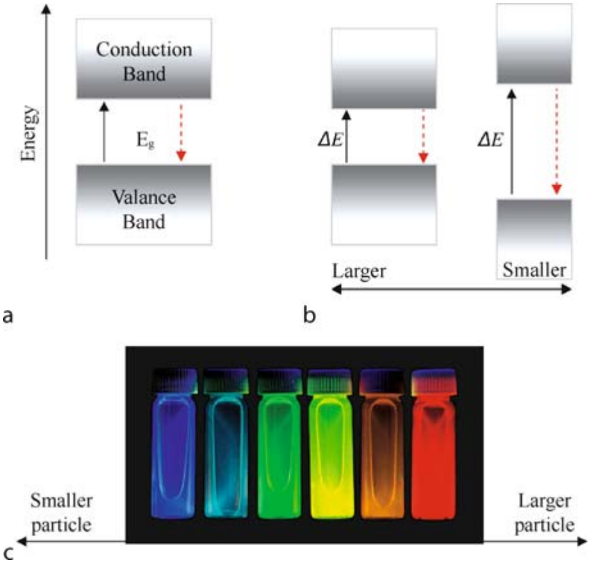
A quantum dot is a semiconductor nanoparticle that confines the motion of electrons and holes in three spatial directions.

Overview

Quantum confinement is defined as the space where the motions of electrons and holes in a semiconductor are restricted in one or more dimensions. This quantum confinement occurs when the size of semiconductor crystallites is smaller than the bulk exciton Bohr radius. Quantum wells, quantum wires, and quantum dots are confined in one, two, and three dimensions, respectively [1, 2]. The confinement can be created due to electrostatic potentials, the presence of an interface between different semiconductor materials, and the presence of a semiconductor surface. A valence band and a conduction band are separated by an energy range known as the band gap (E_g). These amounts



Quantum Dot, Figure 1 Schematics and image of quantum confinement and semiconductor size: (**a**) energy level of high-energy conduction band and low-energy valence band; (**b**) band gap energy increase by decreasing nanoparticle sizes; (**c**) quantum dots of cadmium sulfide in solution fluoresce brightly under ultraviolet light [3]

of energy will be absorbed in order to promote an electron from the valence band to the conduction band and emitted when the electron relaxes directly from the conduction band back to the valence band. By changing the size of the semiconductor nanoparticles the energy width of the band gap can be altered and the optical and electrical responses of these particles are changed (Fig. 1).

A quantum dot containing electrons can be compared to an atom because both have a discrete energy spectrum and bind a small number of electrons. However, a quantum dot different from an atom can be engineered by controlling the geometrical size and shape and the strength of the confinement potential [4].

A quantum dot confines more electrons and holes than those of the bulk semiconductor material. This causes a blue-shift of the interband absorption and a quantum dot of the same material can emit different color light depending on its size [5]. A smaller quantum dot emits shorter wavelength light (bluer) while a larger quantum dot emits longer (redder) wavelength light because of the band gap energy (E_g) levels (Fig. 1a), which determine the fluoresced light. This band gap energy is inversely proportional to the square of the size of the quantum dot. Consequently, a larger quantum dot has more energy and a closer energy band (Fig. 1b). This allows the quantum dot to absorb photons containing less energy, which is closer to red light (Fig. 1c).

The size of a quantum dot is important for the tunable light emission characteristic. A small quantum dot, such as a colloidal semiconductor nanocrystal, can be as small as 2 to 10 nm [6]. A self-assembled quantum dot is typically between 10 and 50 nm in size [7]. A quantum dot defined by lithographically patterned gate electrodes or by etching on two-dimensional electron gases in semiconductor heterostructures can have lateral dimensions exceeding 100 nm [8].

Quantum dots have many promising applications in diode lasers [9], QD-LED for computer displays [10], quantum computing [11], solar cells [12], and biological applications such as medical imaging and disease detection [13].

Reactive Ion Etching (RIE)

SAMI FRANSSILA, LAURI SAINIEMI
Helsinki University of Technology, Helsinki, Finland
sami.franssila@tkk.fi, lauri.sainiemi@tkk.fi

Definition

Reactive ion etching (RIE) is a plasma process where radiofrequency (RF) discharge-excited species (radicals, ions) etch substrate or thin films in a low-pressure chamber. RIE is a synergistic process between chemically active species and energetic ion bombardment. RIE is faster than either pure physical ion bombardment or spontaneous chemical etching. Because ion bombardment is directional, RIE has anisotropic character, with reduced lateral etch rate and vertical (or nearly vertical) sidewalls. RIE is essential when narrow lines or channels are needed, or when high aspect ratio structures need to be fabricated. RIE of silicon is independent of crystal planes, and therefore any shape can be fabricated, unlike anisotropic wet etching. Deep reactive ion etching (DRIE) is an extension of RIE that enables high-rate etching of deep structures.

Overview

Etching has traditionally been divided into wet and dry etching, according to etchant phase. In the case of wet etching, the etch reaction results in soluble products; in the case of dry etching, in volatile etch products:

Solid + gaseous etchant → volatile products

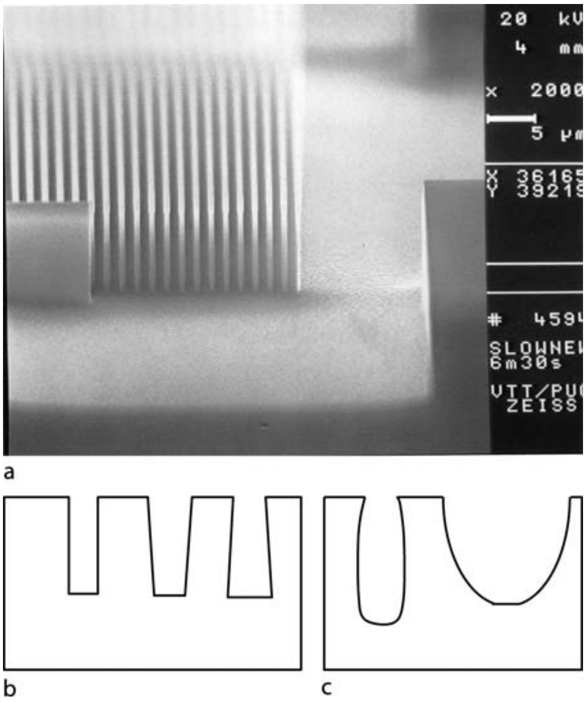
$Si(s) + 2XeF_2(g) \rightarrow SiF_4(g) + 2Xe(g)$

$W(s) + SF_6(g) + O_2(g) \rightarrow WF_6(g) + SO_2(g)$

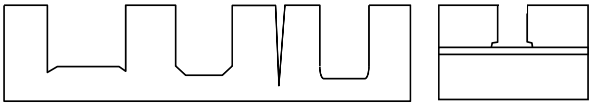
Etch gases are thus selected on product volatility considerations. Halogens F, Cl and Br are the most widely used etch species, coming from SF_6, CF_4, CHF_3, C_4F_8, Cl_2, BCl_3, $SiCl_4$, HBr. Typical etch products include SiF_4, $SiCl_4$, NF_3, WF_6, $AlCl_3$ [1–3]. Non-volatile etch products like AlF_3 or $CuCl_2$ cause problems in the form of residues, micromasking, roughness and non-uniformity.

Other gases used in RIE include oxygen, hydrogen, argon, helium and nitrogen. These have roles in modifying plasma chemistry and physics, heat transfer and surface chemistry. Oxyhalides typically form WO_xF_y type etch products, and CO_2 and H_2O are generated as photoresist mask is etched.

Additive gases are also important for anisotropy mechanism: for instance deposition of SiO_xF_y film is essential for sidewall passivation in silicon etching in SF_6/O_2 plasmas. Similarly, CHF_3 and C_4F_8 etch gases lead to deposition of $(CF_2)_n$ type fluoropolymer films, which passivate sidewalls and minimize lateral etching. Etch rate and anisotropy are manifestations of balancing properly etching and deposition reactions.



Reactive Ion Etching (RIE), Figure 1 RIE etched sidewall profiles (from left to right): vertical (SEM and schematic); positively sloped; negatively sloped (retrograde); bowing (barrelling); isotropic



Reactive Ion Etching (RIE), Figure 2 Bottom of etched structures: trenching; faceting; spearheading, rounding; notching (footing) at insulator interface

Etched profiles are depicted in Fig. 1. Perfectly vertical walls are possible, but both positively and negatively sloped and bowing and isotropic profiles can be found. The bottoms of reactive ion etched structures exhibit similarly a wide variety of shapes (Fig. 2): trenching, faceting, spearheading and rounding. At insulator etch stop layers notching (footing) effects can take place.

Ion beam etching (IBE; also known as ion milling) relies on energetic (argon) ions and differs thus from RIE. Chemically active species are absent in ion beam etching, and etch product volatility is not an issue. IBE rates are very low compared to RIE, only 20 – 100 nm/min. Reactive ion beam etching (RIBE) uses reactive ions, e. g. fluorine or chlorine, but the etching mechanism is dominated by physical bombardment at low pressures.

The term dry etching is sometimes used as a synonym for RIE, but there are also processes which are dry etching without ions or plasmas. The XeF_2 example cited above is a case of spontaneous chemical reaction that proceeds without plasma activation.

Basic Methodology

For many materials there is the choice of both wet and RIE processes. Silicon, silicon dioxide, aluminum, tungsten (and other refractory metals) and glass/quartz can be etched by either method. Silicon and its compounds can be etched in both fluorine or chlorine plasmas, with SiF_4 or $SiCl_4$ as the main reaction products, but because of tighter safety requirements chlorine gas is less popular [4]. In integrated circuit fabrication Cl_2 (and HBr) source gases are used routinely in silicon etching because they offer better anisotropy and higher oxide selectivity than fluorine gases. DRIE of silicon using Cl_2 gas is limited because the etch rate is very slow compared with that of fluorine gases, even by a factor of ten. Another drawback is the need for thick metallic masks (e. g. several micrometers thick electroplated nickel). The advantages of Cl_2 plasmas are in smaller RIE lag (see below) and smaller mask undercut.

Silicon nitride is etched in CF_4- or SF_6-based plasmas. The process is fairly straightforward and the main considerations are the etch rate ratios (selectivities) needed. It is impossible to achieve selectivity against silicon in CF_4 and SF_6 plasmas, but nitride-to-oxide selectivity is ca. 2:1 to 10:1. If selectivity between nitride and silicon is needed, plasmas based on CHF_3, C_2F_6 or C_4F_8 are employed. Nitride-to-silicon selectivities can be in the range 5:1 to 50:1. Oxide etching is carried out with these same plasmas. Nitride etch rate is roughly half of oxide etch rate in the same plasma.

Diamond, silicon carbide, titanium carbide and gallium nitride are materials that do not have wet etch processes, but RIE processes do exist. For some materials neither RIE nor wet processes exist and then IBE can be used to pattern them, or else molding or deposition together with polishing can be used for patterning. Platinum and gold (and other noble metals) can be wet and dry etched, but both processes are difficult since the aggressive etch conditions are damaging the resist mask. These materials are often patterned by lift-off rather than by etching.

Releasing structures by isotropic undercut etching in wet solutions is prone to stiction when capillary force exceeds the mechanical spring force of a cantilever, beam or a plate, leading to contact. Dry release techniques avoid stiction by avoiding liquid-phase processing. Dry release methods include vapor etching (HF; oxide sacrificial layer), plasmaless dry etching (XeF_2; silicon sacrificial layer) and isotropic plasmas (SF_6; silicon sacrificial layer).

In RIE the details of thin-film structure or doping can usually be neglected and for instance PECVD nitride and LPCVD nitride are etched at roughly the same rate, and in silicon etching no doping dependence needs to be accounted for.

Equipment

RIE equipment is usually parallel plate reactors in which both plasma and DC bias voltage are created using one capacitively coupled plasma (CCP) source [5]. The wafers are placed on top of the electrode which is typically in direct contact with plasma glow (Fig. 3). This ensures a reasonable etch rate but the controllability of etching is difficult. A major downside of this type of reactor is that the wafers are exposed to heavy ion bombardment because plasma generation and bias voltage are coupled. The etch rate of silicon is typically 0.1 – 1 μm/min and selectivity against the photoresist mask is usually below 5:1. Anisotropy is based on the directionality of ion bombardment and aspect ratios are usually limited to 2:1.

The difference between RIE and DRIE is not unambiguously defined. The division can be made according to etch rate, selectivity, aspect ratio capability or reactor type. DRIE reactors are typically equipped with two RF power generators instead of one (Fig. 3). An inductively coupled plasma (ICP) source generates plasma that has 1 – 2 orders of magnitude higher plasma density than RIE, which roughly translates to 1 – 2 orders of magnitude higher etch rate. In DRIE reactors the wafer is clamped on the bottom electrode of the CCP power source, which is not in direct contact with the plasma. Bias voltage is controlled separately by the second capacitively coupled source. This arrangement allows low bias voltages and therefore much higher selectivities can be achieved. In DRIE selectivity of photoresist mask is 10:1 to 100:1 vs. 1:1 to 10:1 in RIE.

The parameters available for process optimization include:

- etch gas selection
- RF power (coil power in ICP)
- bias voltage (CCP power in ICP)
- pressure
- flow rate
- temperature

The key process outcomes of a (D)RIE process are:

- etch rate
- anisotropy/sidewall angle
- mask selectivity
- substrate selectivity
- etched surface quality
- throughput

A rough order of magnitude estimate of etch rates is as follows: 100 nm/min for simple research reactors; 1 μm/min for production tools and 10 – 50 μm/min for silicon DRIE reactors. Exact values depend on particular reactor design, RF power source and other hardware factors. Silicon etch rate is much faster than oxide or polymer etch rate in the same reactor. More extensive passivation translates to reduced etch rate but also reduced undercut and more vertical sidewalls.

In most DRIE processes aspect ratios of 20:1 can be quite easily achieved. Directionality of ion bombardment is also better in DRIE reactors because wafers are not in direct contact with plasma and process pressure is also lower (typically 10 – 50 mTorr in DRIE). Low process pressure creates high requirements for vacuum pumps because, in order to achieve high etch rates, high gas flows are essential. Temperature of the wafer can be controlled between −150 and +450 °C. Systems with wafer cooling can utilize higher RF power to increase etch rate while keeping photoresist erosion to a minimum.

Reactive Ion Etching (RIE), Figure 4 Micromasking from aluminum mask

Mask Selection (Selectivity, Mask Material Effects, Removal)

Photoresist is used as a mask practically whenever it is possible because it is the fastest and the simplest way to create patterns. However, its fairly low selectivity in RIE limits the etch depth. Both elevated and cryogenic temperatures are detrimental to photoresists. During conventional RIE process temperature of the wafer increases because of the heavy ion bombardment and photoresist may burn. At cryogenic temperatures photoresists suffer from cracking.

When high selectivity or wider temperature range is needed hard masks such as silicon dioxide, metals and metal oxides are utilized. The most obvious downside of the hard masks is the increase in process complexity. Deposition of the hard mask material might include high-temperature processes and the non-idealities in hard mask etching process degrade the quality of final structures. The most common hard mask material is silicon dioxide (SiO_2). In conventional RIE silicon to oxide selectivity is 10:1 to 100:1 and in DRIE 100:1 and higher. Metals and metal oxides have usually higher selectivities than SiO_2, but they may create new problems, like generation of microroughness (Fig. 4).

In order to avoid photoresist deposition over severe topography, a peeling mask (nested mask) can be used: two mask patterns are fabricated on a starting surface, using a suitable combination of mask materials, e. g. oxide-resist or oxide-nitride. After the first DRIE step, one of the mask materials is selectively removed (oxygen plasma ashing of resist mask; or HF etching of oxide mask), exposing more etchable area, while the non-etchable mask still protects selected areas. The second DRIE step etches both newly opened area and continues deeper in the original areas (Fig. 5).

Hard masks can be patterned by both wet and dry etching, and in the first approximation they are identical. However, if accurate dimensional control is required and hard mask etch selectivity is not very high, the etch profile of a wet etched hard mask can influence the size and shape of the feature. The thin wedges resulting from wet etching are quickly eroded by plasma, and the edge of the hard mask recedes, widening the trench (or narrowing a ridge). With vertical walled plasma etched hard masks this is not an issue. Redeposition of etched material on the mask sidewalls can lead to dimensional changes, however (Fig. 6).

R

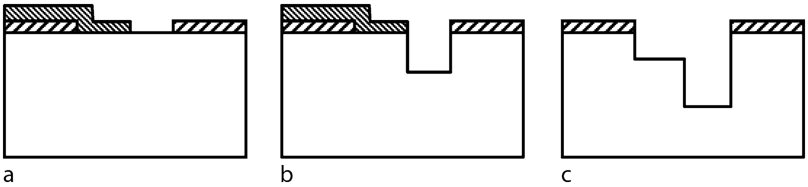
Key Research Findings

Silicon DRIE

By far the two most popular DRIE techniques are the Bosch [6] and cryogenic processes [7].

Bosch Process

The Bosch process was developed and patented by Franz Lärmer and Andrea Schilp in 1994. Because of



Reactive Ion Etching (RIE), Figure 5 Nested (peeling) mask: (**a**) mask layers patterned; (**b**) after first RIE step; (**c**) after peeling the top mask and second RIE step. Bottom mask, e. g. SiO_2; top mask, resist

the nature of the process it is also frequently called the *switched process* and *time domain multiplexed process*. The principle of the Bosch process is shown in Fig. 7. It is based on alternating etch and passivation steps. The etching gas is sulphur hexafluoride (SF_6) that creates fluorine radicals in high-density plasma. After the etch step a thin fluorocarbon film is deposited from cyclic octofluorocyclobutane (c-C_4F_8). This film passivates the surface and prevents etching. At the beginning of the next etch step the fluorocarbon film is removed from horizontal surfaces but sidewalls remain passivated. The SF_6 etch step is not fully anisotropic but the polymer is etched preferentially from the horizontal surfaces due to ion bombardment and the sidewalls remain protected. The repetition of etching and passivation steps results in vertical sidewalls. The microstructure of the etched sidewall, however, shows scalloping (undulation) because of the pulsed nature of the process [8]. The etching and passivation pulse times are typically 5 – 15 s. Etch rate, anisotropy, selectivity and scalloping (sidewall undulation) are all influenced by the duration and overlap of the etch and passivation pulses.

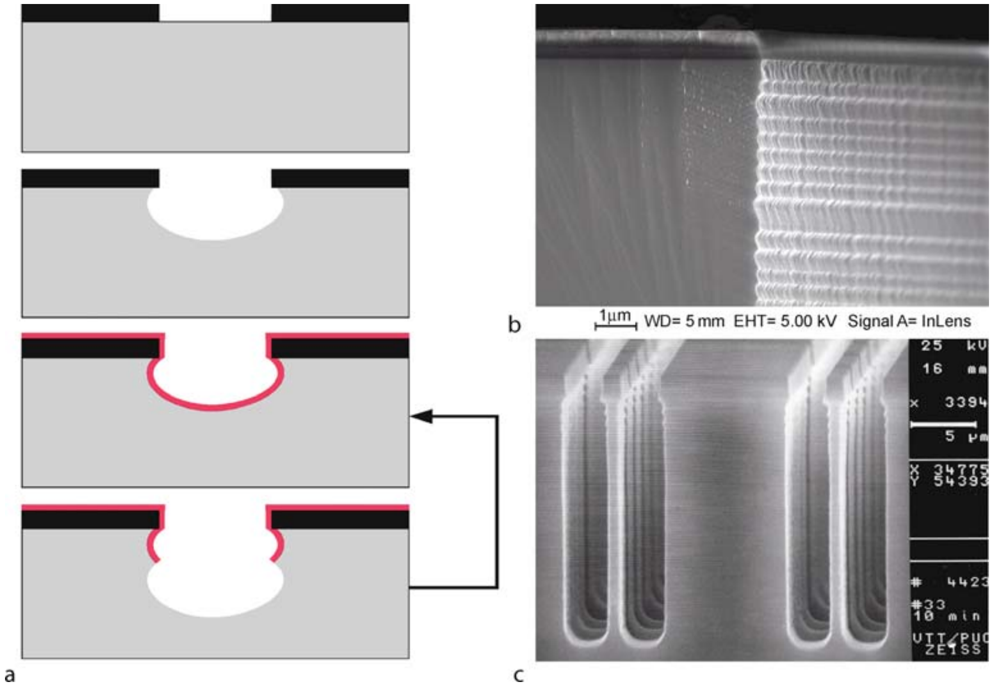
Cryogenic Process

Cryogenic RIE etching was first introduced in 1988 [9]. It was noticed that by cooling the wafer during the RIE the rate of chemical reactions on the sidewalls could be reduced dramatically, leading to improved anisotropy. Selectivity between silicon and masking material is also improved at cryogenic temperatures. The reason for reduced chemical reactions on sidewalls is the silicon oxyfluoride (SiO_xF_y) layer that forms during cryogenic etching process in SF_6/O_2 plasma [10]. Fluorine has very low adsorption coefficient to passivating SiO_xF_y wich therefore inhibits lateral etching. Etching can proceed downwards because ion bombardment removes the passivating layer from horizontal surfaces. Cryo-etched pillars and holes are shown in Fig. 8. Low temperature also reduces spontaneous reactions of free radicals according to the Arrhenius rate law, which also improves anisotropy. Still, the main reason for enhanced anisotropy is the passivating SiO_xF_y layer.

High etch rate in SF_6/O_2 plasma is due to high concentration of fluorine radicals. Oxygen controls the quality of the passivating layer. It is the most important parameter when optimizing the sidewall tapers. If the O_2 content is too low, an isotropic profile results. Too high an oxygen flow leads to overpassivation and formation of so-called black silicon which consists of silicon micrograss.

DRIE Reactor Requirements

The Bosch and cryogenic processes utilize similar DRIE reactors but both processes have their own special requirements [11]. The Switched nature of Bosch-process calls for high speed mass flow controllers, or fast acting valves and buffer tanks. Short step times also necessitate gas line design to minimize delays. In order to reduce the polymer deposition on the chamber walls and pumping lines they should be heated as deposition of fluorocarbon polymer to unwanted surfaces creates particle contamination. In the Bosch process the ratio between the ions and free radicals is important. If relative ion concentration is too high the profile control is lost. By placing the wafer far enough from the plasma glow it is possible to create sufficient ratio



Reactive Ion Etching (RIE), Figure 7 (**a**) Bosch process schematic: repetition of etch and deposit pulses. SEM images of etched structures: (**b**) scalloping of the sidewall; (**c**) perfectly vertical profile

of free radical to ions because of short decay time of ions. Without an ICP source it is impossible to create adequate ratio of free radicals to ions.

In the cryogenic process the temperature of the wafer plays an important role. Accurate wafer temperature control during the process is also essential because the wafer temperature directly affects etch profiles. Cryogenic cooling of the wafer stage is done using liquid nitrogen. The wafer is mechanically or electrostatically clamped on the cooled stage and helium pressure is applied on the backside of the wafer. Because of the high thermal conductivity of the helium, heat transfer from the stage to the wafer is improved. Clamping must be tight to prevent helium leaks to the chamber. Leaks compromise not only the temperature control of the wafer, but also the plasma conditions. In principle a cryogenic process can be operated using a CCP source only, but the etch rate and the selectivity would be considerably lower.

DRIE Special Features

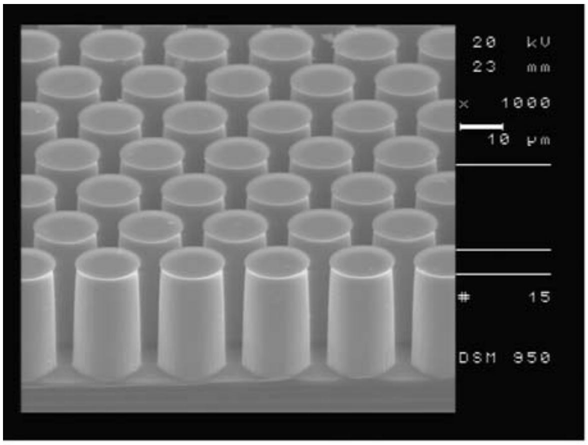
The benefits of the Bosch process are its accurate profile control in high aspect ratio structures and its high etch rate [12]. Etch rates up to 50 µm/min have been reported in special cases, with 10 – 20 µm/min to be considered as more typical production etch rates.

The Bosch process results in scalloping sidewalls due to the pulsed process. This limits its applications in optics, and some fluidic devices are also sensitive to sidewall roughness. The amplitude of scalloping can be minimized by shortening the pulse lengths, and this minimizes the amplitude as well, and 20 nm can be obtained. However, etch rate will be sacrificed. Scallops can also be treated after etching by thermal oxidation or wet etch smoothing.

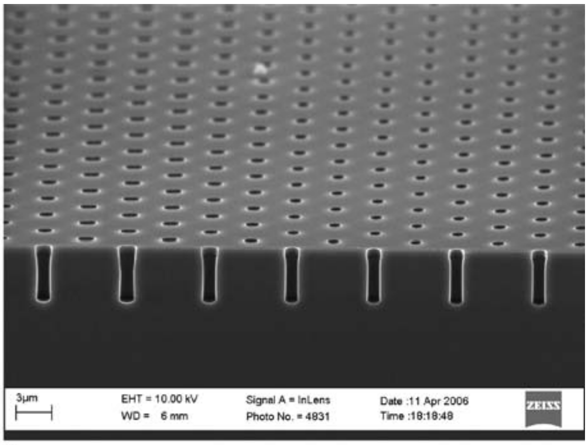
A notching effect (or footing effect) [13] is seen when high-density plasma etching reaches an insulator surface, e. g. SOI buried oxide or oxide on the backside of the wafer in through-wafer etching (Fig. 2). Charging of the interface leads to ion deflection and ion-enhanced sideways etching at the insulator–silicon interface. This can be minimized by running the end point step in RIE mode (low-density plasma) as opposed to high-density plasma mode, and minimized by having only a single feature size which minimizes overetch time. Reactor design can also help: pulsed CCP power, or low frequency (kHz) power give the electrode time to discharge, thus minimizing the notching effect, but unfortunately affecting sidewall quality. Notching has also been utilized as a release step: joining of two lateral etch fronts acts as a dry release method without the isotropic character of SF_6 plasma release.

With the cryogenic process, sidewalls of the etched structures are smooth, but the etch rate of silicon is some-

R



a



b

Reactive Ion Etching (RIE), Figure 8 Cryo-DRIE etched pillars and holes

what lower than in the Bosch process. Because the thickness of the passivation layer is only ca. 10 nm little ion bombardment is needed to remove it from horizontal surfaces. Therefore applied bias voltage can be very low and extremely high selectivities can be reached. A downside of the cryogenic temperature is that not all photoresists can stand it: they shatter like glass. Thick photoresists are especially prone to cracking. Therefore hard masks such as silicon dioxide must often be employed. Another characteristic feature of the cryogenic process is the possibility to create crystallographic-dependent etch results. Crystallographic dependence appears only at the bottom of the trench (Fig. 2) and it is possible only when using extremely low temperatures and low RF powers.

DRIE Processes for Other Materials

Glasses can be etched by SF_6, CHF_3 or C_4F_8 gases in DRIE but the process is more difficult than with silicon [14]. Silicon–oxygen bonds are stronger than silicon–silicon bonds, and higher power is needed to etch glass with DRIE. Fused silica which is pure SiO_2 can be etched more easily than Pyrex glass which has metal oxides. Increased ion bombardment (and thus power) is needed to prevent residues from metal oxides. This high power leads to problems with masking layers. For shallow etching thin silicon films (PECVD, LPCVD) are suitable as etch masks, but for deep etching thick (electroplated) metals, silicon wafers or thick photoresists (SU-8) must be used. Selectivities of 10:1 are typical for both metal and silicon masks.

Etch rates of Pyrex are typically in the range 1 µm/min, which is considerably lower than that of silicon. Aspect ratios of 10:1 are demanding, and sidewall angle is positively tapered because of extensive mask erosion. Even though 88° sidewall angles have been reported, 80° is more typical, and the sidewall angle is more feature size (anodically bonded or shadow masks) dependent than in the case of silicon DRIE. Increasing sidewall roughness is an additional factor limiting higher etch rates.

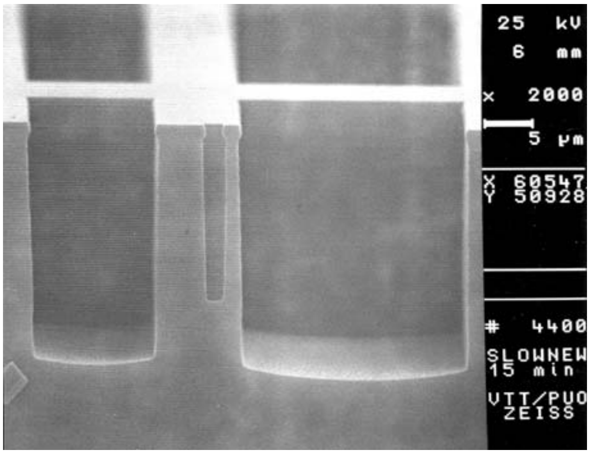
Polymers can be etched by oxygen plasmas using silicon, metal and oxide masks. Etch rates of a few µm/min have been demonstrated with 20:1 aspect ratios. A Bosch process for polymer etching involves an O_2 etch step followed by a C_4F_8 passivation step.

SiC is typically etched in high-density SF_6 plasma that results in etch rate of ~ 300 nm/min. A benefit of low reactivity of SiC is that no sidewall passivation is needed to enhance anisotropy. A downside is that heavy ion bombardment (platen power 50 – 100 W) enhances also mask material etch rate and selectivity becomes a problem. Therefore hard masks such as nickel, indium tin oxide and aluminm are used in SiC etching. Because of sputtering and redeposition of mask material etched surfaces are often rough.

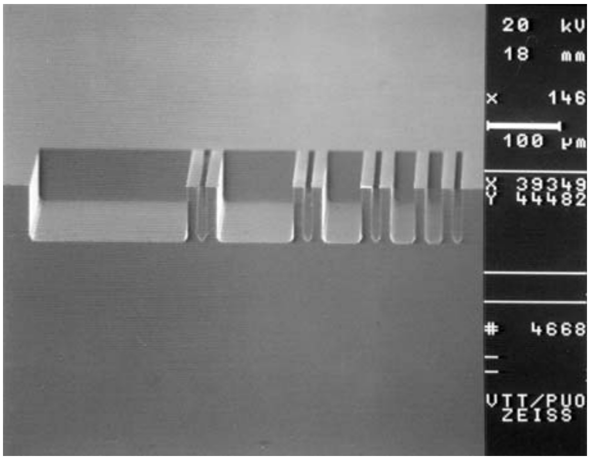
(D)RIE Process Limitations and Problems

Practical (D)RIE processes exhibit a number of limitations regarding etch rate, etchable area, feature size and shape, all of which become more prominent for high aspect ratio structures. Also the sidewall profile non-idealities are discussed.

Loading effect [15] refers to etch rate dependence on etchable area. Loading effect has its roots in reactant supply and consumption balance. When etchable area is small, etch gas flow can supply enough reactive specie,



Reactive Ion Etching (RIE), Figure 9 RIE lag: etched depth depends on feature size



Reactive Ion Etching (RIE), Figure 10 Elimination of RIE lag: DRIE of single sized mosaic subpatterns combined with sidewall removal by TMAH wet etching

but with higher etchable area a deficiency of reactants may develop. Higher gas flow will compensate this but it may be undesirable to increase flow rate for other reasons. Loading phenomenon exhibits itself in various ways: in batch reactors rate depends on the number of wafers in the reactor; in a single-wafer reactor it depends on chip design. On the microscale loading manifests itself between dense and isolated structures. Etchable area also influences etch uniformity: for the Bosch process 1.5% uniformity over a 150 mm wafer has been reported, at 20% loading, with deterioration for higher loads, especially at the edges.

RIE lag refers to the common observation that smaller features are shallower than larger features (Fig. 9). This effect manifests itself in high aspect ratio ($> 1:1$) structures only. Aspect ratio-dependent etching (ARDE) is a similar but not identical effect: etch rate decelerates for longer etching times (i. e. when aspect ratios increase). ARDE occurs for all line widths, and many different etch times are needed to check it, while RIE lag can be seen from one wafer. Reactions (both etching and deposition) are affected as gas transport and ion bombardment change in high aspect ratio structures. At very high aspect ratios, etching of passivation layers also changes.

Combination of RIE lag and wet etching of sidewalls can be utilized either to eliminate RIE lag or to create multidepth microstructures in a single etch step [17]. This necessitates that the larger patterns are redrawn on the mask as a mosaic of smaller structures. If all mosaic elements are the same size, RIE lag is eliminated (Fig. 10); if they are different in size, multiple etched depths are obtained.

The shape of the etchable feature affects etch rate [18]. Holes of 5 μm diameter are etched more slowly than trenches 5 μm wide. This is again related to reactant transport inside the microstructures. Making narrow structures side-by-side with large features, e. g. a pillar filter and a liquid reservoir, or sniffer holes in a microreactor, results in larger areas being deeper than the small ones.

(D)RIE Applications in Microfluidics

In this section RIE applications in fluidics are discussed. Especially, benefits and drawbacks of silicon DRIE processes are highlighted, and special capabilities of DRIE emphasized.

Silicon DRIE is independent of silicon crystal structure, and this enables fabrication of all possible shapes, in contrast to wet chemical anisotropic etching which is limited by silicon crystal planes. In microfluidics this shape freedom has implications for flow profiles, as significantly channel cross-sections can be kept constant on turns, or widened or narrowed. Various microreactors, separation systems, mixers, fuel atomizers and micropower combustion systems make use of meandering, radial or spiralling channels enabled by DRIE. Constrictions of various sorts, converging–diverging structures are essential for example in microthrusters, capillary valves and nozzle-diffuser micropumps. They can be etched easily by DRIE. All sorts of nozzles, emitters and orifices can be optimized for performance when DRIE is used, while wet etched structures are limited in shape. Filters with narrow pass gaps can be made by DRIE (also by bonding and sacrificial layer techniques) but not by wet etching.

DRIE is essential in fabrication of small features. DRIE is capable of reproducing accurately practically any features that have been defined by lithography. Fluid dynamics studies of microflows utilize DRIE for making accurately

R

dimensioned microchannels and orifices. Membrane structures with small holes are useful in many drug delivery, fuel cell and cell probing applications. In a patch clamp application submicrometre apertures have been etched in 20 μm thick silicon membrane. In catalysis studies a small DRIE fabricated capillary leak into a mass spectrometer enabled increased sensitivity and fast response times. Integration of microreactor and mass spectrometer also minimized dead volumes.

DRIE enables high aspect ratio structures. Holes, trenches and pillars with 10:1 to 20:1 aspect ratios can be fabricated, and experimental structures with 40:1 and even higher have been demonstrated. These high aspect ratio structures are limited by RIE lag, however. Applications for high aspect ratio structures include various trapping devices. Depending on feature size, either micro- or nanobeads are trapped, or macromolecules like DNA. For pillars, aspect ratios in excess of 50:1 have been demonstrated: 300 nm feature size, 15 μm structure height.

Random nanopillars can also be utilized in chemical microsystems. Intensity of desorption/ionization on silicon mass spectrometry (DIOS-MS) is dependent on surface area. At first DIOS plate material was porous silicon, but it has been shown that using nanopillars instead of porous silicon, signal intensity can be increased.

Combining DRIE and anisotropic wet etching can produce unique structures. For example, ⟨111⟩ silicon cannot be etched by the standard KOH, TMAH or EDP etchants, but if an initial trench has been etched by DRIE, fast etching crystal planes are exposed, and wet etching can proceed. If this is combined with spacer structures to protect sidewalls and another DRIE step, ⟨111⟩ free-standing silicon structures can be made.

Combination of DRIE and isotropic plasma etching can be used to create channels inside silicon. After the DRIE step, a sidewall passivation step is performed, and etching is then continued with an isotropic etchant. Anisotropic SF_6/O_2 DRIE recipe can quite easily be tailored to be isotropic by for example raising the pressure and eliminating the oxygen. Similarly, isotropic SF_6 plasma release etch can be used to fabricate free-standing silicon structures.

DRIE in combination with electrochemical etching of silicon enhances shape freedom in electrochemical etching. If anisotropic wet etching is used to create the initial pits for electrochemical etching, the usual limitations of crystal plane dependence manifests itself, while by using DRIE complex shapes like circular or curving can be made.

DRIE of silicon is a major method for making masters for polydimethylsiloxane (PDMS) casting and hot embossing. Alternative techniques include silicon wet etching and SU-8 thick photoresist. Silicon offers more durable material properties, but the master fabrication is more tedious. DRIE excels over wet etching because of shape freedom and sidewall profile engineering possibilities, but suffers from inferior surface quality. DRIE process has to be optimized for slightly positively sloping sidewall profile in order to facilitate de-embossing/release. The quality of optimized silicon masters is good, as applications in optofluidic chips demonstrate: PDMS fluidics and optics can be replicated from silicon masters with excellent performance [19].

An DRIE reactor can be used as a CVD-like deposition tool by changing process parameters and gases [20]. An important example is the deposition of $(CF_2)_n$ from CHF_3 or C_4F_8 source gases. This is the basis of anisotropy in the Bosch process but such films have been used in their own right in microfluidics to render surfaces hydrophobic. Patterning on these films can be done by oxygen plasma with standard photoresist masking and acetone resist stripping as Teflon-like films are chemically very tolerant. Alternatively, lift-off techniques or shadow mask techniques with oxygen plasma can be used.

Future Directions for Research

RIE and DRIE are workhorses of micromachining, and they are being applied to an increasing variety of structures. In developing (D)RIE processes, a number of issues have to be dealt with simultaneously: etch rate, mask etch rate, sidewall angle and profile, the various process limitations and process integration issues. There is a need for more robust processes that are insensitive to design changes, and allow small and large areas to be etched with the same rate, sidewall angle and surface roughness. Through-wafer etching still poses challenges, both as regards rate and aspect ratio and process integration. Very high aspect ratio structures still need design-specific optimization. The same challenges apply to other materials even more than to silicon.

Relaxation Time of the Viscoelastic Fluid

Definition

Relaxation time is the characteristic time in which a system relaxes under certain changes in external conditions. Here, it refers to the characteristic time required for the polymer coil to relax from a deformed state to its equilibrium configuration. It is a key parameter for characterizing a viscoelastic fluid.

Residual Stress

Definition

Residual stresses are stresses that remain after the original cause of the stresses (external forces, heat gradient) has been removed. Residual stresses occur for a variety of reasons, including inelastic deformations and heat treatment.

Definition

A resistance temperature detector (*RTD*) is a device to measure temperature by relating it to changes in the electrical resistance of a metallic sensing element. The resistance of a typical RTD increases by about 0.3% to 0.4% of its room temperature value for every degree Kelvin of temperature increase. With care, RTDs can achieve accuracies of better than 0.1 K at temperatures ranging from about 14 K to over 900 °C.

Overview

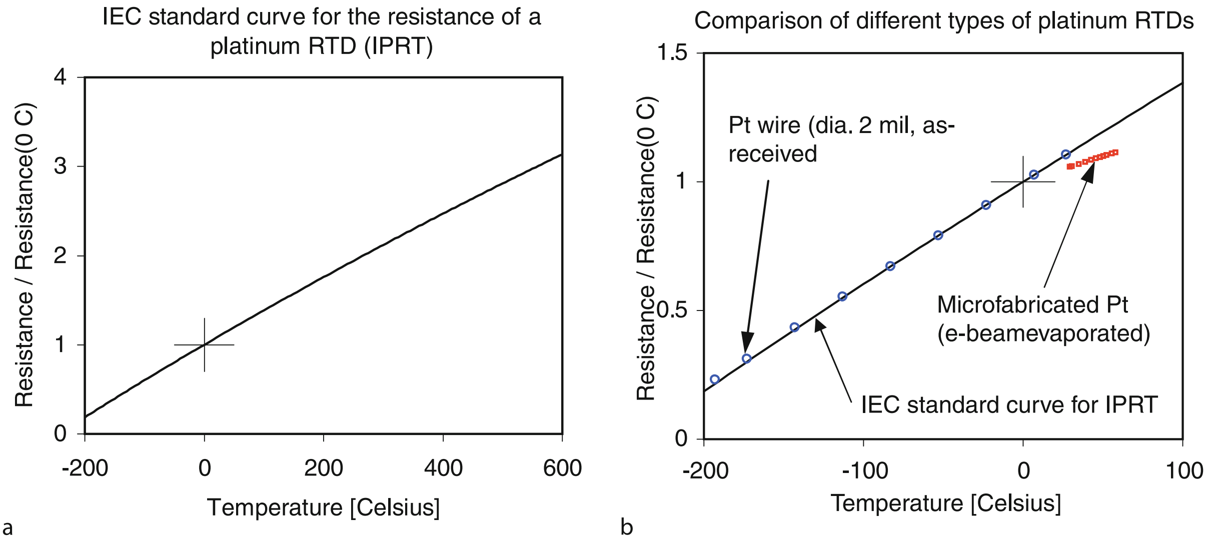
Resistance temperature detectors (*RTD*s) are widely used for general purpose temperature measurements as well as high-accuracy metrology and research applications such as MEMS and microfluidics[1–6]. The key concept is the fact that the electrical resistance of a pure metal increases almost linearly with temperature over a broad range of temperature. The underlying physical reason for the temperature dependence is the scattering of electrons by lattice vibrations (phonons), which vibrate with larger amplitudes at higher temperatures. For example, the resistance of platinum, the most common RTD material, is shown in Fig. 1a from −200 °C to 600 °C. To use an RTD, the resistance of the metallic sensing element is measured and then its temperature is calculated from a known calibration relation. The most important property of an RTD is its ► temperature coefficient of resistance (TCR), often denoted by α. The TCR is defined as the relative change in resistance per unit change in temperature:

$$\alpha(T) \equiv \frac{1}{R}\frac{dR}{dT}\,, \tag{1}$$

where R is the resistance and T is the temperature. A larger TCR results in a more sensitive RTD. For industrial and standards-grade platinum RTDs, the TCR is approximately 0.0039 K^{-1} near room temperature, although this value can be significantly reduced in microfabricated platinum RTDs due to their different microstructures (Fig. 1b). RTDs are traditionally made of loosely wound platinum wire encapsulated in a ceramic, glass, or metallic housing. RTDs are also made from laser-trimmed films of platinum on a ceramic substrate. These chip-style RTDs are cheaper and smaller than the wire-wound variety and offer a faster response time, but historically they have been slightly less accurate and at greater risk of degraded accuracy due to thermal expansion mismatch and impurity contamination from the underlying substrate. Nickel, copper, and tungsten are less widely used for commercial RTDs. In MEMS and microfluidic devices, it is common to microfabricate small metallic RTDs out of a wide variety of metals, including platinum, nickel, copper, and gold.

Typical Applications

RTDs are used in a great variety of applications. At one extreme, carefully-designed platinum RTDs are used in the very definition of temperature between 13.8033 K and 961.78 °C [2], because of their potential for extreme stability and accuracy (uncertainties of better than ±1 mK). At a more practical level, commercial RTDs are widely used for industrial and research applications from 14 K to around 600 – 700 °C, with typical absolute accuracies of around ±0.15 K to ±2 K uncalibrated, or ±0.1 K or better after calibration. Bare platinum RTDs also have a long and illustrious history as velocity sensors for fluid flow, a technique known as hot-wire anemometry. More recently, special RTD configurations have also been developed to measure the thermal properties of fluids and solids [7–9].



Resistance Temperature Detectors, Figure 1 (**a**) The normalized resistance of an industrial platinum resistance thermometer (IPRT or RTD) as a function of temperature. This curve was calculated using the Callendar-Van Dusen equation with the IEC standard coefficients, Eqs. (2a), (2b) and (3). (**b**) The normalized resistance of representative home-built platinum RTDs (points) as compared to the standard curve given in (Fig. 1a) (solid line). The circles are measurements of an unannealed platinum wire of 2 mil (51 μm) diameter. The squares are measurements of a microfabricated platinum line on a substrate, deposited by e-beam evaporation and patterned with a lift-off technique. Although the data for the wire RTD are fairly close to the standard curve, the data for the microfabricated RTD have a very different slope, highlighting the necessity of calibration

RTDs Compared to Other Temperature Sensors

For general-purpose temperature measurements with the convenience of electronic readout, the three most common technologies are RTDs, thermistors, and thermocouples. Thermistors are close cousins to RTDs because both depend on the temperature dependence of the electrical resistance of the sensor. However, thermistors are based on semiconducting films such as oxides of cobalt, manganese, and nickel. The TCR of typical thermistors at room temperature is around $-0.03\,\mathrm{K}^{-1}$ to $-0.05\,\mathrm{K}^{-1}$, which is of opposite sign and about 10 times larger in magnitude compared to RTDs, making thermistors significantly more sensitive than RTDs. However, thermistors have an inconveniently nonlinear relationship between temperature and resistance (roughly following an Arrhenius-type trend $R \propto \exp(-\theta/T)$, where θ is a constant) and they can be somewhat less uniform in manufacturing and less stable in use compared to RTDs. Thermocouples are formed at the junction between two dissimilar metal wires, and exploit the Seebeck effect which gives an open circuit voltage that can be related to the temperature at the junction. Thermocouples are inexpensive, offer measurements at a small point, are more tolerant of vibrations and high temperatures compared to RTDs, and may be more convenient because of their direct voltage readout. However, compared to RTDs, thermocouples are less accurate, are subject to spurious signals from intermediate metals and temperature drifts elsewhere in the circuit, and are less well-suited to microfabrication.

Basic Methodology

Typical RTD Materials

An ideal material for use as an RTD sensing element would have the following properties:

- Linear $R(T)$ relationship over a broad temperature range.
- Moderate resistivity for ease of resistance measurement ($10-1000\,\Omega$ is a good value).
- High TCR for good sensitivity.
- Minimal thermal expansion; or thermal expansion matched to its substrate.
- Chemically stable and inert in oxidizing, reducing, and corrosive environments.
- Mechanically strong.
- Good solderability for making junctions.
- Commercially available as wires and films with highly reproducible properties.
- Able to be deposited by evaporation and/or sputtering for microfabrication applications.
- Low cost.

The material that comes closest to satisfying these diverse requirements is platinum, which is justifiably the most common RTD material. One noteworthy weakness of plat-

inum is that it is unstable in reducing environments, and so performs best when there is some oxygen in the surrounding ambient. Other common RTD materials include copper, nickel, and gold, although in principle almost any metal can be used. Although some RTDs are also made out of alloys, such as platinum and rhodium, in general alloys are less well-suited to RTDs because alloy scattering of electrons is not as temperature-sensitive as phonon scattering.

Types of Sensing Elements

RTD sensing elements are available in a wide range of packages for various applications. The sensors can be roughly grouped into the following three categories:

Standard Platinum Resistance Thermometers (SPRTs)

Standard platinum resistance thermometers (SPRTs) are the most accurate and most delicate RTDs in existence. Their applications are largely limited to standards laboratories and other applications requiring temperature accuracies of 1 mK or better. SPRTs are the primary interpolation instrument in the very definition of temperature in the International Temperature Scale of 1990 (ITS-90) from 13.8033 K (the triple point of hydrogen) to 961.78 °C (the freezing point of silver) [2]. An SPRT can therefore cover the vast majority of practical temperatures, although extra care is required above about 400 – 500 °C due to risks of contamination, defect generation, and other materials issues [6]. SPRT sensing elements are typically made of platinum wire of diameters from 10 to 100 μm, gently wound on an insulating support such as mica or quartz. The wire and support are housed in an insulating sheath and may be packed loosely with electrical insulation for additional mechanical support. Electrical connections are always of the 4-wire variety to eliminate the influence of lead resistances. These instruments are very sensitive to shock and vibrations, which can plastically deform the platinum sensing element and alter its calibration.

Industrial Platinum Resistance Thermometers (IPRTs)

For the vast majority of applications, the extreme accuracy of SPRTs cannot justify their high cost, large size, and fragile construction. Instead, manufacturers offer a wide selection of industrial platinum resistance thermometers (IPRTs), which are smaller, far more robust, and only slightly less accurate than SPRTs. They can be either wire-wound or made of thin films evaporated on a substrate, and are most commonly provided with 100 Ω resistance at 0 °C. Various package styles are available, including cylinders, washers, and glue-on chips.

Microfabricated RTDs

Standard commercial RTDs (that is, IPRTs) are typically at least several millimeters in size, which is much larger than would be desired for many applications in MEMS and microfluidics. For these applications there is a clear need for integrated temperature sensors that are smaller than commercial sensors. Microfabricated metallic RTDs are the most common solution to this challenge, although microfabricated thermocouples and thermistors (e. g. doped silicon) have also been used. Micron-sized metallic RTDs are easily patterned using standard microfabrication techniques such as wet or dry etching, liftoff, or electrodeposition. Although platinum is probably still the preferred material for microfabricated RTDs, other metals (e. g. Au, Ni, Cu) are also widely used. For simplicity it is common practice to pattern a microfabricated RTD in the same mask step as other metallization required in the microdevice, thus eliminating the need for a separate deposition and lithography step. An important consideration for microfabricated RTDs is that the properties of the deposited metal can differ significantly from the properties of bulk metals. Microfabricated metals often have more defects and grain boundaries than the wires used most macro-scale RTDs. This leads to increased resistivity in the microfabricated metals, and more importantly to a reduced temperature sensitivity. It is not unusual for the TCR of a microfabricated metal to be tens of percent lower than a well-annealed bulk sample (Fig. 1b). Thus, calibration is essential for microfabricated RTDs, and the literature values of TCR for the bulk metal should be considered only as an upper bound.

Describing the Relationship Between Temperature and Resistance

Depending on the application, the relationship between resistance and temperature will be determined using one of two approaches: a standardized $R(T)$ curve, or a calibration by the end user.

Standardized Curves Relating Temperature to Resistance

For general purpose temperature measurements the user will generally select a commercial platinum RTD (that is, an IPRT) which conforms to existing codes and standards for the relationship between temperature and resistance. Several different standards govern the performance

of IPRTs. By far the most widely used is the International Electrotechnical Commission (IEC) standard 60751, which is essentially equivalent to the Deutsches Institut für Normung (DIN) standard 43760 and the American Society for Testing and Materials (ASTM) standard E1137. The uncertainty tolerances on commercial RTD elements are commonly specified as Class A or Class B. As seen from the expressions in Table 1, the uncertainty is minimum at $t = 0\,°C$ and increases linearly with the absolute value of t, where we have followed the usual convention in this field that t denotes temperature in degrees Celsius. Thus, an uncalibrated Class A RTD at 100 °C has an uncertainty of $\pm 0.35\,°C$. The IEC tolerance specifications of Table 1 apply to as-received IPRTs without any calibration, and the uncertainty can be improved to $\pm 0.1\,°C$ or better over all temperatures after calibration.

Manufacturers also sometimes specify RTD tolerances with fractions such as *1/10 Class B*, or *1/10 DIN*. These RTDs have reduced uncertainty at 0 °C but are still subject to the same temperature dependence of the uncertainty given in Table 1 for either Class A or Class B. For example, the tolerance formula for *1/10 Class B* is $\pm (0.03 + 0.005\,|t|)\,°C$.

The IEC/DIN standards are based on platinum with some level of impurities such that the $R(T)$ relationship follows a standard curve known as the European curve (described in more detail below). This curve is also designated by its resistance at 0 °C and 100 °C, such that the quantity $\left[R\,(100\,°C) - R\,(0\,°C)\right] / \left[(100\,°C) \times R\,(0\,°C)\right]$ is approximately $0.00385\,K^{-1}$, which is also known as the European Fundamental Interval. Therefore these RTDs are also known as *385* or *0.00385* type RTDs. Note that although this quantity $0.00385\,K^{-1}$ is also sometimes known as *alpha* and denoted α, it is only approximately equal to the average value of the TCR (as defined in Eq. 1) over this temperature range. Less commonly, IPRTs with higher purity platinum are also available with a value of $0.00392\,K^{-1}$ for the quantity $\left[R\,(100\,°C) - R\,(0\,°C)\right] / \left[(100\,°C) \times R\,(0\,°C)\right]$. This is also known as the American Fundamental Interval or American curve, even though most IPRTs available in the United States now follow the European curve. IPRTs are most commonly available with 3-wire or *Siemens* connections as described below, although 2-wire and 4-wire connections are also available.

Commercial platinum RTDs are almost always described by the following $R(t)$ relationship, known as the Callendar-Van Dusen equation:

$$R(t) = R(0\,°C)\left[1 + At + Bt^2 + C\left(t - 100\,°C\right)t^3\right], \quad -200\,°C < t < 0\,°C \tag{2a}$$

$$R(t) = R(0\,°C)\left[1 + At + Bt^2\right], \quad 0\,°C \leqslant t < 850\,°C \tag{2b}$$

where t is the temperature in degrees Celsius. For the large majority of IPRTs which conform to the IEC/DIN standards, the Callendar-Van Dusen constants are assigned the values

$$A = 3.9083 \times 10^{-3}\left[°C^{-1}\right], \tag{3a}$$

$$B = -5.775 \times 10^{-7}\left[°C^{-2}\right], \tag{3b}$$

$$C = -4.183 \times 10^{-12}\left[°C^{-4}\right], \tag{3c}$$

It is often necessary to invert the Callendar-Van Dusen equation to express t as a function of R. For the high temperature range ($t \geqslant 0\,°C$), the quadratic Eq. (2b) is readily solved for $t(R)$ in closed form:

$$t(R) = \frac{-A \pm \sqrt{A^2 - 4B\left(1 - R(t)/R(0\,°C)\right)}}{2B}, \quad 0\,°C \leqslant t < 850\,°C \tag{4}$$

while below 0 °C numerical or iterative solutions may be preferred. Many commercial meters are available to convert directly from resistance to temperature using these equations with the standard coefficients. However, users should be aware that slightly different values of the coefficients may be provided by an RTD manufacturer, or determined by a user after careful calibration. In particular, RTDs are still commercially available that follow the *American curve* (0.00392-type), and should be used with different values of the Callendar-Van Dusen constants. If one of these 0.00392-type RTDs is mistakenly used with the IEC/DIN standard coefficients given above (0.00385-type), the calculated temperature will be correct at 0 °C, but will be in error by about 3 K at −200 and 200 °C, with errors increasing to nearly 10 K at 600 °C.

Calibration

Because microfabricated metals generally have more defects and grain boundaries than the metals used in commercial RTDs, they will have different $R(t)$ relationships, making it essential to calibrate microfabricated RTDs prior to use. There are many approaches to calibration depending on the desired accuracy. For many MEMS and microfluidics applications it will be satisfactory to calibrate the RTD against a second thermometer with trusted temperature readings. In these calibrations it is important

Resistance Temperature Detectors, Table 1 Temperature accuracy of industrial platinum resistance thermometers (IPRTs) according to the most common standard, which is known variously as IEC, DIN, ASTM, 0.00385-type, and/or the European curve. Note that t is the temperature in degrees Celsius

	Class A	Class B
Temperature Range	$-200\,°C < t < 650\,°C$	$-200\,°C < t < 850\,°C$
Formula for Temperature Uncertainty	$\pm(0.15 + 0.002\,\lvert t\rvert)\,°C$	$\pm(0.3 + 0.005\,\lvert t\rvert)\,°C$
Uncertainty at −100 °C	±0.35 °C	±0.8 °C
Uncertainty at 0 °C	±0.15 °C	±0.3 °C
Uncertainty at 100 °C	±0.35 °C	±0.8 °C
Uncertainty at 500 °C	±1.15 °C	±2.8 °C

that the standard thermometer and RTD to be calibrated are subject to the same temperature. Thus it is important to minimize conduction heat transfer through any leads or supports which will alter the local temperature at the sensing element. Convection and radiation may also be concerns. Calibrations are generally performed in an oven, cryostat, vacuum chamber, or well-stirred bath, often with both RTD and standard thermometer in intimate thermal contact with a common substrate of high thermal conductivity. For example, a copper block may have two holes bored into it to accommodate the RTD and standard thermometer. The practice of taping or gluing the two thermometers to the surface of a substrate which is then placed on a hot plate can result in significant errors, because of the large thermal resistance between thermometer and substrate and potential for large heat transfer along the thermometer leads and supports. For a chip or wafer with microfabricated RTDs, it may be acceptable to firmly attach the wafer to a larger, thermally conducting substrate which is fitted with a standard thermometer in good thermal contact.

The goal of calibration is to obtain data for the temperature-dependent resistance of the RTD being calibrated. This is often done by measuring the RTD resistance at several fixed points, for example at 20, 30, …, 100 °C. It is not unusual for the experimental apparatus used for the calibration to take a long time (from tens of minutes to an hour or more) to reach stable thermal equilibrium at each intermediate temperature. As an alternative calibration procedure, it is sometimes more efficient to slowly sweep the temperature between the minimum and maximum temperatures of interest. In this case the temperature and resistance should both be recorded periodically, or even continuously. If both thermometers are in good thermal contact and the sweep rate is slow enough, the lag in temperature between the two thermometers will be negligible. This can be confirmed by repeating the sweep in the opposite direction and verifying that there is negligible hysterisis in the plot of resistance versus temperature.

After obtaining the calibration data for resistance as a function of temperature at various known temperatures, it is convenient to fit this data with a continuous function for ease of future use. In many cases a linear approximation will be adequate:

$$R(t) = R(0\,°C)\,[1 + c_1 t] \tag{5}$$

where again t is the temperature in degrees Celsius, and R (0 °C) and c_1 are fitting constants determined by the calibration. For example, over the range from 25 °C to 75 °C, a linear approximation for a commercial RTD introduces less than 0.1 °C of error. For improved accuracy a parabolic fit may be used by introducing a third fitting constant c_2:

$$R(t) = R(0\,°C)\left[1 + c_1 t + c_2 t^2\right] \tag{6}$$

This is the same form as the high-temperature Callendar-Van Dusen equation given in Eq. (2b), but in general the constants c_1 and c_2 will be different from A and B. A parabolic fit with the form of Eq. (6) should be adequate for microfabricated metallic RTDs over temperature ranges spanning several hundred degrees. (Recall that *semiconducting* resistance elements are known as thermistors, which are beyond the scope of this article and would be better described by an Arrhenius-type $R(T)$ behavior.)

Measurement Considerations

To achieve a typical accuracy of ±0.1 °C around room temperature with an RTD, the resistance of the sensing element must be measured with accuracies of a few hundredths of one percent. Thus, for typical RTDs with resistances in the range of 10 – 100 Ω, the resistance measurement must have an accuracy of tens of milliohms or even better. This level of accuracy is readily achieved with commercial RTD readers, standard laboratory multimeters, and

bridge circuits, each of which is described later. Regardless of the measurement technology, several additional issues must be considered for a quality measurement:

Lead resistances are unlikely to be negligible compared to the required resistance accuracy. For some simple RTDs, two-wire measurements may still be satisfactory, but most commercial RTDs use a 3-wire connection, and for the utmost in accuracy a 4-wire approach should always be used.

Thermoelectric effects occur whenever more than one type of metal is used in the measurement circuit, which includes the sensing element, the leads, and the readout instrumentation. The typical Seebeck coefficient between different metals is around $10\,\mu V/K$ or more, and it is not unusual for temperature to vary by $5-10\,°C$ between different parts of an apparatus even for room-temperature measurements. Thus thermoelectric effects can be expected to contribute voltages of $100\,\mu V$ or more if no precautions are taken, which may lead to errors of $\pm 1\,°C$ when measuring the RTD temperature around 300 K, and potentially much worse away from 300 K. The first guideline to minimize thermoelectric errors is to minimize the number of junctions between dissimilar metals. When such junctions are necessary, they should be designed as pairs that occur at the same temperature (ideally in a region close to room temperature). For example, if copper leads are connected to a platinum RTD, the two (or 3 or 4) copper-platinum junctions should be placed nearby to each other and thermally anchored to the same common temperature. Thermoelectric voltage errors typically vary slowly with time and are insensitive to the magnitude and direction of the test current. Therefore one effective technique to minimize the impact of thermoelectric voltages in DC measurements is to use a current-reversal method, whereby the true RTD resistance can be estimated from the average of the apparent resistances recorded with both forward and reverse currents. AC measurements are also very good at minimizing thermoelectric errors as well as many other types of noise, and are typically conducted at a few hundred Hertz where inductive and capacitive effects can be neglected.

Self-heating effects occur because the finite measurement current inevitably causes some joule heating (I^2R) within the temperature sensing element. This heating will cause the temperature of the sensing element to rise slightly above that of the surroundings, especially if large sensing currents are used. The heating can be minimized by reducing the sensing current, but this will also reduce the voltage signal thereby increasing the uncertainty in the resistance measurement. As a compromise, common test currents are around 1 mA. It is worth noting that a 1 mA test current through a typical $100\,\Omega$ RTD at room temperature results in a voltage sensitivity of approximately $400\,\mu V/K$, which is about 10 times more sensitive than the common type K thermocouple ($\approx 40\,\mu V/K$). Self-heating errors can also be minimized by ensuring good thermal contact between the sensing element and the fluid or solid being measured. In many cases the strength of this thermal coupling between the sensing element and the fluid can be estimated and expressed as a thermal conductance, G, with units of W/K, in which case the self-heating temperature error is given by

$$\Delta T_{\text{self-heating}} = I^2 R/G \tag{7}$$

where I is the test current and R is the electrical resistance of the sensing region. This simple relationship also provides a means to experimentally estimate the thermal conductance G and ensure that self-heating effects are negligible. For a constant temperature of the surroundings, the sensor resistance can be measured with several different test currents. The resistance is then plotted against the square of the test current(Fig. 2), and is expected to follow the relationship

$$R(T, I) \approx R_0 + \alpha R_0^2 I^2/G \tag{8}$$

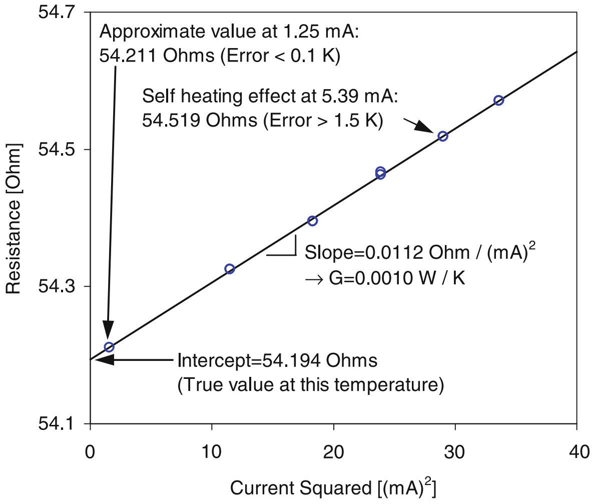
where $R_0(T)$ is the actual resistance of the sensor at the temperature T of the surroundings. This resistance R_0 is sometimes known as the *cold-wire* resistance (as opposed to the *hot-wire* resistance used in anemometry). The slope of resistance versus the square of the current gives the thermal conductance:

$$G = \frac{\alpha R_0^2}{\mathrm{d}R / \mathrm{d}\left(I^2\right)} \tag{9}$$

which is useful for estimating the magnitude of the self-heating errors.

Strain gauge effects are an important concern whenever the RTD element is subject to mechanical stress or strain. This can be due to shock, vibration, or damage during handling or operation, or mismatched coefficients of thermal expansion between the RTD and its substrate if they are tightly bonded. For modern commercial RTDs this is not usually an issue.

Non-uniform temperature profiles in the RTD sensing element can occur due to self-heating effects, temperature gradients within the fluid being measured, or thermal losses through the leads and supports of the sensor. Because any such temperature nonuniformities are typically well within the temperature range over which the $R(T)$ relation can be approximated as linear, and the sensing elements have a uniform cross section, it is easily shown that the measured resistance corresponds to the *average* temperature of the sensing element.



Resistance Temperature Detectors, Figure 2 Representative data to illustrate self-heating effects in an RTD. The true value of the RTD resistance at this temperature is 54.194 Ω. Test currents of around 1 mA cause small self-heating errors of less than 0.1 K. Larger test currents of around 5 mA cause significant self-heating errors of 1.5 K or more. The slope of the curve is related to the thermal coupling G between the sensing element and the fluid or solid being measured

Measurement Hardware

Commercial Temperature Readers

For commercial platinum RTDs that follow the IEC/DIN (0.00385-type) standard, the most convenient method to determine temperature is to use a commercial temperature reader which automatically measures resistance and converts it to temperature by using the standardized Callendar-Van Dusen coefficients given in Eq.(3). Some of the more sophisticated readers are also capable of handling non-standard curves or lookup tables as provided by the RTD manufacturer or determined by a user calibration. Commercial RTDs are used in 2, 3, or 4-wire configurations. The 2-wire configuration is the simplest but is subject to errors from the finite lead resistances. The 3-wire configuration (*Siemens-type*) is the most common, and can remove the effect of lead resistance as long as all 3 leads are identical (Fig. 3a). The 4-wire configuration is used whenever the utmost in accuracy is required (better than around 0.01 °C.

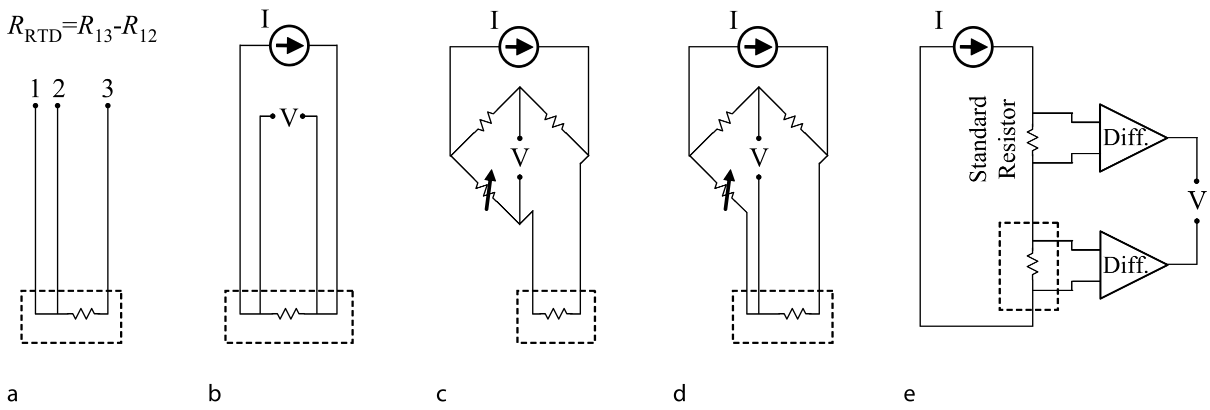
Direct Measurement with a Digital Multimeter or Lock-in Amplifier

In many cases a commercial temperature reader may not be desirable or available, especially for microfabricated RTDs which do not conform to the IEC/DIN standard. In this case it is common to use a digital multimeter to monitor resistance. Four-wire operation is essential to avoid the effect of lead resistances (Fig. 3b). Widely-available benchtop multimeters typically measure 100 Ω resistances with better than ±0.02 % accuracy, and a test current of 1 mA which is appropriate for typical RTD measurements. At room temperature this resistance uncertainty corresponds to a temperature accuracy of approximately ±0.05 °C, which is adequate for many applications. For increased accuracy a nanovoltmeter can be used along with a stable current source, leading to a typical resistance uncertainties of ±0.005% which corresponds to a temperature accuracy of around ±0.015 °C at room temperature. Thermoelectric effects are likely to be important in these measurements, and should be checked by the current reversal method mentioned above. If AC methods are chosen then a sinusoidal current source should be combined with a lock-in amplifier to ensure the best accuracy. Typical lock-in amplifiers can have voltage accuracies better than one part in 10^4, corresponding to a temperature accuracy of around ±0.03 °C at room temperature.

Because voltage sources are much more common than current sources, especially for AC measurements, experimentalists will sometimes place a *ballast resistor* in series with a voltage source in order to approximate a current source [7]. Furthermore the current is sometimes estimated from the ratio of the source voltage to the total resistance of the circuit, as measured separately at a baseline condition. This practice is generally acceptable as long as the ballast resistor is very stable (ideally TCR = 0) and much larger in magnitude than the RTD element being studied. However, if the RTD resistance is *not* negligibly small compared to the total circuit resistance, the temperature-induced voltage changes across the RTD will be smaller than the analysis assumes, leading the experimenter to underestimate the temperature changes. In this situation a simple correction factor can be applied for improved accuracy [7].

Bridges

Bridge arrangements were the standard approach for all RTD measurements circuits prior to the development of highly-accurate digital electronics, and are still used at standards laboratories to achieve the utmost extremes of accuracy. Carefully-made DC and AC bridges can have accuracies of better than 1 part in 10^7, which for a typical platinum RTD at room temperature corresponds to a temperature uncertainty of a few tens of micro-Kelvin. Although a classical Wheatstone bridge can be used in a 2-wire arrangement (Fig. 3c), in practice a 3-wire or 4-wire arrangement is always used in order to compensate for the effects of lead resistances. The 3-wire arrangement



Resistance Temperature Detectors, Figure 3 Several methods for measuring the resistance of an RTD sensing element. (**a**) The 3-wire connection which is most widely used in commercial RTDs. (**b**) A 4-wire arrangement for use with a digital multimeter or lock-in amplifier. (**c**) 2-wire arrangement in a classical Wheatstone bridge, which is subject to errors due to the lead resistances. (**d**) An improved bridge using the Siemens arrangement, a common 3-wire connection where the lead resistances cancel (as long as the leads have the same resistance). (**e**) A half-bridge with two differential amplifiers [8]. The standard resistor is chosen to have nearly the same resistance as the RTD sensing element, resulting in reduced common-mode background voltage for the same RTD signal

is also known as the Siemens arrangement and is shown in Fig. 3d. To the extent that all 3 wires have the same resistance, the unknown lead resistance cancels out at the balance condition. However, because the lead resistances are never truly identical, there is always some residual uncertainty which limits the accuracy of this arrangement to around ±0.01 °C. For the utmost in accuracy, 4-wire arrangements such as the Mueller bridge are used.

It may sometimes be worthwhile to use a half-bridge in combination with simple operational amplifier (op-amp) circuit, as shown in Fig. 3e. The standard (or *series*) resistor should have a very low TCR and its value is chosen and/or adjusted to be close to the value of the RTD resistance at some baseline temperature. The two differential amplifiers remove most of the common-mode background voltage, allowing the output voltage to be dominated only by the *changes* in the RTD voltage due to temperature. This can improve the measurement accuracy by making better use of the available dynamic range of the multimeter or lock-in amplifier and by making the measurement much less sensitive to fluctuations in the current source. A multiplying digital-to-analog converter element (not shown) can also be incorporated to allow computer control of the adjustments of the standard resistor [8].

Key Research Findings

RTDs already have a long history for both industrial and standards-grade thermometry [2–6]. Over the last century the key enabling results have included: the ability to fabricate low-stress platinum sensing elements that are mechanically supported yet free to expand and contract with temperature changes; the evolution of accurate potentiometers and ratio transformers; the evolution of standards such as IEC 60751 which allow industrial RTDs to be interchanged without calibration; and the development of relatively low-cost, highly-accurate digital instrumentation for sourcing current and measuring voltage, with typical accuracies of ±0.005% to ±0.02%.

Future Directions for Research

The state of the art in thermometry research is generally reported at the International Temperature Symposia, with conference proceedings published by the American Institute of Physics [1]. For metrology applications at standards laboratories, an important research direction for platinum RTDs is to extend the upper temperature limit at which the RTDs can be used. For example, the International Temperature Scale of 1968 (ITS-68) only used platinum RTDs up to 630.74 °C, while requiring a Pt-PtRh thermocouple above this temperature. But subsequent research improved the stability and accuracy of platinum RTDs so that they are now used in ITS-90 up to 961.78 °C. It is likely that research will continue to extend the high-temperature limits of platinum RTDs. Applied research continues to improve the accuracy and reliability of thin-film RTDs, making them a good compact, low-cost alternative to the more traditional wire-wound RTDs.

Finally, there is considerable interest in using what are essentially self-heated RTDs as tools to measure thermal properties. Referring back to Eq.(9) and Fig. 2, it is possible to evaluate the thermal conductance G between an RTD and its environment by studying the RTD's resistance

R

as a function of current. For many situations the thermal conductance can be directly related to one or two thermal properties of the surrounding environment. For example, this concept is used in the hot-wire method of measuring the thermal conductivity of a fluid, whereby a long insulated platinum filament is immersed in a fluid and subject to varying electrical currents. The higher the thermal conductivity of the fluid, the smaller the temperature rise of the wire for a given amount of heat dissipation. In many cases additional information can be extracted by studying the response over a range of frequencies. Related methods can be used to study fluid velocity (hot-wire anemometry) and the thermal conductivity and/or specific heat of wires, fluids, and semi-infinite solids both with and without thin films [7–9].

Resistance Thermometers

Definition

A resistance thermometer uses the temperature dependency of the electric resistance of the used material. Therefore a well defined and very low current is applied onto the sensor by measuring the voltage simultaneously. For precise measurements pure platinum is often used since the temperature coefficient is almost constant and the variations of the electric resistance are higher than for alloys. When semiconductors are used, much higher temperature coefficients and therewith higher sensitivity can be obtained; these thermometers are called thermistors.

Rotary Peristaltic Pump

Definition

Rotary peristaltic pumps transport fluid through a flexible duct using traveling contraction waves. In a typical rotary peristaltic pump, revolving contact elements close off sections of flexible tube, defining moving volumes of fluid. Because a moving boundary displaces fluid and induces the flow, rotary peristaltic pumps are an example of positive-displacement pumps.

Synonyms

Rough channels; Surface features to enhance transport

Definition

► Roughness on the surface of a channel wall directly affects the transport processes at the wall. In fluid mechanics applications, roughness is generally defined in terms of the average roughness parameter *Ra*, which represents the average height of the roughness elements on a surface. Newer parameters are being proposed to capture the roughness effects on fluid flow. Recent experimental evidence indicates that the roughness affects laminar flow and transition to turbulence. Roughness effects become especially important in microfluidics as the roughness features offer a unique opportunity to control the level of transport processes occurring at the wall.

Overview

Our understanding of ► roughness effects on fluid flow at macroscale is largely derived from the experimental data obtained by Nikuradse [1] in 1933. He used sand grain coated pipes of 25 to 5486 mm diameter tubes coated with sand grains in his experiments. The sand grains were coated on the inside of the tube in a monolayer, separated by some unknown distance from each other, with the help of a coating of Japanese lacquer. The diameter of the sand grains was used as the roughness parameter ε, and the ► relative roughness was defined as the ratio ε/D, where D is the root diameter of the pipe. The widely used Moody [2] diagram depicts the effect of Reynolds number and relative roughness ε/D on the friction factor. The relative roughness varied from 0 to 0.05, or 5%, and the Reynolds number ranged from 600 to 10^6. Based on his data, Nikuradse concluded that there is no effect of roughness in the laminar range under the experimental conditions employed in his experiments.

Nikuradse's conclusion on the roughness effect in the laminar region was disputed by Kandlikar [3]. It was shown that the experimental uncertainty in Nikuradse's data was of the same order as the pressure drop measurements between the two adjacent pressure taps. Experiments conducted [4] clearly show a roughness effect on friction factor and transition Reynolds number. A comprehensive summary of the research in this field is given by [4] and [5].

In the microfluidic application, since the flow channel size is small, it is possible to achieve high values of relative roughness with only a modest size rough roughness. For example, in a 200 μm channel, a roughness of 5 μm results in a relative roughness of 2.5%. Relatively large relative roughnesses, on the order of 10%, can be easily fabricated using the microfabrication techniques. Since the Reynolds numbers in the microchannels are generally low, a clear understanding of the roughness effects in laminar and transition regions becomes important.

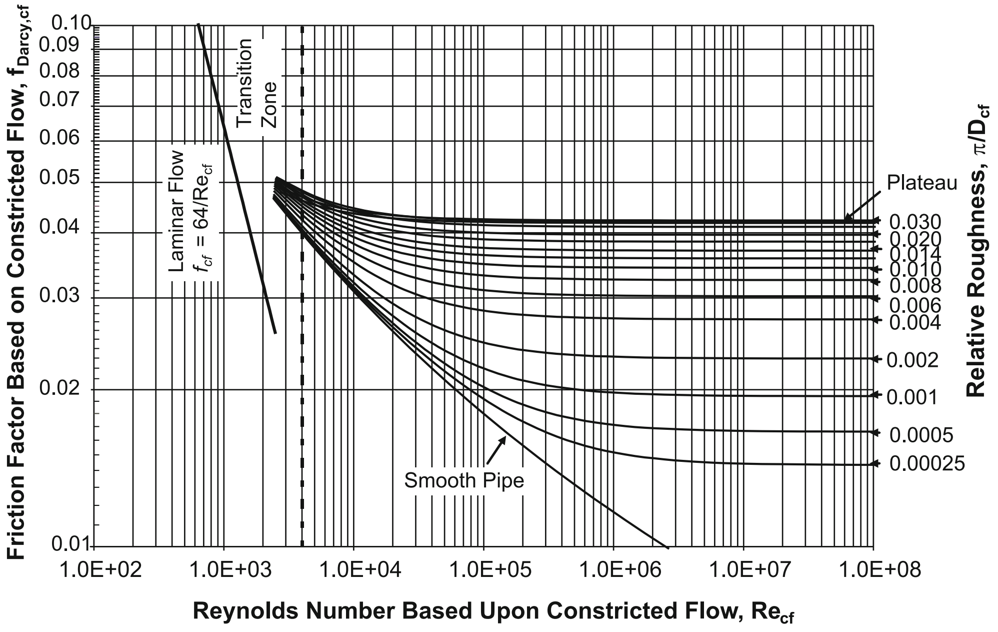
Basic Methodology

The roughness effects on the transport processes are not well understood. Our current knowledge is mainly based on the experimental data available in the literature. In recent literature, the flow over roughness elements is also being investigated using CFD simulation. Some models are also being considered by incorporating an effective viscosity and slip velocity at the wall. But these formulations are still in very preliminary stages.

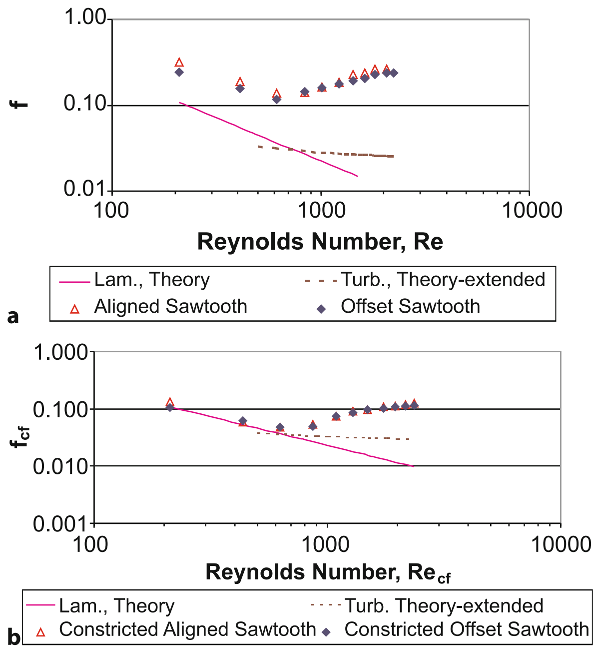
Key Research Findings

The effect of roughness on incompressible fluid flow was studied extensively by a number of investigators, with the experimental work of Nikuradse [1] being one of the most noteworthy. He clearly established that the roughness affected the friction factor using turbulent flows in circular channels. Moody [2] presented these results in his well-known Moody diagram. The relative roughness was defined as the diameter of the sand grains used by Nikuradse to make the roughened pipes. The relative roughness was defined as the ratio of the sand grain diameter to the pipe internal diameter without the sand grains, or the root diameter of a rough pipe.

Two key features in the Moody diagram were discussed further by Kandlikar et al. [4]. Firstly, the fully developed rough turbulent flow region at higher Reynolds numbers is seen to be dependent on the relative roughness. As the relative roughness increases, the friction factor increases for a given Reynolds number. Secondly, the laminar region was represented as being unaffected by the wall roughness. A new hydraulic diameter $D_{h,cf}$ was introduced based on the ► constricted flow dimensions. For a circular pipe with wall roughness ε, the constricted flow diameter is



Roughness Effect on Microscale Transport, Figure 1 Variation of transition Reynolds number with relative roughness based on constricted flow diameter, Kandlikar et al. [4]



Roughness Effect on Microscale Transport, Figure 2 (**a**) Fully developed friction factor versus Reynolds number for water flow, $D_h = 953\ \mu m$ and $\varepsilon/D_h = 0.0735$, adapted from [4]. (**b**) Fully developed friction factor versus Reynolds number, both based on constricted flow diameter for water flow, $D_h = 953\ \mu m$ and $\varepsilon/D_h = 0.0735$; $D_{h,cf} = 684\ \mu m$ and $\varepsilon/D_{h,cf} = 0.1108$, adapted from [4]

defined as:

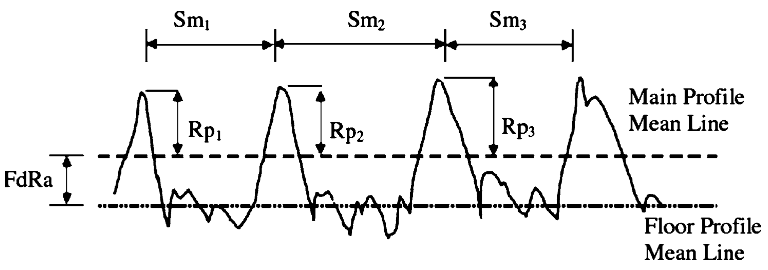
$$D_{h,cf} = D - 2\varepsilon \quad (1)$$

Moody diagram is replotted using the new constricted flow diameter in defining the friction factor as well as the Reynolds number. The resulting plot is shown in Fig. 1. It should be noted that all the lines in the fully rough turbulent region for $\varepsilon/D_{h,cf} > 0.03$ collapse on a single line with $f_{Darcy,cf} = 0.042$. This introduces a significant simplification and also provides some insight into the roughness effect on the turbulent flows at high $\varepsilon/D_{h,cf}$ values. Another fact that is introduced in the modified plot shown in Fig. 1 is that the laminar region was represented by a line similar to that in the original Moody diagram, but was modified to include the constriction effect:

$$f_{cf} = \frac{Po}{Re_{cf}} \quad (2)$$

Where f_{cf} and Re_{cf} are constriction based friction factor and Reynolds number respectively, and Po is the Poiseuille number specific to the cross-sectional geometry of the channel, 16 for circular pipes, 14.23 for a square channel and 24 for flow between two parallel plates.

Since Nikuradse's data in the laminar region was obtained with a high degree of uncertainty, the original Moody plot



Roughness Effect on Microscale Transport, Figure 3 Roughness parameters for application in fluid flow [4]

erroneously indicates that a relationship of $f = \mathrm{Po}/\mathrm{Re}$, with both f and Re based on the root diameter of the pipe. Extensive experiments conducted by [4, 6] show the validity of the constricted diameter approach as indicated by Eq. (2). Figures 2a and 2b show the plots of the experimental data for water in an artificially roughened rectangular channel with sawtooth ridges. The use of the conventional base channel dimensions in Fig. 2a clearly underpredicts the friction factor significantly, while using the same data with the constricted flow parameters shows excellent agreement with the experimental data.

Roughness representation: A set of three parameters are proposed to represent the roughness compatible with the constricted flow parameters discussed in the earlier sections: Maximum Profile Peak Height (*Rp*), Mean Spacing of Profile Irregularities (*RSm*), and the Floor Distance to Mean Line (*Fp*), as shown in Fig. 3. Two of these parameters (*Rp* and *RSm*) are defined in the ASME B46.1-2002 and the other (*Fp*) is proposed by Kandlikar et al. (2005)

Maximum Profile Peak Height (*Rp*): The distance between the highest point of the profile and the mean line within the evaluation length. The mean line represents the conventional average roughness value (*Ra*).

Mean Spacing of Profile Irregularities (*RSm*): Consists of the mean value of the spacing between profile irregularities within the evaluation length. The irregularities of interest are the peaks, so this is equivalent to the Pitch.

$$RSm = \frac{1}{n}\sum_{i=1}^{n} Sm_i \tag{3}$$

Floor Distance to Mean Line (*Fp*). Consists of the distance between the main profile mean line (determined by *Ra*) and the floor profile mean line. The floor profile is the portion of the main profile that lies below the main profile mean line.

From the above parameters, the equivalent roughness ε can be estimated by the following relationship:

$$\varepsilon = Rp + Fp \tag{4}$$

Future Directions for Research

The concept of constricted flow diameter is seen to be applicable in the laminar and turbulent flows as illustrated in the above sections. The effect of different roughness structure is also important and needs to be investigated further. The roughness parameter ε defined by Eq. 4 is proposed for replacing the conventional average roughness parameter *Ra*. Further work to validate this concept is currently under way [6]. Experiments with biological application are also being conducted and indicate a need for further investigation in this field [7]. Numerical simulation of the flow with rough walls is also being pursued [8–10]. In future, a close tie-in between the numerical simulations and experimental work is expected. The size and shape of the roughness structure and its effect on the flow can be effectively used to create the desired transport effect at the wall, such as enhanced mixing, localized mass transport enhancement or more effective heat transfer surfaces.

MACS (magnetic-activated cell sorting)

Definition

Isolation of specific content from a cocktail using paramagnetic particles in a magnetic field.

Overview

Under a certain magnetic field, a magnetic particle is forced to move depending on its susceptibility and volume [1]. The magnetic force [2] is

- paramagnetic particle:

$$F_M = \frac{\chi V}{\mu_0} B \nabla B \qquad (1)$$

- superparamagnetic particle (saturation of field in the case of a relatively small particle, in general less than 100 nm in diameter):

$$F_M = m_s \nabla B \qquad (2)$$

where the magnetic field (B) is $\mu_0(H+M)$ and the magnetization (M) is the product of a dimensionless magnetic susceptibility (χ_m) and a uniform external field (H_{app}). The strength of the magnetic source is expressed by the magnetic moment (μ_0 and m_s, respectively, in Eqs. (1) and (2)). The consideration of magnetic property is critical to perform sample purification using magnetic particles.
Magnetic sample purification is conducted by binding magnetic particles on a specific content such as DNA, protein, bacteria or cells in an equivalent contents pool. By applying magnetic particles, a target material which has no magnetic property can be controlled under the magnetic field.
There are three methods in sample purification using magnetic particles [3].
The positive method is to label magnetic particles only with the target molecule. The target molecule is isolated from the others by magnetic force balance under the field. After the isolation process, magnetic particles should be removed from target molecules to reduce the interference during post-processes such as cell culture and gene work. To remove the possibility of this interference clearly, the negative method is used. All other molecules except the target molecule are conjugated with magnetic particles using each specific binding partner. The purifying efficiency of the two methods is reported as 60–90%. The

depletion method, which removes partial unwanted contents but not all from a cocktail in a single step, is also used. The sequential depletion shows 99.9% purifying efficiency in general.

Sampling Unit

Synonyms

Fluidic multiplexer; Fluidic sequencing circuits

Definition

A fluidic device performing spatio/temporal conversion of fluid flows in response to a control signal. It allows only one of the inlet fluid flows at a time to progress to the outlet.
Essential part of sampling units is an array of microfluidic valves. There are many advantages in using for the purpose the no-moving-part valves, but their property of the flow paths not being separated by a solid partition requires a somewhat sophisticated design, with the fluid purity ensured by guard flows. Sampling units find an application in microfluidic systems for combinatorial chemistry, where they deliver a sample at a time from several test reactors allowed to flow to the composition analysis connected to the sampling unit outlet.

Definition

Scanning Probe Microscopy (SPM) is the branch of microscopy concerned with the formation of images of a surface using a physical probe that scans the specimen.

Overview

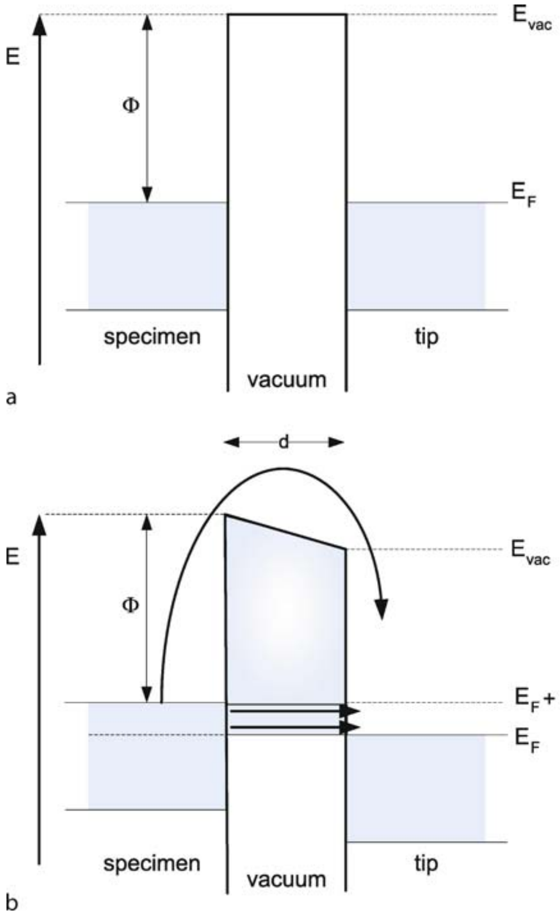
Scanning probe microscopy originated with the invention of the scanning tunneling microscope (STM) in 1981 by Gerd Binning and Heinrich Rohrer (Nobel Prize for Physics in 1986). The STM relies on the principle of electrons *tunneling* through the gap between a sharpened tip and the sample in a vacuum. For tunneling to take place, both the sample and the tip must be conductors or semiconductors, STMs cannot image insulated materials.

To understand how atomic resolution can be achieved, it is necessary to consider the electronic structure of a metal as illustrated in Fig. 1. The electrons of the metal occupy all the available energy levels up to the energy E_F known as the *Fermi* energy (at this level they precisely compensate the positive charge of the metal ions). For an electron to be able to exit the metal, an additional amount of energy of Φ above the Fermi energy is required. This brings the electron up to the vacuum level, at which point it is free to move away from the metal. The energy Φ is known as the *work function* of the metal.

To allow the electrons to tunnel through the vacuum, a second conductive object needs to be placed a small distance d away from the first. When an electrical voltage V is applied between the specimen and tip, a net electrical current (known as the tunneling current) flows. The current depends on the tip-surface distance d, the voltage V and on the height of the barrier Φ. The relationship is given by Eq. (1).

$$I(d) = \text{constant} \times \text{eV} \exp\left(-2\frac{\sqrt{2m\Phi}}{\text{h}}d\right) \quad (1)$$

The other quantities in Eq. (1) are the electron charge and mass e and m, and Planck's constant h. Eq. (1) shows that



Scanning Probe Microscopy, Figure 1 Schematic illustrating the tunnel phenomena. (**a**) In a metal, the energy levels of the electrons are filled up to a particular energy known as the Fermi energy E_F. In order for electrons to leave the metal and travel to the other body (in this case specimen and tip), an additional amount of energy known as the work function is required. (**b**) If the distance d between the specimen and tip is small enough, electrons can 'tunnel' through the vacuum barrier and with an applied voltage between the specimen and tip, a tunneling current is achieved

the tunneling current obeys Ohm's law (i. e., $I \propto V$). It also depends exponentially on the distance d. For a typical work function value of 4 electronVolts (eV), the tunneling current reduces by a factor of 10 for every 0.1 nm increase in d. Considering a typical atomic diameter to be 0.3 nm the tunneling current would change by a factor of 1000 over this range.

The most common and possible most versatile SPM is the Atomic Force Microscope (AFM). The AFM relies on the principle of the atomic forces exerted between two objects as they are brought close to each other (Fig. 2). At a distance of tens to hundreds of angstroms, the interatomic forces are attractive (predominantly due to long-range van der Waals forces). On approaching the surface

S

to a distance of a few angstroms the force becomes repulsive. To observe this phenomenon, a sharp tip of a few μm in length with a diameter of less than 100 μm is used to probe the surface. The tip is located at the free end of a cantilever (typically 100 to 200 μm in length). The forces between the tip and the sample cause the cantilever to bend or deflect and this movement is measured by a detector. Unlike the STM, the AFM is not restricted to only conducting material.

In comparison with other microscopy techniques such as optical microscopy or scanning electron microscopy, SPM offers a number of advantages in terms of resolution and magnification. However, due to image acquisition by raster scanning, the measurement is slower and the maximum image size is generally smaller as well. Table 1 list some of the more common applications for SPMs.

In addition to the STM and AFM, the SPM family has expanded to include a whole array of instruments for detecting various probe-surface interactions. Figure 3 shows a comparison of the measurement scale of scanning probe microscopes in relation to other types of microscopy.

Basic Methodology

A generalized scanning probe microscope is shown in Fig. 4. The sample is typically mounted on a piezoelectric scanner which allows precise movement in the x-, y- and z-directions. The image is generated by the sample moving under the probe (or vice versa depending on instrument configuration) in a raster pattern. Typical scan step sizes range from a few angstroms to hundreds of nanometres with scan areas ranging from a couple of nanometres to around 50 μm depending on the instrumentation.

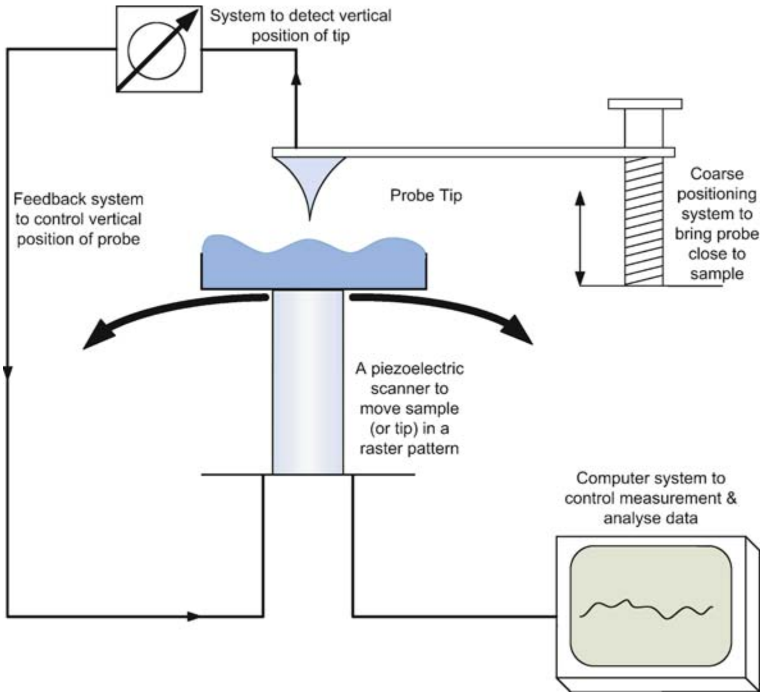
Scanning Probe Microscopy, Figure 3 Lateral and vertical measurement ranges of various microscopes



Scanning Probe Microscopy, Figure 4 Schematic of a generalised Scanning Probe Microscope

Depending on what physical phenomena is being measured, the probe will either maintain contact with the surface or remain a fixed distance above the surface. This height control is maintained by a feedback system which inputs and amplifies the tunneling current (low voltage) and drives the piezo scanning tube (high voltage). The shielding and layout of the feedback control is critical to the performance of the system as a whole.

Scanning Tunneling Microscopy

The STM typically employs a probe, made of tungsten (W) or platinum–iridium (Pt–Ir) alloy to scan the surface at a distance of 5 to 10 angstroms. The magnitude of resolution achievable is in the range of a fraction of 1 angstrom. This is highly dependable on the size and shape of the probe tip which will determine the lateral resolution.

The STM has a number of very real limitations. The instrument probes the electron cloud structure of the surface with great precision however, this reveals nothing about other important sample properties. As only the electronic structure is observed, information such as distinguishing between different elemental atoms within a compound is not achievable.

Atomic Force Microscopy

Limitations in the STM and its inability to investigate non-conducting surfaces led to the development of the AFM. Based on similar principles to the STM, the AFM can operate on both conducting and non-conducting surfaces.

A cantilever scans the surface and the deflection of the cantilever is detected by the reflection of a laser beam. The cantilever is typically made of Si_3N_4 of approximately 200 μm in length and with a spring constant of between 0.2 and 40 N/m. In many AFM instruments deflections in the cantilever are measured optically by bouncing a laser off the top of the cantilever, minute changes (as small as 10 angstroms) in the light path can be measured using a photodiode array. An alternative detection technique involves the incorporation of a piezoresistive element into the cantilever which generates a small voltage when deflected.

As the AFM relies on actual contact to sense the sample surface (as opposed to current flow for the STM), it can be used on biological molecules, organic materials, polymers, ceramics and insulating materials like diamond or glass.

Once the AFM has detected the cantilever deflection, it can generate the topographic data by operating one of two modes – *constant height* or *constant force*. In constant

height mode, the spatial variation of the cantilever deflection can be used directly to generate the surface data as the scanner height is fixed as it scans. In constant-force mode, the deflection of the cantilever can be used as input to the feedback circuit so that the scanner is moved up or down vertically in order to keep the deflection constant. In general, the AFM operates under a constant force mode.

For the cantilever, the two most important characteristics which will affect its performance are the spring constant and the resonant frequency. The spring constant for the cantilever is normally measured directly. For a beam with a rectangular cross section loaded at one end, the spring constant is given by Eq. (2).

$$k_{\text{spring}} = E_{\text{Y}} w_{\text{width}} / 4(\text{t}_{\text{thickness}} / l_{\text{length}})^3 \tag{2}$$

Where k_{spring} is the spring constant, E_{Y} is the Young's modulus and w_{width}, $t_{\text{thickness}}$ and l_{length} are the respective beam width, thickness and length. The resonant frequency of the cantilever will be dependant on which measurement mode or AFM variation is employed (these will be discussed in the proceeding sections) and whether a stiff or flexible cantilever is desirable. The formula for determining the resonant frequency is given by Eq. (3) where m is the mass of the cantilever.

$$\text{resonant frequency} = \frac{1}{2\pi}\sqrt{\frac{k_{\text{spring}}}{m}} \tag{3}$$

The AFM has three common modes or regions of operation; these are contact, intermittent contact and non-contact and are shown in Fig. 2.

Contact Mode

In contact AFM mode (also known as repulsive mode), the AFM tip makes soft physical contact with the sample. As the scanner traces the tip across the surface, the contact force causes the cantilever to bend to accommodate changes in topography. From Fig. 2 it can be seen that the slope on the left side of the graph is relatively steep suggesting the force increases significantly for a very small movement towards the surface. In other words, when the cantilever pushes the tip against the surface, the cantilever will bend rather than forcing the tip against the sample.

In addition to the repulsive force between the tip and sample, two other forces are generally present during contact AFM measurement. These are a capillary force exerted by the thin water layer often present in an ambient environment and the force exerted by the cantilever itself. The capillary force arises when water adheres itself to the tip and creates a strong adhesive force (about 10^{-8} N) that holds the tip in contact with the surface. The force exerted by the cantilever on the surface can be likened to that of a compressed spring with the magnitude and force direction dependent on the spring constant. However, as long as the tip is in contact with the surface the capillary force should remain constant. The magnitude of the total force exerted on the sample varies from 10^{-8} N to the typical operating range of 10^{-7} N to 10^{-6} N.

Non-Contact AFM

Non-contact AFM is one of several vibrating cantilever techniques in which an AFM cantilever is vibrated near the surface of a sample. Tip-sample spacing is in the order of tens to hundreds of angstroms.

Non-contact AFM is desirable where little or no contact between the tip and sample is required. The total force between the tip and sample is relatively low at about 10^{-12} N which makes it advantageous for studying soft or elastic samples. As no contact is made, there are no tip contamination issues to consider.

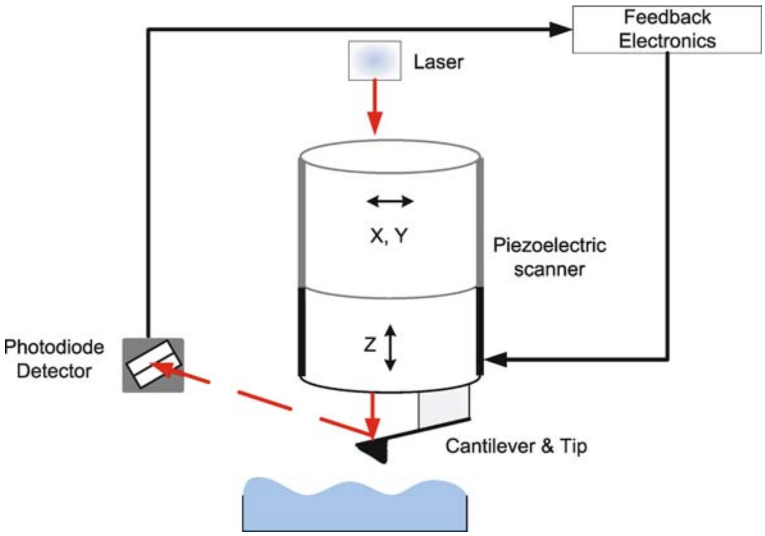
Cantilever selection differs from that for contact mode as they are required to be stiffer to prevent being pulled into the sample surface.

In non-contact mode, the system vibrates a stiff cantilever near its resonant frequency (typically 100 to 400 kHz) with an amplitude in the range of ten to several hundred angstroms. Any change in resonant frequency or vibration amplitude as the tip nears the surface can be detected. The sensitivity of this technique allows sub-angstrom vertical resolution to be achieved.

Intermittent Contact

Intermittent Contact AFM is similar to the non-contact AFM mode except that the vibrating cantilever is brought closer to the sample so that at the maximum amplitude it makes slight contact with the surface (i. e., 'taps' the surface). The intermittent contact region is shown on Fig. 2. As with non-contact measurement, the change in cantilever oscillation amplitude is in response to variation in tip-to-sample spacing.

In some cases, intermittent contact is preferred as it is less likely to damage the sample than contact mode as it eliminates lateral forces (i. e., friction or drag) between the tip and sample. Compared to non-contact measurement, intermittent contact is more effective for imaging larger scan areas that may include greater surface topographic variation. In recent years, intermittent contact AFM has become a popular tool for cell biologists as it can measure hydrated biological samples- overcoming the adhesive forces of the water by vibrating at a sufficiently high frequency.



Scanning Probe Microscopy, Figure 5 The basic components of an Atomic Force Microscope showing the stationary sample configuration with the tip mounted on the scanning tube

Calibration

Due to the measurement range that SPMs work in, calibration is an essential procedure which needs to be carried out on a regular basis. The calibration of STM and AFM in the x–y direction is carried out using a standard of regular and known structure such as Highly Oriented Pyrolytic Graphite or a grid. The real challenge has been calibration in the vertical direction. Currently used procedures are based on calibration standards consisting of gold samples with one layer steps of gold, lipid layer deposited on a Langmuir-Blodgett film or macromolecules with known dimensions.

Other Types of SPM

Magnetic Force Microscopy

Magnetic Force Microscopy (MFM) images the spatial variation of magnetic forces on a sample surface. The tip is coated with a thin film of ferromagnetic material. To obtain the necessary surface topographic and magnetic information, a two-pass measurement approach is used. The first measurement pass obtains the topographic data by either contact or intermittent contact mode while the second pass uses the non-contact mode to detect changes in the resonant frequency of the cantilever induced by the magnetic fields influence on the tip.

Lateral Force Microscopy

Lateral Force Microscopy (LFM) measures the lateral deflections in the cantilever that are present from forces on the cantilever parallel to the plane of the sample surface. Lateral deflections of the cantilever are normally attributable to changes in surface friction or changes in slope. The LFM has been used to image variation in surface friction which can arise from inhomogeneity in the surface material.

Force Modulation Microscopy

A further extension to AFM imaging is that of Force Modulation Microscopy (FMM) which characterises the sample's mechanical properties while simultaneously obtaining the surface topographic information.

In FMM mode, the AFM tip is scanned in contact with the sample while a constant cantilever deflection is maintained by the feedback system. In addition, a periodic signal is applied to either the sample or the tip. Any variation in the amplitude of cantilever modulation that results from the applied signal can be attributed to a change in the elastic properties of the sample.

Electrostatic Force Microscopy

Electrostatic Force Microscopy (EFM) works on the same two-pass measurement technique as MFM. Rather than measure the magnetic force, in EFM a voltage is applied between the tip and the surface. Any deflection in the cantilever can be attributed to locally charged domains on the sample surface. EFM can be used to map electrostatic fields in electronic devices when switched on and off in a technique known as voltage probing.

Scanning Thermal Microscopy

The scanning probe based thermal microscope (SThM) gives information about the temperature distributions and allows for quantitative determination of the local thermal conductivity in a sample. A resistive probe is employed which both captures the topographic information as well as the temperature/thermal conductivity profile with a resolution of a few milliKelvin. Table 2 provides a list of the more established members of the scanning probe microscope family.

Future Directions for Research

Research in SPMs appears to follow two distinct directions; one as a characterisation instrument and the other as a nanomanipulation instrument. In terms of characterisation, it has found use in many areas as described in Table 1 however, there are demands on the performance of these instruments to allow them to measure larger, rougher samples with greater speed. This has led to new developments in cantilever design as well control systems which is envisaged to continue to satisfy new areas of application.

As a tool for nanotechnology, the STM has been well publicised in its ability to 'push' or manipulate atoms into specific locations to create nanopatterns. However, this is a relatively slow process and would not be commercially viable. A more feasible approach has been undertaken using the AFM to create nanolithographic patterns by using the tip to remove material from a surface and create the desired pattern.

Molecular self-assembly fabrication

Definition

Self-assembly refers to the fundamental principle which generates autonomous organization of components into structural patterns or well-defined structure without external instructions or human interventions. Molecular self-assembly is the spontaneous organization of molecules under thermodynamic equilibrium conditions into stable, structurally well-defined aggregates joined by a number of noncovalent bonds (Whitesides et al. [1]).

Overview

As a fundamental natural principle, self-assembly exists everywhere at all scales from molecules to galaxies. Self-assembly describes the spontaneous association of numerous individual entities into a structural organization without external interventions. It is defined as reversible processes in which pre-existing parts or disordered components of a preexisting system form structures of patterns. Molecular self-assembly is the most well-studied subfield, which refers to the spontaneous organization of molecules under thermodynamic equilibrium conditions into stable, structurally well-defined arrangements through noncovalent interactions such as hydrogen bonds, ionic bonds, hydrophobic interactions, van der Waals interactions and water-mediated hydrogen bonds [1–4].

There are two major types of self-assembly, static and dynamic [5]. Static self-assembly describes the process that the ordered state occurs when the system is in equilibrium and does not dissipate energy. One special example of static self-assembly is the formation of atomic, ionic and molecular crystals [6–8]. In dynamic self-assembly, the process occurs only if the system is dissipating energy. The patterns formed in oscillating chemical reactions are simple examples [9, 10].

In recent years, self-assembly was successfully applied in micrometer scale structures. Self-assembled monolayer (SAM) [11] is the representative example of self-assembly microfabrication, in which surfaces consist of a single layer of molecules on a substrate. SAMs can be prepared simply by adding a solution of the desired molecule onto the substrate surface and washing off the excess. The technique was utilized on the metal substrates with PDMS stamps to form the combined system for controlling of crystal nucleation [12]. Another example involves a fluidic technique based on patterned hydrophobic SAMs and capillary forces to self-assemble micro fabricated silicon blocks onto silicon and quartz substrates [13].

The shear-driven technique is an alternative flow driving principle for the creation of fluidic flows through micro- and nanochannels. It is created when two flat surfaces are translated relative to each other resulting in a movement of the fluid in between the two surfaces. The fluid flow is characterized by a linear flow profile and is independent of the channel size.

Overview

During the last decade, miniaturization has been a major issue in analytical and bio-analytical chemistry. Microsystems have generated a considerable activity at economic and scientific levels and their importance in our everyday life is expected to increase considerably over the next few years. The drive towards miniaturization follows from an ever increasing demand (from such fields as organic (polymer) synthesis, medical diagnostics and therapeutics, genomics, etc.) for analytical tools capable of identifying and quantifying all compounds within small sample volumes. Furthermore, methods should generate more precise results, higher sensitivity and this in the fastest possible way. An efficient handling of minimal sample consumption can become possible by miniaturizing the analysis systems. Miniaturized fluidic systems can have several applications, such as amplification, digestion, and analysis of deoxyribonucleic acid (DNA) sequences or the separation and analysis of single defective cells in order to diagnose specific diseases at early stages. With the completion of the Human Genome Project, the analysis of gene and protein functions creates a huge demand for advanced biotechnological systems. These systems can only be realized using miniaturized fluid handling systems, which allow the rapid and efficient analysis of structures and functions with minimal sample volume. Due to this increasing demand, microfluidics has rapidly turned into an interdisciplinary research field equally including physics, chemistry, materials science and engineering.

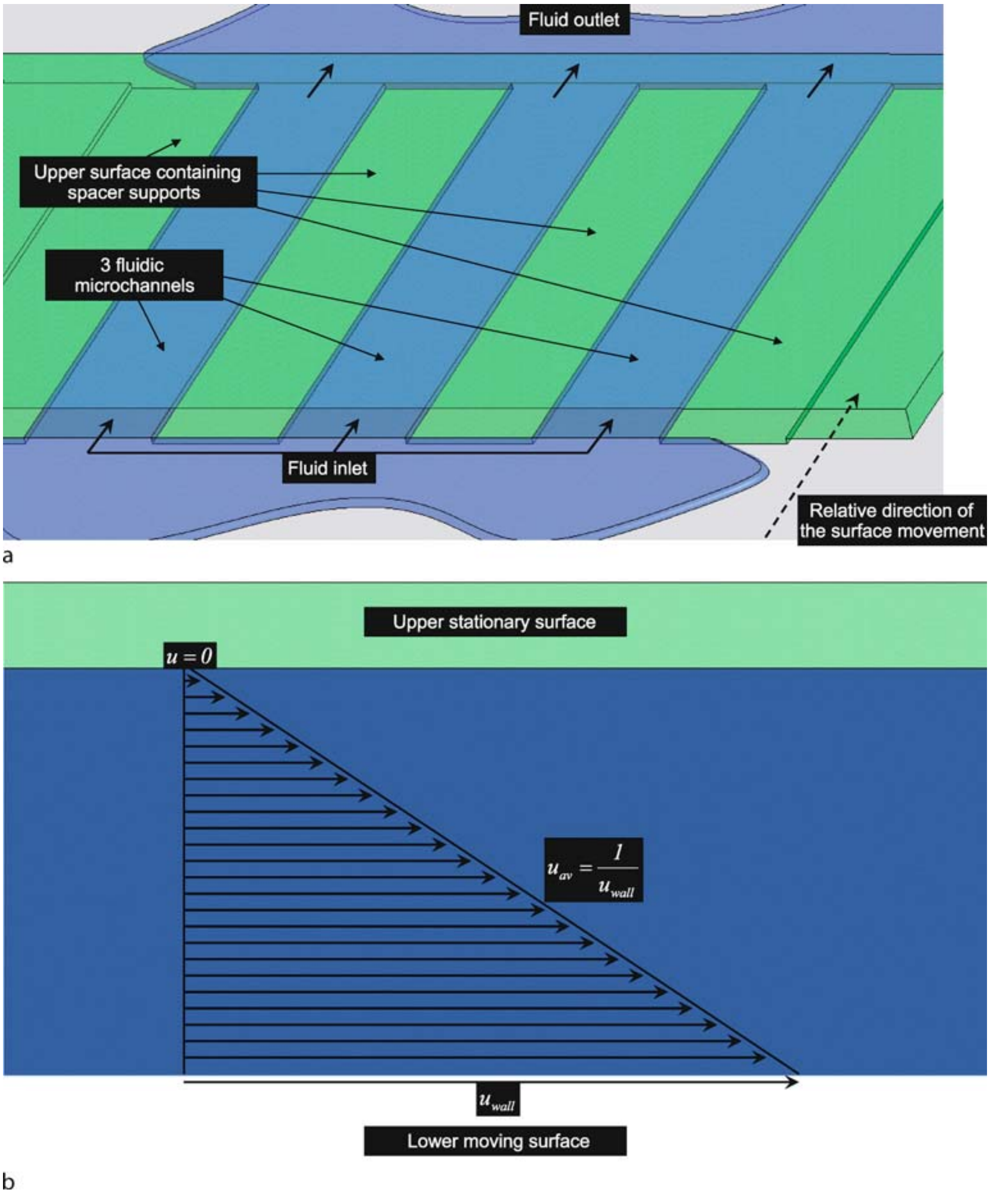
The generation of a stable and controllable fluid flow in microfluidic devices is a major issue and a lot of research work has been put into optimizing the flow driving methods. Not only conventional methods (derived from macroscopic applications) like pressure-driven and ►electro-osmotic flows have been scaled down, but also novel methods like ►shear-driven flows (SDF) have been introduced. There are several problems associated with the conventional flow driving methods: ►pressure-driven flows suffer from pressure drop limitations, while electro-osmotic flows suffer from Joule heating, fluctuations of flow velocity and double-layer overlap [1]. Therefore other approaches to evade these problems and limitations have been proposed (centrifugal forces, magneto-hydrodynamic forces, etc.).

The shear-driven fluidic approach is based on a radical modification of the fluidic channel concept. This recently developed technique for the transport of fluids in ultra-thin channels based on the SDF [2] relies on a very basic hydrodynamic effect: the viscous drag. This effect is present in every fluid flow, be it a liquid or a gas flow. In pressure-driven flows, the viscous drag manifests itself in an undesirable manner, as the stationary column and particle surfaces tend to slow down the fluid flow. In SDF, the viscous drag effect is turned into an asset. By conceiving channels with a moving wall element, this part of the channel wall no longer acts as a flow resistance but instead provides a net source of impulse, dragging along the fluid through the channel without the need to apply a pressure- or voltage gradient.

Instead of considering channels which are hermetically sealed along their longitudinal axis, the channels are axially split into two separate surfaces (Fig. 1a). While one of the surfaces is kept stationary, the other one is translated or rotated past the first. A large number of different channel layouts can be used to put this principle into practice. In the “Basic methodology” section the more practical side of this technology is described in more detail.

Pure hydrodynamic considerations [3] easily allow showing that, when the flat wall element is moved (Fig. 1b) relative to the element carrying the open channel, a flow is obtained which does not generate any pressure drop or pressure build up. The flow rate is only determined by the velocity of the moving wall element. As is taught in nearly every basic hydrodynamics course, the axial velocity in a laminar flow between two flat plates displays a perfectly linear profile, going from $u = 0$ near the stationary wall to $u = u_{\mathrm{wall}}$ near the moving wall [4]. As the viscous drag effect sustains this so-called shear-driven flow (SDF) at literally each point of the channel axis, the flow is generated without any pressure-drop or pressure build-up. This also implies that none of the fluid will leak through the axial split, which in turn implies that the use of axially split channels, forming the basis of the SDF concept, does not pose any sealing problem. It can be shown [3]

S



Shear-Driven Micro- and Nanofluidics, Figure 1 Figure showing the basic concept of a shear-driven flow apparatus. (**a**) The upper wall is kept stationary while the lower wall moves (driven by a linear translating stage) at a constant velocity. In this way the fluid in the channel is flown through the channel. The dimensions of width, length, and thickness are not to scale. (**b**) This shear-driven flow technique results in a linear flow profile inside the microchannel with an average fluid velocity that is half the velocity of the moving wall

that in a channel with a flat rectangular cross-section (width $w \gg$ thickness d), if neglecting the small regions (width of order d) near the side walls, a flow with a substantially linear radial velocity profile (Fig. 1b) is established, with the mean fluid velocity (u_m) given by:

$$u_m = \frac{1}{2} u_{wall} \quad (1)$$

wherein u_{wall} is the velocity of the moving wall.

Since the factor 2 in Eq 1 can also be considered as a geometrical factor, representing the ratio of the moving channel wall surface to the total channel wall surface, it should be noted that Eq 1 only holds in a channel with a flat-rectangular cross-section, wide enough to neglect the surface of the side-walls. It also shows that the SDF method intrinsically is an open-tubular technique: the moving wall cannot be used to generate a significant flow through a packed bed, as the stationary surface area

in a packed bed is typically orders of magnitude larger than the surface area of the moving wall ever could be.
The striking difference between Eq 1 and the pressure-driven case that follows from Poiseuille's pressure drop law:

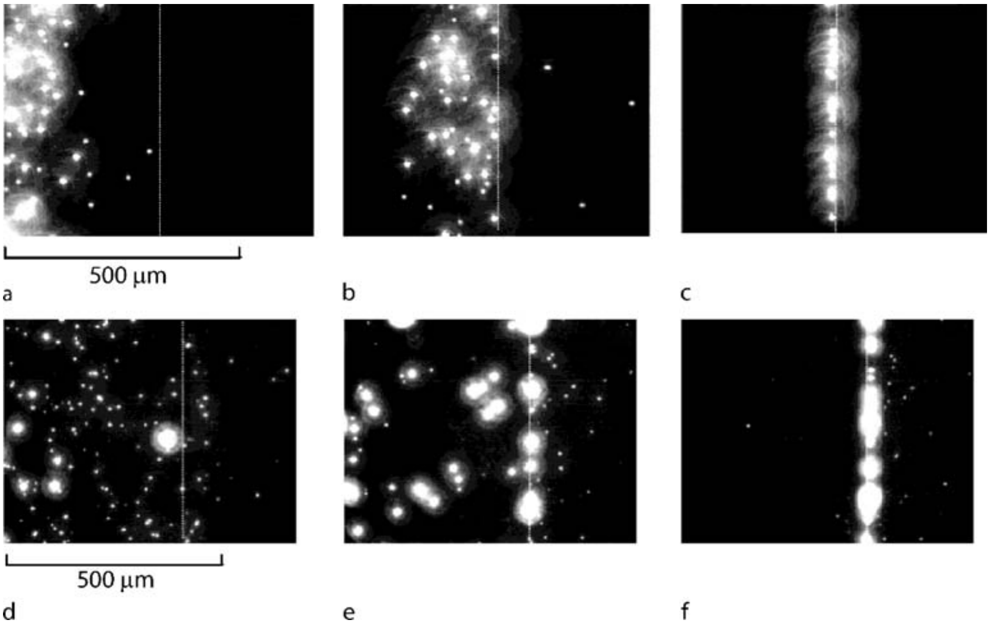
$$\Delta P = \frac{u_{\mathrm{m}} \psi \eta L}{\mathrm{d}^2} \tag{2}$$

is that the fluid velocity is totally independent of the channel diameter (d) and the channel length (L), implying that the SDF concept offers an intrinsic possibility to get around Poiseuille's pressure drop limitation on d and L. The fact that neither the length and/or the thickness of the channels, nor the physical properties of the fluid influence the fluid velocity is one of the most interesting properties of shear-driven flows. The SDF concept also retains all the beneficial characteristics of pressure-driven systems (same choice of stationary- and mobile-phase composition, same ruggedness and same possibility to perform temperature and solvent gradient programming, etc.).
The advantage with respect to the electro-osmotic flow is that SDF does not rely on the generation of an electrical double layer but is purely controlled by mechanical means, allowing for much larger fluid velocities, and as the established velocity field is independent of the nature of the fluid (3), the system also offers a perfect flow rate controllability and repeatability.
It should be noted that, with the basic principle described above, a large number of column shape variants for SDF can be conceived. The use of spiral- or helical shaped channels to increase the path length is such an example.
In our group, this type of flow principle has been researched extensively and one of the most important applications is situated in the field of chromatographic separations [5]. For chromatographic purposes, SDF creates the possibility to use longer and thinner separation channels without any theoretical restriction on the fluid velocity. Other advantages are the perfect predictability, reproducibility of the established flow rates and the selection of the solvent or buffer composition solely on the basis of its ability to maximize selectivity or detection [6]. Shear-driven ►chromatography therefore leads to a high separation efficiency and numerous experimental set-ups have been used to demonstrate the theoretical expected gain.
SDF has also proven to be a successful technique when it comes too enhancing the ►DNA hybridization on ►DNA-microarrays. The DNA microarray technology is a recently developed technique that can be used to study gene expression, mutation detection or genome analysis and allows the analysis of hundreds of thousands of genes or complete genomes in parallel. The power and universality of DNA microarrays as experimental tools are derived from the exquisite specificity and affinity of complementary base-pairing of the nucleic acids (the hybridization process). During the pas decade DNA microarrays have become an important biological tool for obtaining high-throughput genetic information in studies of human disease states, toxicological research and gene expression profiling. However, this technique still suffers from a number of inherent shortcomings such as lack of uniformity and slow hybridization speed. The main cause for these shortcomings is the fact that the hybridization process on the microarrays is governed by the slow diffusion process of the target molecules towards their complementary probes. Using the SDF technique this slow diffusion process could be circumvented by transporting small target volumes over the microarray surface, hence enhancing the hybridization rate and sensitivity of the hybridization process
The flexibility of the SDF fluid transport system in nano- and micrometer thin channels enables to exploit numerous other possible applications, especially if a high degree of spatial confinement or an increase in the diffusion transport rates is required. Vankrunkelsven et al. used the SDF system for the size separation of macromolecules and micro-particles in nano- and micrometer deep channels using micro-steps [7] (Fig. 2). The separation of 0.5 and 1.0 μm carboxylated polysterene beads; mixtures of *Staphylococcus aureus* and *Saccharomyces cerevisiae*; and mixtures of *Saccharomyces cerevisiae* and *Escherichia coli* cells in a micro- or nanochannel that is only slightly larger than the molecules themselves and is narrowed in a stepped structure.

Basic Methodology

Shear-Driven Chromatography (SDC)

As it already has been described in the overview, SDC is based on two well-polished surfaces, slid one at the top of the other generating a fluid flow thanks to the viscous drag. For chromatographic purposes, like in reverse phase-HPLC (RP-HPLC) (►high performance liquid chromatography (HPLC)), the sample solution (present in the mobile phase) needs to flow over a separation surface (the stationary phase) that can adsorb or absorb the sample molecules that need to be separated. The smallest (stationary) plate carries the stationary phase, whilst the longer (moving) plate should either be inert or have an opposite hydrophobicity. Thus far the majority of the conducted separation experiments have been carried out with monolayer coatings of C8 and C18. Given the sub-micron channel heights, these monolayer coatings already provide a sufficient retention capacity to separate a 4 component



Shear-Driven Micro- and Nanofluidics, Figure 2 Compilation of a series of captured CCD-images (20× magnification) of a micro-step separation experiment of a mixture of 0.5 μm and 1.0 μm polystyrene beads (**a-c**) ($u_{wall} = 100$ mm/s) and a mixture of *E. coli* and *S. cerevisiae* cells (**d-f**) ($u_{wall} = 10$ mm/s, pure PBS). The channel depth changes respectively from 3.3 μm to 0.7 μm (a-c) and from 5.2 μm to 1.6 μm (d-f) at the micro-machined step, indicated by the white dashed line. The relation between the apparent size of the particles and cells does not correspond to the actual size ratio, due to the disproportionately stronger fluorescence of the larger particles and cells (reproduced from [7])

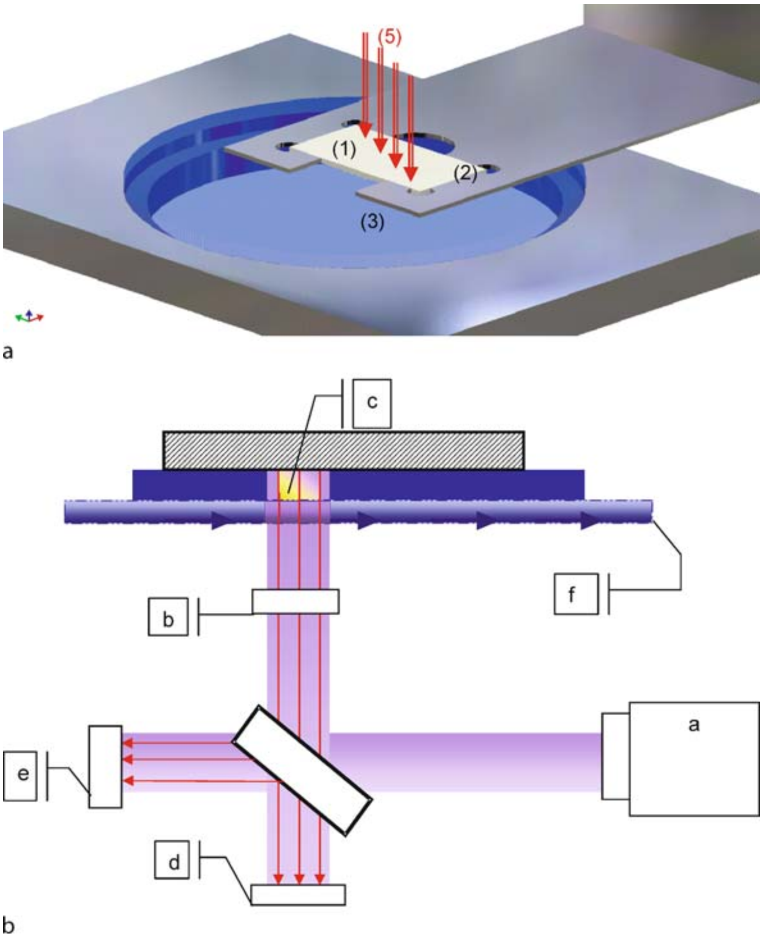
coumarin dye mixture in the first few mm of a C8-coated nano-channel. The stationary plate also contains an etched rectangular nanochannel. These channels are prepared by Deep ► reactive ion etching (RIE) using a state of the art etching machine: the AMS 100 SE (Adixen, France).

During the separation, the stationary channel is placed on top of a well polished fused silica plate (Photox Optical Systems, Sheffield, UK). This plate can be translated along the channel direction while the channel is kept in a fixed position (Fig. 3a). The velocity of the moving channel part is controlled using an automatic translation stage. This translation stage is held in the microscope table. The epi-fluorescence microscope is equipped with an Hg-vapour lamp and a UV-1 filter cube set that allows to excite the components at the right wavelength and to detect the emitted fluorescent light (Fig. 3b). The passage of the excitation and emission light is ensured via the moving bottom part made of fused silica. The SDC channels are positioned above the objective lens of the microscope. The emitted fluorescent light is taped by a ► charge coupled device (CCD) camera.

The actual injection method is semi-automated and consists basically of five successive steps. In the first step, the inlet of the channel is cleaned and all liquid present in front of the channel is removed. In the second step, a small drop of the sample mixture is deposited in front of the channel inlet. During the third step, the moving wall is rapidly displaced over a given prescribed distance depending on the injection volume. This movement forces the sample deposited in front of the inlet into the channel. During the fourth step, the non-entered sample is aspirated and replaced by pure buffer solution. When this is completed, the motion of the translation stage is restarted to perform the actual separation run (step 5). Apart from the second step, everything is automated. Using a computer controlled vacuum switch (needed in steps 1 and 4) and a syringe pump (needed in step 4), the entire injection process is currently completed in a couple of seconds [3].

The efficiency of chromatographic separations can be determined by calculating the plate heights. For the SDC system the theoretical plate height (HETP) can be calculated using Eq 3.

$$HETP = 2 \times \frac{D_m}{u_m} + \frac{2}{30} \times \frac{1 + 7k' + 16k'^2}{(1+k')^2} \times u_m \times \frac{d^2}{D_m} + \frac{2}{3} \times \frac{k'}{(1+k')^2} \times u_m \times \frac{\delta^2}{D_s} \quad (3)$$

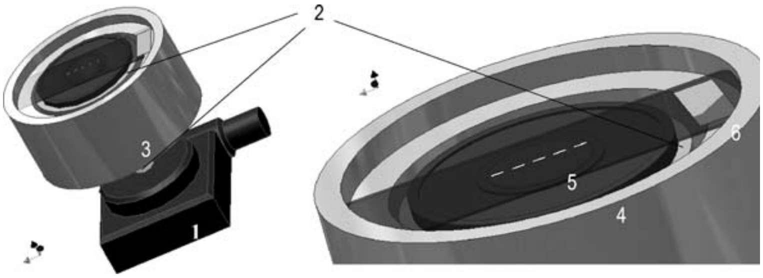


Shear-Driven Micro- and Nanofluidics, Figure 3 (**a**) This figure shows the employed mechanical set-up. The stationary phase is deposited on the bottom surface of a rectangular nanochannel [1]. The channel is placed on top of a well polished fused silica plate [3] which is moved along the channel direction while the channel is kept in a fixed position by a home-made holder [2]. (**b**) The main part of the detection set-up is an inverted epi-fluorescence microscope equipped with a Hg-vapour lamp (**a**) and a UV-1 filter cube set (**b**) to excite the four coumarin dyes (**c**) at the right wavelength (375 nm) The detection system consists of the two detectors, A CCD camera and a PMT device (**d-e**). The organization of the employed flow principle is represented, as well as the orientation and direction of the light paths of the employed fluorescence detection scheme. The passage of the excitation and emission light is ensured via the moving bottom part made of fused silica (**f**)

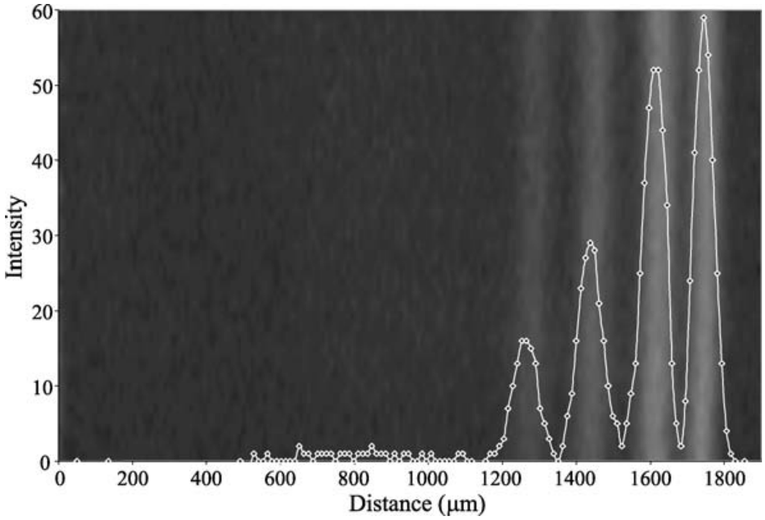
The plate height is calculated using the molecular diffusion coefficient of the mobile phase (D_m), the mean fluid velocity (u_m), the retention factor (k'), the channel depth (d), the molecular diffusion coefficient of the stationary phase (D_s) and the stationary phase thickness (δ). In general higher plate heights will lead to more efficient separations or the possibility to perform more complex separations.

Shear-Driven Hybridization (SDH)

The system used to perform shear-driven hybridization (SDH) on microarrays consists of a circular microchamber (diameter= 2 cm) etched in the center of a round, flatly polished (flatness= $\lambda/4$ at $\lambda = 512$ nm) borosilicate glass wafer (Radiometer Nederland, The Netherlands) with thickness 6 mm and diameter 5 cm [9]. This wafer was subsequently clamped in a home-built, hybridization device (Fig. 4). The wafer is rotated with an automated rotation stage equipped with a stepper motor (M-060, Physik Instrumente, Karlsruhe, Germany), and controlled with NetMove420-software (Physik Instrumente, Karlsruhe, Germany). The circular PVC holding cup surrounding the glass wafer makes it possible to control the temperature using a Julabo$^{\text{ő}}$ F32-MD Heating (and Refrigerated) Circulator (JD Instruments Inc., Houston, TX, USA), set at T= 42 °C during all the experiments.



Shear-Driven Micro- and Nanofluidics, Figure 4 Bird's eye view schematic of the rotating micro-chamber hybridization set-up, showing the rotation stage (1) and the stainless holding shaft (2). The PVC-cup (3) is used for temperature control. The etched glass consists of an outer etched ring (4) made to limit the contact area between the rotating bottom substrate and the microarray slide surface, and the microchamber (5). Finally the microarray slide (6) seals the entire system



Shear-Driven Micro- and Nanofluidics, Figure 5 Compilation of a series of subsequent CCD-camera images of the separation of a mixture of four coumarin dyes (C440, C450, C460 and C480) injected at a concentration of 10^{-4} M in a channel with $d = 280$ nm

To carry out the hybridization experiments, a freshly spotted microarray slide was gently deposited (spotted surface facing downwards) on the top surface of the glass wafer. A volume of 10 μL was applied in the 3.7 μm deep micro-chamber with diameter 2.0 cm. During the rotation of the glass wafer, the microarray slide was kept stationary and a pressure of 1 bar was used to push the microarray substrate and the microchamber against each other. For other hybridization experiments (coverslip and Slidepro) the standard hybridization procedures of the MicroArray Facility Lab (www.microarray.be) were followed. For the coverslip hybridization 30 μl sample was used to hybridize the microarray slide for an overnight (16 h) period in an incubator at 42 °C. Hybridizations using the Slidepro-system (GE Heatlhcare) are performed in independently temperature-controlled chambers, allowing customized process parameters to be used for each slide. Up to 210 μl can be injected into each chamber.

All hybridization experiments were conducted using conventional microarray procedures and made use of the VIB_Mouse_21K_II chip (MicroArray Facility, Leuven, Belgium). As array elements, mouse spleen and heart total RNA was used (BD Biosciences Clontech, Palo Alto, CA, USA). All different cDNA strands were obtained by PCR amplification and were arrayed on Amersham type 7 star slides (Amersham Biosciences, Buckinghamshire, UK) using a commercial Generation III Array Spotter (Amersham Biosciences, Buckinghamshire, UK). The array elements were all spotted at a concentration of 200 ng/μL. The spots (diameter 100 μm and spaced 20 – 30 μm apart), situated in the circular spotted area were grouped in 2 × 5 different blocks of 21 × 44 spots.

Prior to each experiment the arrays were slightly dampened and UV-crosslinked at 50 mJ followed by a prehybridization in 2xSSPE/0.2%SDS at 26 °C for 30 minutes. After hybridization the slides were washed

3 times for 10 minutes in respectively 1xSSC/0.2%SDS, 0.1xSSC/0.2%SDS and 0.1xSSC/0.2%SDS at 56 °C and 1 time for 1 minute in 0.1xSSC at room temperature. The slides were then scanned at 532 nm using a commercial Array Scanner Generation III (Amersham Biosciences, Buckinghamshire, UK). Image analysis was done using Array Vision 7.0-software (Imaging Research, ON, Canada) and Spotfire 8-software (Spotfire Inc., Somerville, MA, USA).

All experiments were started from 5 µg testis total RNA and 5 µg lung total RNA per sample. This was first amplified by T7-in vitro transcription and 5 µg aRNA was used for every labeling reaction. After labeling with ► Cy3/Cy5-dye, both samples were mixed and for every experiment, identical amounts of sample, i.e. 5, 20 or 40 pmol Cy3/Cy5-dye were applied. The cDNA was further dissolved in a solution containing 50% formamide, 25% buffer, 15% Mouse COT and 7.5% polydT35. This cDNA-mixture was then respectively denatured at 96 °C for 3 minutes, set on ice for 2 minutes, heated to 42 °C for 5 minutes, centrifuged at $\omega = 12.000$ rpm for another 5 minutes and subsequently held on ice before applying it on the microarray slide.

Key Research Findings

Shear-Driven Chromatography (SDC)

In our lab the use of the shear-driven technology to perform chromatographic separation has been investigated since 1999, and the results obtained thus far are remarkable. Yet there is still room for improvement. Especially the enhancement of the detection system and the automation of the injection procedure have been the two main focus points. They are considered as the Achilles' heel of this technique. It has already been proven that a separations of four coumarin dyes is possible in less than 2 s. Figure 5 shows such a separation of a mixture of four coumarin dyes (C440, C450, C460 and C480) in a 300 nm deep channel in 1.8 sec. The velocity of the moving wall is 2 mm/s (i. e., far below the optimal flow velocity which is situated around 10 mm/s) in order to be compatible with the scan rate of the Charge-Coupled Device (CCD) camera. About 2000 plate numbers per second can be achieved. This offers the possibility to yield over 10,000 plates per centimeter in a few seconds. A separation at 8 mm far from the inlet of the channel does not yield unfortunately the hoped 8000 plates per second but 4000. The reason of the drop in efficiency is explained by the channel irregularities and the use of 10 times more concentrated solutions to allow detecting far from the injection region.

Detection Enhancement

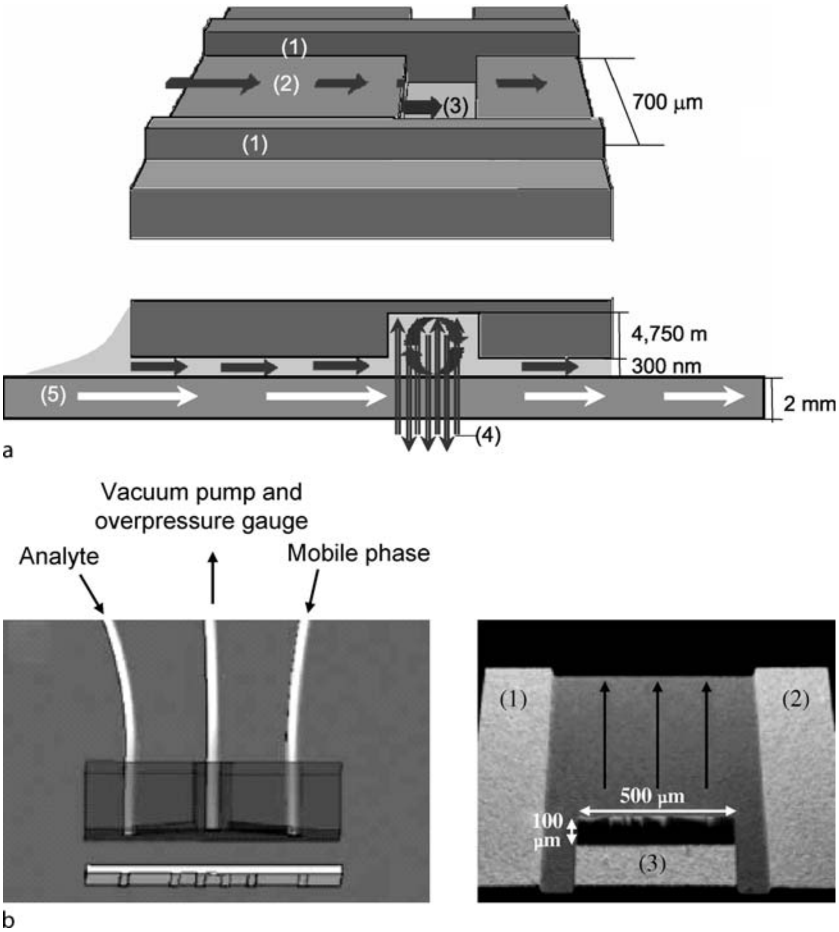
The observation that the SDC technique couldn't reach the theoretical predicted efficiency, led us to find a way to enhance the detection system. A very simple idea about locally deepened channels was investigated. By creating a small but 10 to 30 times deeper region (► detection groove, Figure 6a) in the channel structure near to the exit a 10 to 30 times more intense fluorescent signal can be expected. The groove accumulates the fluid passing in the channel and instead of detecting in the 300 nm deep region of the nanochannel, the detection occurs in a small but much deeper region enabling an enhanced detection. An experimental study was carried out in order to proof the efficiency of the detection grooves. A 4.75 µm deep and 4 µm wide detection groove, running perpendicular to the mean flow direction, was etched (Fig. 6a). This resulted in a 5-fold lower detection limit in a 300 nanometer deep nano-channel. This 5-fold gain in S/N-ratio is however about three times lower than the theoretically expected gain, based on the ratio of the channel depth outside and inside the groove. Measurements performed under stationary conditions indicated that this underachievement is due to scattering light losses. The plate number loss accompanying the passage of the peaks through the detection groove in a 1 cm long and 300 nm deep channels coated with a retentive layer would be of order of 20%.

The separation experiments with the detection groove were however still insufficient for more qualitative studies. This can be attributed to the semi-manual injection procedure that is not reproducible enough. The standard variation of three consecutive injections can vary from 1 up to 50% mainly due to the manual handling in this injection procedure.

Fully Automated Injection System

To tackle the injection problems a new automated injection system was tested (Fig. 6b). An ► injection slit etched by Bosch avoids any formation of asymmetric shaped plugs, which typically occurs during loading of the sample in wide channels. The slit is connected to a vacuum system and syringes for the supply of the analyte and the mobile phase. A CFD simulation was first performed to compare different injection well shapes and configurations in order to account for less profitable configurations.

The main problems related to the semi-automated injection method (the definition of plugs is highly dependent on the dicing quality of the substrate, the method is slow which gives rise to peak broadening by diffusion, reproducibility is bad because of uncontrolled dilution and manual handling and no gradient in the mobile phase composi-



Shear-Driven Micro- and Nanofluidics, Figure 6 (**a**) Schematically overview of the detection groove structure. In the nanochannel structure (1–2) a deeper groove (3) is etched to enhance the detection. With this type of groove (with a depth of 4.75 μm, see side view) a 5 fold decrease in the detection limit could be obtained. (**b**) Outline of the automated injection system. (**a**) The supply channels in the PMMA connect to a cavity above the injection micro-well. (**b**) Wyko (optical profilometry) scan of the backside of the etched well, showing the position of the injection slit in the channel, together with the non-etched channel spacer regions (1, 2) delimiting the lateral extent of the channel and the non-etched region (3) preventing the mobile phase that is present in front of the channel to enter the channel. The flow direction is indicated by the arrows

tion can be created) could be resolved by this new method. It would hence allow performing complex separations.

It was experimentally shown that a good reproducibility occurred both for the peak width as for the sample concentration (standard deviations are max. 4 and 8%, respectively), where as the plug concentration was 80% of the original sample concentration. It was also observed that with the current setup the lower limit of the peak width was 122 μm. This is a consequence of the fact that peak width originating from convection becomes negligible to the contribution of diffusion during filling and flushing. This automated and closed system paves the way for further functionalities in shear driven chromatography, i. e. gradient elution and parallelization.

Shear-Driven Hybridization (SDH)

A second important application of the shear-driven technology based on the microarray technique has been investigated as well in our group. Earlier reports show that the most ideal flow principle for hybridization on the microarrays is an intermitting flow mode where the fluid is kept stationary for a certain period, followed by a short movement of the fluid. The stationary period is necessary to allow the target molecules to form hybrids with their complementary probes, while the short fluid pulses are necessary to refresh the target mixture above the microarray spots.

A further evaluation of the efficiency of the SDH system consisted of a series of hybridizations with complex tar-

get samples (mouse spleen and heart) on slides containing more than 21,000 cDNA fragments. In order to compare SDH with other types of hybridization approaches all experiments started from the same amount of genetic material (i. e. 40 pmol Cy3/Cy5- labeled cDNA) (Table 1). As the amount of labeled sample was kept the same for all experiments, SDH had an immediate advantage as the sample concentration is increased from 3 to 21 fold compared to the conventional coverslip and Slide Pro, respectively. A comparison of these three types of hybridization systems (Table 1) showed that, compared to the results with an automated slide processor (SlidePro, GE Heatlhcare), the relative intensity of the spots increased with a factor 2 for the coverslip hybridization and with a factor 4 for the shear-driven hybridization. Furthermore the total number of spots that could be flagged as being hybridized rose from 67% with the Slidepro system and 80% under the coverslip to 87% with the SDH system. This significant rise in the number of spots points to the great potential of SDH as it will be possible to detect a larger number of hybridized spots with the same amount of sample, or detect the same amount of spots with a smaller sample consumption. An even better gain could be obtained by making the shear driven hybridization last longer than two hours. All experiments with the SDH system lasted two hours while the SlidePro and coverslip hybridizations lasted for 16 hours.

Shear-Driven Micro- and Nanofluidics, Table 1 Comparison of hybridization conditions on the shear-driven rotating micro-chamber system, the diffusion-driven coverslip system and the SlidePro (GE healthcare) for a mouse heart and spleen total RNA sample on the VIB_Mouse_5KI microarray chip

	Shear-driven hybridization-system	Diffusion under cover-slip	SlidePro auto-mated hybridiza-tion
Amount incorporated Cy3/Cy5 (in pmol)	40	40	40
Sample Volume (in μL)	10	30	210
Sample Concentration (in pmol Cy3/ μL)	3.00	1.00	0.14
Hybridization Time (h)	2	16	16
Surface Micro-chamber (in mm^2)	314	1000	1000
Hybridized spots	87%	80%	67%
Relative Intensity	396%	189%	100%

Figure 7 shows images of experiments identical to the ones from table 1. It was clear from these images that the overall intensity of the spots was much greater for the SDH system than for the coverslip and SlidePro hybridization. For this series (Fig. 7a) of experiments the SlidePro hybridization was conducted with a total amount of 40 pmol incorporated Cy3/Cy5 dyes while the SDH and coverslip hybridizations were performed with only 20 pmol incorporated Cy3/Cy5 dyes. It is even possible to drop the concentration even further to 5 pmol incorporated Cy3/Cy5 dyes in the sample (Fig. 7b) and still be able to get good results with the SDH system, compared to SlidePro, where almost no hybridization occurred.

This report shows how a working prototype for microarray hybridizations based on the shear-driven technology has been developed and tested. The key factor for the success of the SDH method was the combination of the mixing, circumvented the slow molecular diffusion, and the reduction of sample volume generated more concentrated samples and higher final intensity values of the microarray spots. The concentration was indeed found a major factor on the effect of convection to reach higher signals intensities.

Future Directions for Research

The investigations into the fundaments of the shear-driven technique and the different applications (SDC, SDH, . . .) is still ongoing. Fundamentally different types of spacer walls are being tested in order reduce the channel depth under the 100 nm boundary. Until now 100 nm has been the limit of the shear-driven fluidics. Other channel designs and etching techniques are now being used to reduce even

All experiments were done with mouse heart (Cy3) versus spleen (Cy5) total RNA sample on the VIB_Mouse_21KII microarray chip

further the channel depths in order to reach sub 100 nm nanofluidic flows. Also the development towards infinite moving wall elements and high-throughput formats are being studied.

For SDC applications, apart from detection enhancement and the automation of the injection system, much effort is put into the development of novel stationary phases and the application of gradient elutions.

Currently a novel SDH prototype is being developed to enable a 100% coverage of the microarray slide, where our current prototype covers only 30% of the microarray slide. In order to use shear driven convection on standard microarray slides, the prototype needs to be redesigned from a rotating to a lateral movement or change the standard microarray slides to microarrays on round disks.

Department of Mechanical Engineering, IIT Kanpur, Kanpur, India
panig@iitk.ac.in

Definition

Fluid flow past a surface or boundary leads to surface forces acting on it. These surface forces depend on the rate at which fluid is strained by the velocity field. A stress tensor with nine components is used to describe the surface forces on a fluid element. The tangential component of the surface forces with respect to the boundary is known as shear stress. The nature or origin of shear stress depends on the nature of flow, i. e., laminar or turbulent. The stress components for a laminar flow are functions of the viscosity of the fluid and are known as viscous stresses. The turbulent flow has additional contributions known as Reynolds stresses due to velocity fluctuation, i. e., the stresses of a laminar flow are increased by additional stresses known as apparent or Reynolds stresses. Hence, the total shear stresses for a turbulent flow are the sum of viscous stresses and apparent stresses. In a turbulent flow, the apparent stresses may outweigh the viscous components.

Overview

The ► wall shear stress is an essential quantity of interest in a wall-bounded flow. The time averaged value of wall shear stress can be used to determine the skin friction drag acting on the body by the fluid flow. The time-resolved behavior of surface shear stress indicates the unsteady flow structures responsible for individual momentum transfer events and turbulence activities. The instantaneous shear stress values at distributed locations on the surface can be used to feedback control the turbulence events inside a boundary layer. Shear stress measurement also helps in assessment and control of power consumption rate and therefore is an important quantity of interest in various industrial applications.

The importance of shear stress measurement is even more crucial for small-scale devices, i. e., MEMS applications, due to their higher surface to volume ratio. There have been many efforts in literature for successful shear stress measurements. The success of these efforts primarily relies on the complexity of the flow, the nature of solid boundaries and limitations of the measurement techniques. The other drawback of shear stress measurements is its smaller magnitude, i. e., the estimated value of shear stress

of a typical car moving at 100 km/hour is about 1 Pa. Hence, highly sensitive shear stress measuring devices are required for successful measurements of surface shear stress and it is essential to have proper understanding of the various noise sources that can effect shear stress measurements.

Shear stress sensors provide qualitative information about the flow field, i. e., separation, transition, reattachment, etc., and proper calibration of shear stress sensors is required for quantitative measurement/information. Hence, this review concentrates on: principle of operation, noise sources and calibration of various shear stress sensors. The spatial and temporal resolution requirements for turbulent flow applications and the benefit of MEMS sensors are also discussed.

Requirements for Turbulent Flow

Turbulence is characterized by the existence of numerous length and time scales. The time scale is a measure of the fact that at a given point in a turbulent flow field, distinct patterns get repeated regularly in time. Similarly, distinct patterns may be repeated in space at a given instant and the size of the patterns are known as length scales. Different length scales and time scales have been defined for characterization of turbulent flow field. The smallest eddy of turbulent flow is expressed by the Kolmogorov length (l) and time scale (τ) which is uniquely determined by dissipation (ε) and kinematic viscosity (ν):

$$l = \left(\frac{\upsilon^3}{\varepsilon}\right)^{\frac{1}{4}} \tag{1}$$

$$\tau = \left(\frac{\nu}{\varepsilon}\right)^{\frac{1}{2}} \tag{2}$$

Using the inviscid assumption for calculation of the dissipation rate, the non-dimensional length scale and time scale respectively reduce to

$$\frac{l}{l_S} = (\mathrm{Re})^{-\frac{3}{4}} \tag{3}$$

$$\frac{\tau}{l_S} u = (\mathrm{Re})^{-\frac{1}{2}} \tag{4}$$

Here, l_S is the characteristic length of the inertial sublayer, u is the characteristic velocity of the eddy and Re is the Reynolds number (ul_S/ν). Equations (3) and (4) indicate that with an increase in Reynolds number, the length and time scales of eddies decrease. To spatially resolve the small eddies, sensors that are of same size as the Kolmogorov length scale for that particular flow are needed. Hence, smaller sensors are required as the Reynolds number is increased. For a flat plate boundary layer with momentum thickness Reynolds number equal to 4000, the Kolmogorov length scale is of the order of 50 μm. A large-dimension sensor integrates the fluctuation due to small eddies over its spatial extension. Therefore, when measuring fluctuating quantities, small eddies are counted as mean flow and the fluctuating energy is lost. This leads to lower estimated value of turbulence intensity. The other important issue is the spacing between the sensors, which is primarily determined by the spacing between the coherent structures present in the flow. For the turbulent wall boundary layer, the spacing between the sensors needs to be less than the distance between the low-speed streaks, i. e., the near-wall region coherent structures.

Basic Methodology

Classification

Various shear stress measurement techniques have been proposed in the literature. Some of the principal measurement techniques are: Stanton tube, Preston tube, electrochemical technique, velocity measurements, thermal method, floating element sensors, sublayer fence, oil-film interferometry and shear stress sensitive liquid crystal.

The Stanton tube is a rectangular shaped pitot tube located very close to the boundary wall and the mean velocity measured from this pitot tube pressure difference is directly related to the shear stress. The Preston tube is similar to the concept of the Stanton tube using a pitot static tube close to the surface and the difference between the stagnation pressure at the center of the tube from the static pressure is related to the shear stress. The electrochemical or mass transfer probe is flush mounted with the wall and the concentration at the wall element is maintained constant. The measurement of mass transfer rate between the fluid and the wall element is used for determination of the wall shear stress. One of the limitations of the mass transfer probe is that at very high flow rates, the mass transfer rate becomes large and it may not be possible to maintain the wall concentration constant. A detailed discussion on the above three techniques can be found in Hanratty and Campbell [1]. These shear stress measurement techniques are not ideal MEMS-based techniques.

Benefits of MEMS-Based Sensors

MEMS-based shear stress sensors offer many advantages over traditional shear stress sensors. These are:

- MEMS-based shear stress sensors can meet the spatial and temporal requirement of turbulent flow due to their small size.

- MEMS-based sensors have low thermal inertia leading to higher dynamic response.
- MEMS-based sensors are less intrusive compared to the traditional sensors due to their small size and therefore do not effect the flow significantly.
- The energy consumption is low for MEMS-based sensors.
- MEMS-based sensors are ideal for distributed measurements and control, as a large number of sensors can be fabricated on the same chip in a cost-effective manner.

Due to numerous benefits of MEMS-based shear stress sensors, the following shear stress measurement techniques having great promise for future MEMS applications are discussed in the following sections: velocity measurements, thermal sensors, floating element sensors, sublayer fence, oil-film interferometry and shear stress-sensitive liquid crystal.

Velocity Measurements

Velocity measurements close to the wall or the velocity profile measurement in the near-wall region can be used to determine the wall shear stress. Clauser proposed an approach for shear stress measurement of turbulent flow [1]. Here, the mean velocity measurements away from the wall are used with the assumption that the mean velocity ($\bar{U}$) varies with the logarithmic distance from the wall (y), i. e.,

$$\frac{\mathrm{d}\bar{U}}{\mathrm{d}y} = \frac{u^*}{\kappa y} \tag{5}$$

where $u^* = (\tau_\mathrm{w}/\rho)^{1/2}$ is the friction velocity and κ is the von Karman constant. The slope of a semi-logarithmic plot between $\bar{U}$ and y gives u^*/κ and therefore τ_w. The difficulty in this approach is the validity of the logarithmic region assumption and the value of the von Karman constant, which is approximated to be equal to 0.40. For flows with large pressure gradient, a well-defined logarithmic layer does not exist. If the wall is flat and in equilibrium situation Clauser proposed a relationship as

$$\frac{\bar{U}}{u^*} = f\left(\frac{yu^*}{\nu}, \Delta\right) \tag{6}$$

where $\Delta = |\mathrm{d}P/\mathrm{d}x|\left(\nu/u^*\tau_\mathrm{w}\right)$ and $\mathrm{d}P/\mathrm{d}x$ is the pressure gradient. Comparison of measured variation of mean velocity with distance from the wall gives the wall shear stress τ_w.

The Spalding formula represents a good fit to the velocity profile in a turbulent boundary layer, i. e., from the wall to the end of the log region, thus including both the linear sub-layer and the logarithmic region. The Spalding formula is given by

$$y^+ = \frac{yu^*}{\nu} = u^+ + \frac{1}{E}\left[e^{-\kappa u^+} - 1 - \kappa u^+ - \frac{(\kappa u^+)^2}{2} - \frac{(\kappa u^+)^3}{6} - \frac{(\kappa u^+)^4}{24}\right] \tag{7}$$

where $u^+ = u/u^*$ and E is a constant equal to 8.6. An iterative procedure is carried out for curve fitting the experimental velocity profile to the Spalding formula and the shear stress is determined from the best fit. The Spalding formula represents the mean velocity profile in a turbulent boundary layer at all pressure gradients and until about $y^+ = 200$.

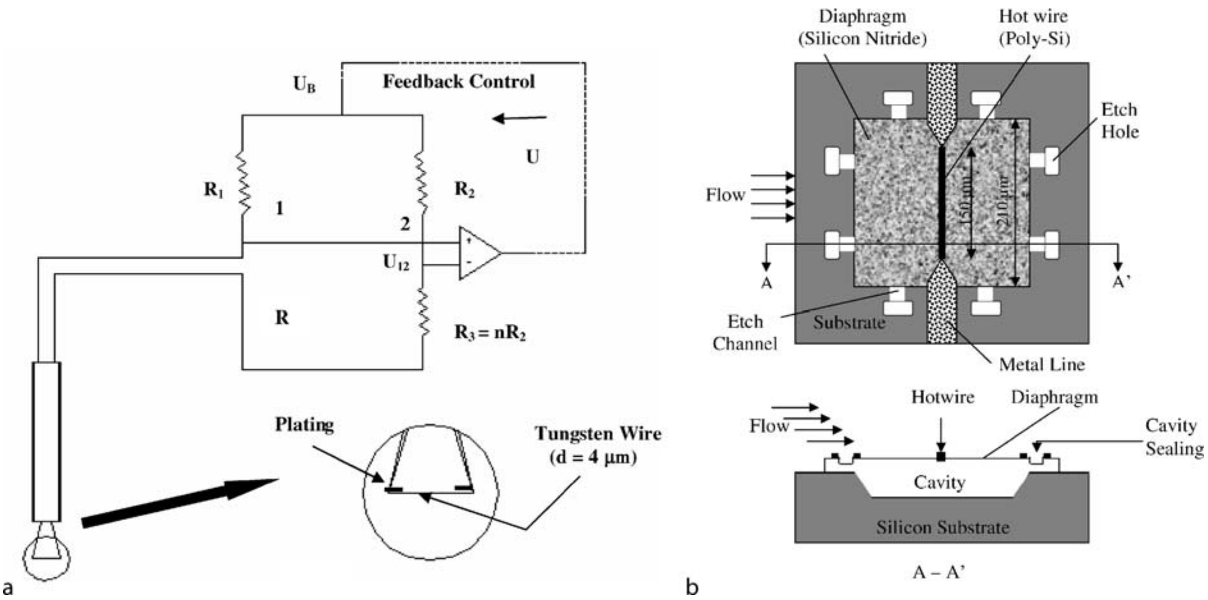
Optical techniques, i. e., laser Doppler velocimetry (LDV), particle image velocimetry (PIV) and holographic PIV, have matured as successful non-intrusive velocity measurement techniques for large-scale applications. Panigrahi et al. [2] obtained the shear stress from PIV measurements by assuming the validity of law of the wall for turbulent flow. In recent years, the μ-PIV has matured as a successful velocity measurement technique for MEMS applications [3]. The PIV techniques provide instantaneous velocity field information. The spatial and temporal resolution of PIV can be controlled with proper selection of lighting source, i. e., laser, imaging system, i. e., camera and frame grabber, and optical arrangements/components. The continuous development of this hardware in near future is expected to result in very high spatial and temporal resolution velocity measurements. Therefore the μ-PIV and μ-holographic PIV techniques will develop as high-resolution indirect instantaneous shear stress measurement techniques in the near future.

Thermal Sensors

The operational principle of a thermal sensor is based on the relationship between the heat transfer from the sensor exposed to the flowing fluid and the shear stress. For the heat transfer to take place the sensor element temperature must differ from the temperature of the flowing medium, i. e., the sensor is raised to a temperature above the medium temperature. The thermal sensor forms one of the resistances of a Wheatstone bridge circuit (see Fig. 1a). The resistance of the thermal sensor is given by

$$R = R_0\left(1 + \alpha\,(T - T_0)\right) \tag{8}$$

where R is the sensor resistance at temperature T and R_0 is the sensor resistance at reference temperature (T_0); T is the temperature of the sensor and α is the temperature



Shear Stress Sensors, Figure 1 (**a**) Schematic of a hot wire sensor connected to a Wheatstone bridge circuit and (**b**) schematic of a flush-mounted thermal shear stress sensor

coefficient of resistance. The heat transfer rate depends on the nature of fluid flow past the sensor leading to drop in temperature of the sensor. The drop in sensor temperature affects the sensor resistance leading to imbalance of the Wheatstone bridge circuit. The relationship between the bridge circuit imbalances and the heat transfer can be obtained from two approaches: deflection method and null method. In the deflection method, the change in bridge balance due to the input signal is measured. In the null method, an electronic feedback is used to keep the bridge balanced. The null method is usually preferred due to better frequency response. For the electronic feedback, there are three possible modes of operation:

- *Constant current mode* (CC). Here the current through the sensor is kept constant and the change in current needed to maintain its constant value is related to the flow signal, i. e., shear stress.
- *Constant voltage mode* (CV). Here the voltage across the sensor is kept constant and the change needed to keep the voltage constant is related to the shear stress.
- *Constant temperature mode* (CT). Here the temperature of the sensor is kept constant and the voltage or current change needed to keep the temperature constant represents the wall shear stress.

The thermal sensors for shear stress measurements can have two principal modes of variation: elevated hot wire probe and surface-mounted hot wire probe. The principle of operation of these two types of thermal shear stress sensors is discussed in the following sections.

Elevated Hot Wire Probe

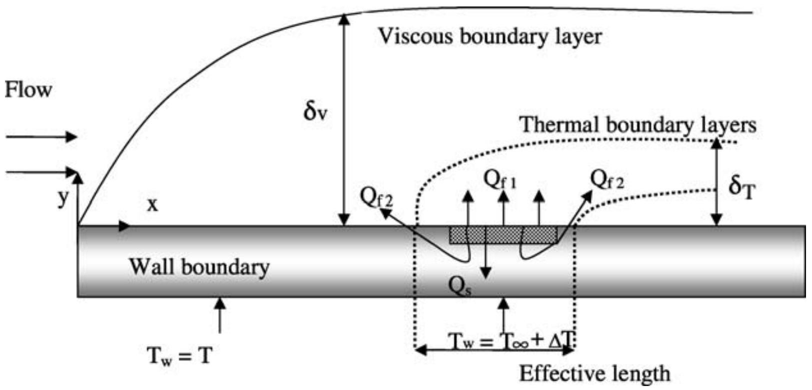
In the elevated hot wire approach, the hot wire is mounted a small distance away from the wall. The velocity increases linearly with the wall distance in the near-wall region of both laminar and turbulent flow. For turbulent flow, this assumption is valid for the instantaneous velocity profile up to the wall normal location $y^+(yu^*/\nu) < 5$. The linear relationship between the shear stress (τ_w) and the velocity u at distance y from the wall is given as

$$\tau_\mathrm{w} = \frac{\rho \nu u}{y} \tag{9}$$

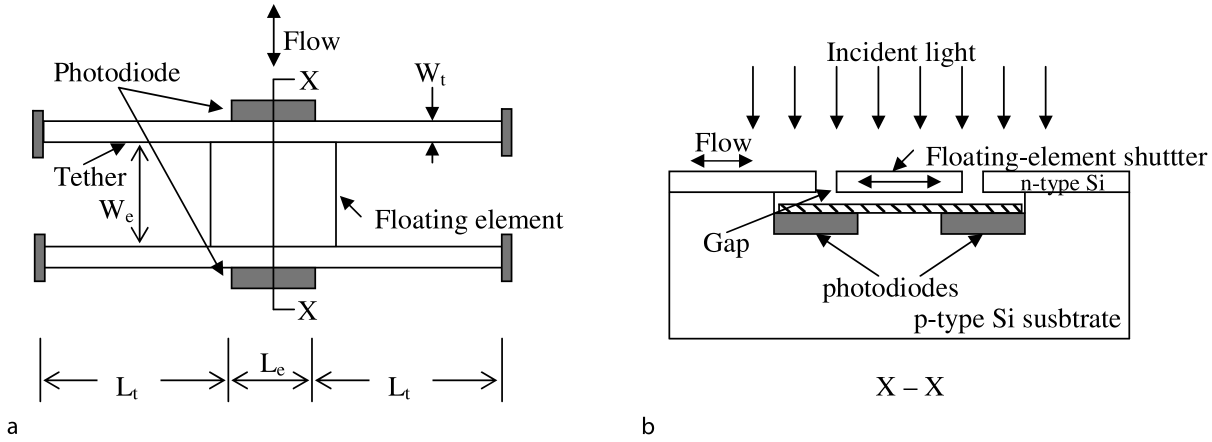
The true velocity in the near-wall region determined from the hot wire calibrated in the free stream is affected due to the heat conduction in the near-wall region. Therefore, the velocity obtained from the hot wire needs to be corrected based on the empirical relationship. The substitution of this corrected velocity in Eq. (9) provides the wall shear stress. The sensitivity of this approach depends on the wall distance, i. e., there is an optimal wall distance at which the hot wire sensitivity is optimal. In addition to that, the hot wire should be located inside the inertial sublayer to satisfy the basic assumption essential for the shear stress measurement.

Surface-Mounted Hot Wire Sensor

Figure 1b shows a schematic of a flush-mounted thermal shear stress sensor. The sensor element is either positioned



Shear Stress Sensors, Figure 2 The flow and heat transfer mechanism of a flush-mounted thermal shear stress sensor



Shear Stress Sensors, Figure 3 Schematic of a floating element shear stress sensor: (**a**) top view and (**b**) cross-sectional view

on the top of a substrate or on a thin diaphragm above a vacuum cavity. As the thermal shear stress sensor is flush mounted along the surface of the wall, this technique is considered as non-intrusive with negligible disturbance to the mean flow. The ohmic heating (Q_{ohmic}) due to the current flow through the sensor element transfers heat to both fluid (Q_{fluid}) and the substrate ($Q_{\text{substrate}}$), i. e.,

$$Q_{\text{ohmic}} = Q_{\text{fluid}} + Q_{\text{substrate}} \tag{10}$$

Figure 2 shows the heat transfer mechanism from a surface-mounted thermal sensor. The total heat transfer to the fluid from the thermal sensor (Q_{ohmic}) has two components, i. e., the heat transfer to the fluid (Q_{fluid}) and the heat lost to the substrate ($Q_{\text{substrate}}$). The heat transfer to the fluid has two parts, i. e., direct heat transfer from the sensor element (Q_{f1}) and the indirect heat transfer from the substrate heated by the conduction of heat from the sensor to the substrate (Q_{f2}). The heat transferred to the fluid via the substrate affects the temperature distribution near the sensor. This affects the net heat transfer rate from the sensor element and limits the performance of thermal shear stress measurement. The effective length of the thermal sensor is higher than the size of the sensor element thus limiting the spatial resolution of shear stress measurement. Therefore, effective thermal isolation between the sensor element and substrate is an important issue for optimum performance, fabrication and packaging of thermal shear stress sensors. For thermal isolation, the resistor of the sensor sits on the top of a diaphragm above a vacuum cavity (see Fig. 2). The presence of the vacuum cavity and thin diaphragm reduces the convective and conductive heat transfer to the substrate. Better insulation improves the thermal sensitivity of the sensor, i. e., higher temperature rise ($T - T_0$) of the thermal sensor is achieved for a particular power input (P).

In experimental aerodynamics, the surface hot wire probe has proved to be the most successful standard measure-

ment technique to determine the laminar-to-turbulent flow transition, local separation and shear stress fluctuations. The flush-mounted thermal shear stress sensor is one of the most successful techniques for shear stress measurement and is available in various forms, i. e., sensor skin, etc. [4], due to the rapid development of MEMS manufacturing processes. The quantitative determination of shear stress depends on the proper calibration with a reference method. The calibration issues are described in a later section.

Floating Element Sensors

Direct measurement of tangential force exerted by the fluid on the sensor element is possible using floating element shear stress sensors. Therefore, the floating element-based shear stress sensor is classified as a direct measurement device. A schematic of a floating element shear stress sensor is shown in Fig. 3. The floating element is connected to the substrate by four tether elements. The movement of the floating element due to the surface force, i. e., shear stress acting on it, is sensed by suitable transducer and is related to the shear stress. The movement of the floating element can be inferred using the capacitive, piezo-resistive and optical detection schemes. The axial compression and expansion of the tethers due to the imposed shear stress cause a change in piezo-resistive effect for piezo-resistive sensing element. The change in resistance is a measure of the shear stress magnitude and direction. In the capacitive scheme, the sensor element displacement leads to change in the capacitance value. In the photodiode-based scheme, photodiodes are integrated below the floating element at its leading and trailing edge. A coherent light source illuminates the sensor element from above. The differential photocurrent generated due to the movement of the floating element is related to its displacement (see Fig. 3).

No assumption regarding the flow field is required for the floating shear stress sensor. The displacement (δ) of the floating element sensor as a function of shear stress (τ_w) can be derived from Euler–Bernoulli beam theory as

$$\delta = \tau_w \frac{L_e W_e}{4Et} \left(\frac{L_t}{W_t} \right)^3 \left(1 + 2 \frac{2 L_t W_t}{L_e W_e} \right) \tag{11}$$

where L_t is the tether length; W_t is the tether width; E is the elastic modulus of the tether; t is the floating element thickness; L_e is the length of the floating element; W_e is the width of the floating element; and g is the recessed gap of the floating element (see Fig. 3). Equation (11) indicates a linear relationship between the displacement of the floating element and the shear stress. The above linear relationship has been verified from the static calibration results of floating element sensors. The flow under the floating element and the pressure gradient acting on its lip introduce error to the measurement of skin friction. This relationship between the effective shear stress (τ_{eff}) and the actual shear stress (τ_w) is given by [5]

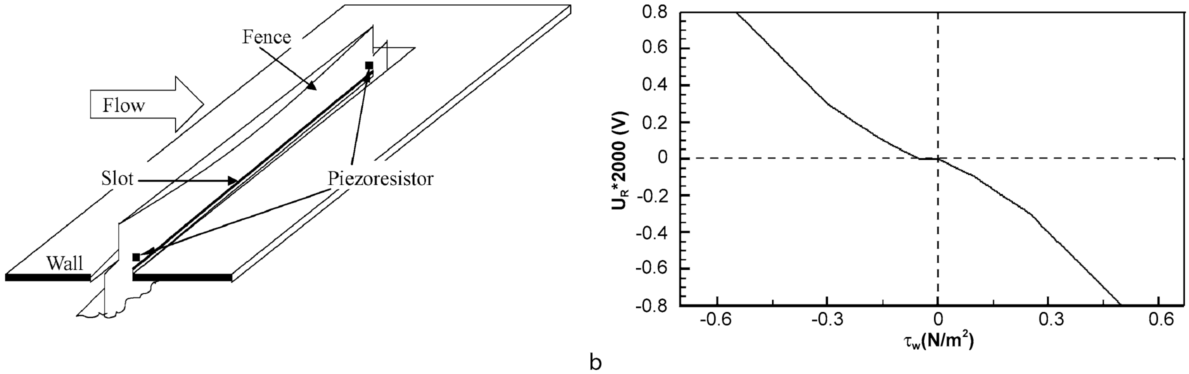
$$\tau_{eff} = \left(1 + \frac{g}{h} + \frac{2t}{h} \right) \tau_w \tag{12}$$

where h is the channel height of the wind tunnel used for calibration. The second and third term of the above equation relate to the effect of gap height and pressure gradient on the measurement error respectively. Equation (12) indicates the benefit of MEMS-based shear stress sensors, as both gap height and the floating element thickness can be maintained at a very small value ($\sim 1\,\mu$m) leading to considerable reduction in errors. In addition, the MEMS-based sensor element results in high spatial resolution and higher frequency bandwidth due to lower effective size and mass respectively. Due to the rapid advancement of MEMS-based fabrication techniques, it is also possible to place pairs of sensors in close proximity at right angles to each other for detection of both streamwise and spanwise shear stress.

The capacitive and piezo-resistive sensing-based floating element sensors may show sensitivity to electromagnetic interference due to the impedance of the electronics elements used for detection. The size of the floating element, the misalignment and gaps around the floating element, pressure gradient, sensitivity to acceleration, vibration and thermal expansion are some of the general drawbacks of floating element sensors. The availability of MEMS fabrication techniques has enhanced the capability of floating element sensors.

MEMS Skin Friction Fence

The generic skin friction fence and its principle has been explained by Hanratty and Campbell [1]. Recently, Schober et al. [6] developed a MEMS-based skin friction fence (see Fig. 4a). The surface fence is a fence protruding from the wall. There is a slot below the surface fence with support at both ends. Two pairs of piezo-resistors are located at both ends of the fence. These piezo-resistors are connected to a Wheatstone bridge circuit. The voltage output of the Wheatstone bridge circuit is related to the strain acting on the fence. The strain due to the deflection of the fence is directly related to the pressure difference across the fence. Hence the voltage output is indirectly related to the shear stress acting on the fence. The surface fence should remain inside the viscous sublayer ($y^+ < 5$). However, there is no requirement on the validity of the law of



Shear Stress Sensors, Figure 4 Schematic of (**a**) MEMS skin friction fence and (**b**) its calibration curve between the bridge voltage (U_B) and the shear stress (τ_w)

the wall for the turbulent boundary layer. The pressure difference between the front and back of the fence is related to the shear stress, i. e.,

$$\Delta P = A\tau_w + B\tau_w^2 \quad (13)$$

where A and B are constants. From Eq. (13), the measured voltage (V_{br}) from the Wheatstone bridge circuit can be related to the shear stress as

$$V_{br} = A_{br}\tau_w + B_{br}\tau_w^2 \quad (14)$$

where A_{br} and B_{br} are the constants to be obtained from the calibration. Figure 4b shows the calibration curve between the bridge voltage and the shear stress of a micro-fence inside a zero pressure gradient turbulent boundary layer. It may be observed that the sensitivity of the micro-fence is higher at higher shear stress.

Optical Sensors

The optical-based shear stress sensor can be classified into two categories based on the measurement principle: oil-film interferometry and shear sensitive liquid crystal. These techniques are discussed in the following sections.

Oil-Film Interferometry

The oil film technique is a direct method for skin friction measurement based on the movement of interference fringes of a thin film. In this method, an oil film is applied to the smooth solid wall, which spreads out by the flow into a thin layer whose thickness is of the order of 1 μm. The thickness of the oil film is dependent on the shear force acting upon it. Interferometry is used to measure the thickness of the oil film. Monochromatic light of wavelength λ from a light source is incident on the film at an angle θ (Fig. 5a). The light partially gets reflected from the oil/air interface. The remainder of the light passes through the film and reflects from the solid surface and travels back through the oil film. These two beams interfere constructively and destructively with each other in the image plane depending on the phase difference between the two leading to formation of bright and dark bands known as interference fringes.

The local height of the oil film can be obtained from the fringe patterns. The height of the oil film at the kth black fringe is given by

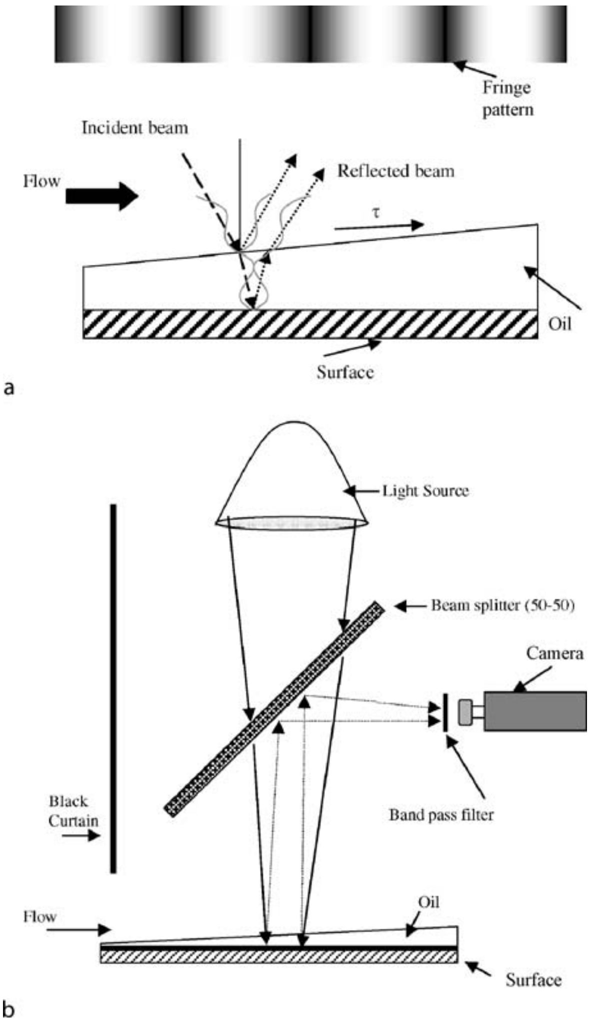
$$h_k = h_0 + k\Delta h\ ;\ k = 0, 1, 2, \ldots \quad (15)$$

where h_0 is the height of the zeroth black fringe at the film edge, i. e., at $k = 0$, and Δh is the difference in height between two consecutive fringes given by

$$\Delta h = \frac{\lambda}{2\left(n^2 - \sin^2\alpha\right)^{1/2}} \quad (16)$$

Here, n is the refractive index of oil and λ is the wavelength of light. A general oil-film interferometry experimental setup is shown in Fig. 5b. Here, the light from preferably a He – Ne laser (wavelength = 632.8 nm) or sodium lamp (wavelength = 589 nm) is incident on the thin oil film through a beam splitter. A camera collects the reflected light from the oil film and a portion of the incident light from the beam splitter against a black background. The motion of the interference fringes is collected by imaging through the camera.

For oil-film interferometry, it is assumed that the oil film is so thin that it does not influence the flow above it and is driven by the skin friction distribution of the flow. Using a control volume analysis of the thin oil film with its height



Shear Stress Sensors, Figure 5 Schematic showing (**a**) fringe formation for oil height measurement and (**b**) an experimental setup using oil film interferometry

h in wall normal (y) direction as a function of streamwise (x) and spanwise (z) coordinate and assuming the shear stress contribution to be dominant compared to the pressure gradient and surface tension force, the governing equation for the thin oil-film flow is

$$\frac{\partial h}{\partial t} + \frac{\partial}{\partial x}\left(\frac{\tau_{w,x} h^2}{2\mu}\right) + \frac{\partial}{\partial z}\left(\frac{\tau_{w,z} h^2}{2\mu}\right) = 0 \qquad (17)$$

Using the distribution of oil film height from interferometry measurements and the integration of equation (16) the skin friction can be determined. The benefit of oil-film interferometry is that no calibration is required for measurement of shear stress and the basic analytical expression is used. It can be used for three-dimensional flow situations and provides both magnitude and direction of shear stress. The disadvantage is that it does not possess any temporal resolution and therefore cannot be used for fluctuating skin friction measurements.

Liquid Crystal Sensors

Liquid crystal is a phase of matter that exists between the liquid and solid phase. It exhibits optical properties similar to a solid crystalline material. The molecular arrangement of a liquid crystal is a function of either temperature or shear stress. When the molecular arrangement is sensitive to temperature, the liquid crystal coating can be used for temperature measurement and when the molecular arrangement is sensitive to shear stress, the liquid crystal can be used for shear stress measurement.

Shear sensitive liquid crystal coatings applied to a solid surface consist of helical aggregates of long planar molecules arranged in layers parallel to the coated surface. This molecular arrangement is affected by the application of shear stress on the thin film of liquid crystal. Each layer of molecules is rotated relative to the layer above and below it due to the application of shear stress. The incident light on the coating surface selectively scatters at a wavelength proportional to the pitch of the helix. The local pitch of the helical structure is altered due to application of shear stress relative to the no shear state. The liquid crystal selectively scatters the incident white light as a three-dimensional spectrum in color space depending on the molecular arrangement. The color change observed at a particular direction by the imaging device is a function of both shear stress vector magnitude and direction (see Fig. 6a). The shear vectors with components directed away from the observer exhibits color change responses of the liquid crystal depending on the shear magnitude and direction. At any surface point, maximum color change occurs when the shear stress vector is aligned and directed away from the observer. The location with shear stress directed to the observer exhibits no color change response. The above behavior of the shear sensitive liquid crystal is used for determination of the shear stress magnitude and direction.

A sample experimental setup for the application of shear sensitive liquid crystal is shown in Fig. 6b similar to the one proposed by Fujisawa et al. [7]. The off-axis angles of the camera and the light source with respect to the horizontal are α and β respectively. Two cameras are situated on opposite sides of the axis with an off-axis angle δ. As the color images are acquired at an oblique angle to the test surface, it is important to convert the images at oblique angle to the normal observation angle by using a geometrical transformation technique. The two color cameras

S

Shear Stress Sensors, Figure 7 (**a**) The relative hue (H_R) versus the shear stress angle (γ) for different shear stress magnitude (τ_w). (**b**) The relative hue (H_R) versus the shear stress angle (γ) for two cameras (left, $\delta = -30°$; right, $\delta = 30°$) at a particular shear stress magnitude

are synchronized with the lighting source. The test section can be rotated leading to variation of the shear stress angle (γ) for calibration. There are different color formats, i. e., RGB, HIS, for quantitative representation of color. The hue has been observed to be the best indicator for expressing the change in color. It can be calculated from

$$H = \left[\pi/2 - \tan^{-1}\left(\frac{2R - G - B}{\sqrt{3(G - B)}}\right) + \pi\right] \Big/ 2\pi ; \; G > B \tag{18}$$

The color change of the liquid crystal depends on the illumination and observation angle with respect to the liquid crystal coating surface. Therefore, the calibration of the liquid crystal is carried out by the relative hue ($H_R = H_\tau - H_{no-\tau}$), where H_τ is the hue value of the liquid crystal with applied shear stress and $H_{no-\tau}$ is the hue value of the liquid crystal without applied shear stress. The hue value for a particular shear stress magnitude and direction depends on the camera and lighting angle. Therefore, two separate calibration curves for two cameras in stereo arrangement can be used to determine the two unknowns, i. e., the shear stress magnitude and direction. Figure 7a shows the calibration curve between the relative hue (H_R) and the shear stress angle (γ) at different shear stress amplitudes (τ_w) for a particular camera and lighting angle. Figure 7b shows the relative hue (H_R) versus the shear stress angle (γ) for two different cameras (left and right). For quantitative determination of the shear stress, the two cameras and lighting source are set at optimum off-axis (δ), observation (α) and illumination (β) angles respectively. The calibration curve between the relative hue of both the cameras (left and right), i. e., $H_{R-left}(\tau_w, \gamma)$ and $H_{R-right}(\tau_w, \gamma)$ with respect to the shear stress magnitude (τ_w) and direction (γ) is established during the calibration process. The determination of shear stress magnitude and direction for an actual measurement is carried out by an iterative process. Initially, the shear stress magnitude (τ_w) and direction (γ) are assumed. The corresponding hue values for both left and right cameras are determined from the

calibration curve. The measured hue value for both left and right cameras $\left(H_{\mathrm{R-left-M}}(\tau,\ \gamma)\right.$ and $\left.H_{\mathrm{R-right-M}}\right)\ (\tau,\ \gamma)$ are compared with the calibrated hue values. The iteration is carried out, i. e., the shear stress magnitude (τ_{w}) and direction (γ) are changed, until the error (E) between the calibrated hue and actual hue value for both left and right cameras is minimized close to a zero value.

$$E = \left(H_{\mathrm{R-left}}(\tau,\gamma) - H_{\mathrm{R-left-M}}(\tau,\gamma)\right)^2 + \left(H_{\mathrm{R-right}}(\tau,\gamma) - H_{\mathrm{R-right-M}}(\tau,\gamma)\right)^2 \quad (19)$$

Calibration Procedure

Calibration is one of the important issues for quantitative determination of the shear stress vector from measurement. The suitability of the shear stress sensor for a particular application is based on the complexity of the calibration procedure. The calibration of thermal-based shear stress sensors and the calibration setup required is described below. Similar setup can be used for calibration of other types of shear stress sensors. The calibration process is categorized as static and dynamic.

Static Calibration

The heat transfer rate from a flush-mounted shear stress tensor depends on the near-wall flow, i. e., the magnitude of the velocity gradient. For a laminar two-dimensional thermal boundary layer developing over the heated sensor with an approaching linear velocity profile (Fig. 2) and negligible free convection effect the heat loss from the thermal element can be derived from the thermal boundary layer equation as

$$\frac{q}{\Delta T} = \frac{I^2 R}{\Delta T} = 0.807 \frac{C_{\mathrm{p}}^{1/3}\, k^{2/3}}{L^{1/3}\, \mu^{1/3}} (\rho \tau_{\mathrm{w}})^{1/3} \quad (20)$$

where ρ is the density; k is the thermal conductivity; C_{p} is the specific heat; L is the length of heating element; T is the temperature; μ is the viscosity of the fluid; and τ_{w} is the shear stress. Equation (19) for the ohmic heating of the thermal sensor can be written as

$$\frac{I^2 R}{\Delta T} = A(\rho \tau_{\mathrm{w}})^{1/3} + B \quad (21)$$

where I is the heating current and R is the resistance of the sensor. The term B represents the heat loss from the substrate and depending on the design can be more than the heat loss to the fluid, i. e., the first term of the above equation. The term A is a weak function of temperature. The length of the sensor calculated from the experimentally determined value of A is more than the actual sensor length due to the heat transfer to the fluid from both substrate and the sensor (see Fig. 2). The forced convection heat transfer assumption is limited by the effective length of the sensor. It is also difficult to satisfy the thermal boundary layer to be within the linear velocity profile. Hence, for a turbulent flow the above equation is modified as

$$\frac{I^2 R}{\Delta T} = A_{\mathrm{T}}(\rho \bar{\tau}_{\mathrm{w}})^{1/n} + B_{\mathrm{T}} \quad (22)$$

Here, the constants A_{T}, B_{T} and n should be determined empirically from the calibration procedure. If the resistance of the heating element is held constant and the voltage (E) / current (I) is measured, than the above equation can be rearranged as

$$\tau_{\mathrm{w}} = \left(A_{\mathrm{T,New}}\, E^2 + B_{\mathrm{T,New}}\right)^n \quad (23)$$

Equation (23) between shear stress and the voltage can also be represented as a polynomial function as

$$\tau_{\mathrm{w}} = C_0 + C_1 E + C_2 E^2 + \ldots + C_n E^n \quad (24)$$

One possible experimental arrangement for shear stress calibration is a rotational rig consisting of a rotational disc above a bottom stationary disc (see Fig. 8a). The gap size (δ) between the discs is very small (0.3 mm to 0.45 mm) to maintain a small Reynolds number ($\mathrm{Re_s} = \omega\delta^2/\nu \ll 5$), where ω is the rotating disc angular velocity. For small Reynolds number, the tangential shear stress can be derived as

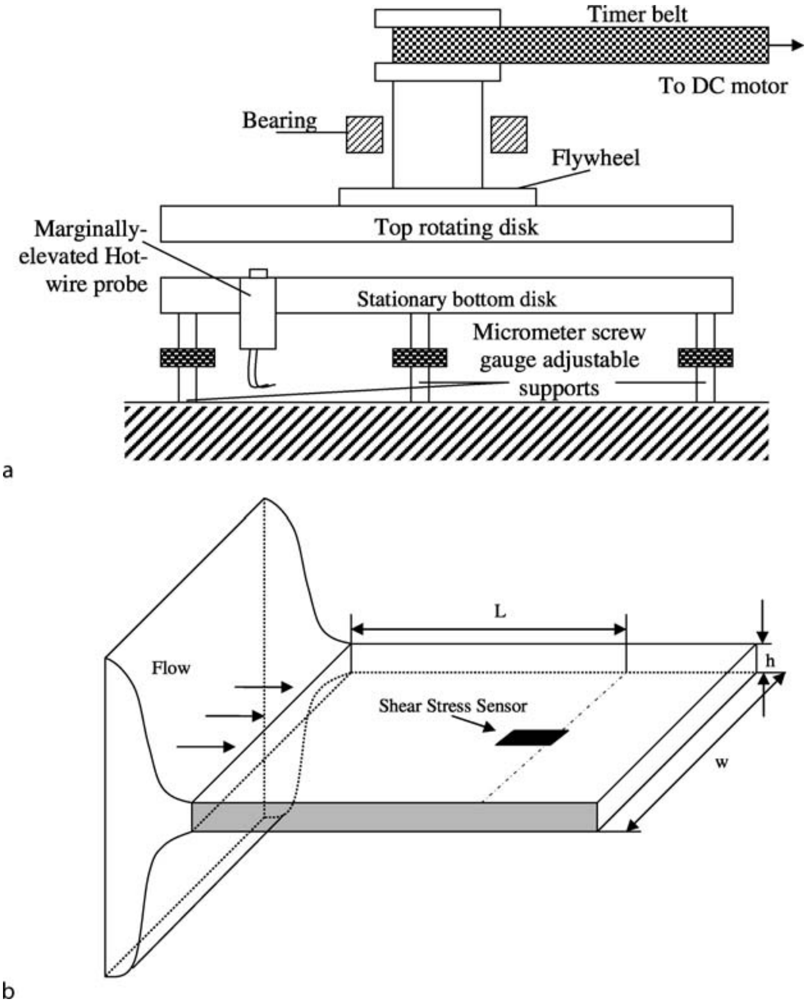
$$\tau = \mu(\omega r/\delta)\left[1.0 + (1/1050)\mathrm{Re}_{\mathrm{s}}^2 + O(\mathrm{Re}_{\mathrm{s}}^4)\right] \quad (25)$$

During calibration, the shear stress sensor is mounted on the stationary plate at various radial positions with different gap size and rotational speed to achieve wide range of shear stress values for static calibration.

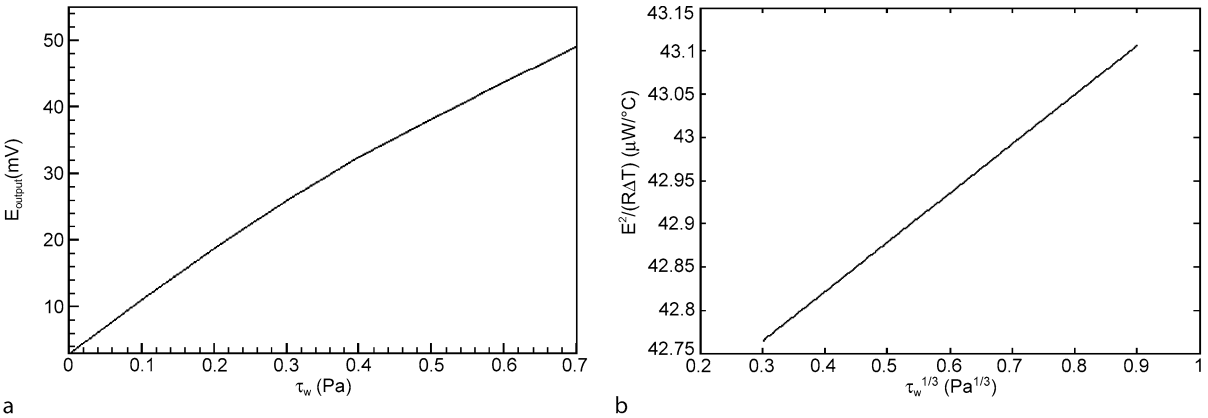
Another possible setup for the static calibration uses a wind tunnel (Fig. 8b). The wind tunnel test section should be sufficiently long to establish fully developed flow. The width over height ratio of the test section also needs to be high, i. e., greater than 30, for the flow to be two dimensional. The shear stress values (τ_{w}) for this configuration is related to the local pressure gradient as

$$\frac{\mathrm{d}P}{\mathrm{d}x} = -\frac{\tau_w}{h} \quad (26)$$

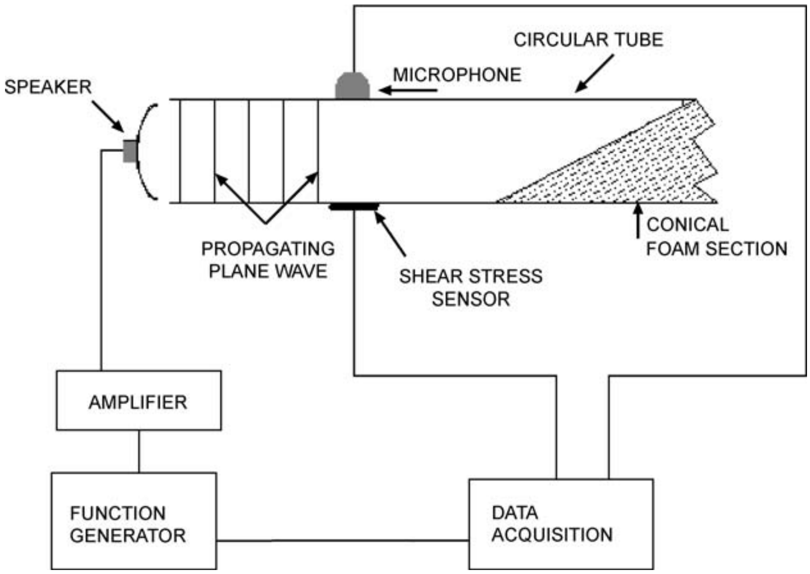
Here, P is the local pressure, x is the streamwise coordinate and h is the half height of the channel. The pressure gradient can be measured by mounting pressure taps along the channel before and after the shear stress sensor location.



Shear Stress Sensors, Figure 8 Schematic of a static calibration apparatus: (**a**) using a rotating disc and (**b**) long, high aspect ratio smooth channel flow



Shear Stress Sensors, Figure 9 Static calibration curve: (**a**) the bridge output (E) versus shear stress (τ_W) and (**b**) the input power versus (shear stress)$^{1/3}$ of a thermal shear stress sensor



Shear Stress Sensors, Figure 10 The schematic of a dynamic calibration apparatus for the shear stress sensor

Figure 9a shows one representative calibration curve between the Wheatstone bridge output (E) and the shear stress (τ_w) of the shear stress sensor operating in constant temperature mode. The same calibration curve have been re-plotted in Figure 9b using the heating power ($P = E^2/R$) divided by the temperature difference (ΔT) with respect to shear stress to one-third (0.33) power. A linear variation as expected from Eq. (21) is clearly observed. The laminar value of the exponent (0.33) may change due to the restriction by the experimental condition during calibration, i. e., wall presence, mounting location and size of the sensor element. Hence, the exponent value around 0.4 in contrast to the laminar value of 0.33 has been observed in many investigations.

Dynamic Calibration

The shear stress sensor for turbulent flow needs to accurately capture the complete turbulent fluctuation spectrum. Therefore, the shear stress sensor should possess a large bandwidth with flat and minimum frequency–phase relationship. For direct measurement, i. e., floating point sensors, the resonant frequency of the floating element and the fluidic damping determines the usable bandwidth. For the thermal sensor, the thermal inertia of the sensor element and the frequency-dependent heat conduction to the substrate influence the usable bandwidth. It is complicated to analytically predict the frequency response of the thermal sensor. Therefore, dynamic calibration is essential to characterize the frequency response of the sensor.

The Stokes-layer excitation in a cylindrical duct is one of the effective techniques for dynamic calibration of shear stress sensors [8]. The flow inside the duct is driven by an oscillating pressure gradient generated by loud speaker (see Fig. 10). The loud speaker driven by an amplifier generates an acoustic wave. The amplifier receives sinusoidal input from a function generator. The microphone and shear stress sensor are mounted at opposite locations of the tube. The data acquisition system records the signal from the microphone and shear stress sensor.

The solution of the compressible momentum equation provides the relationship between the shear stress and the pressure gradient and the excitation frequency as

$$\tau(z,t) = -\frac{p' e^{j(2\pi f t - kz)}}{c} \sqrt{\frac{j2\pi f \mu}{\rho}} \frac{I_1\left(R\sqrt{j2\pi f/\nu}\right)}{I_0\left(R\sqrt{j2\pi f/\nu}\right)} \tag{27}$$

Here, p' is the magnitude of pressure fluctuation; c is the speed of sound; f is the frequency of acoustic wave; $k = 2\pi f/c$ is the wave number; z is the axial direction; μ is the fluid viscosity; ρ is the density; R is the radius of tube; ν is the kinematic viscosity; and I is the Bessel function. The frequency response function $H(f)$ from Eq. (27) is used to determine the frequency response of the shear stress sensor as

$$H(f) = \frac{V(f)}{\tau(f)} \frac{\delta\tau}{\delta V} \tag{28}$$

Here, $V(f)$ is the sensor voltage, $\tau(f)$ is the shear stress calculated from Eq. (27) as a function of the pressure fluc-

tuation magnitude and $\delta\tau/\delta V$ is the static sensitivity from the static calibration of the shear stress sensor. For an ideal sensor the static and dynamic sensitivity should be equal leading to a normalized frequency transfer function ($H(f)$) of 0 dB at all measurable frequencies.

Uncertainty and Noise

For proper design and practical implementation of shear stress measurement procedure, it is important to be aware of different sources of noise and uncertainty during the measurement. When using shear stress sensor based on MEMS technology, all circuit elements are located on the substrate surface. Hence, the electronics is one of the primary sources for drift or noise during shear stress measurement. The other important contribution to noise is physical sources, i. e., during low flow velocity situations the free convection effect disturbs the signal. The packaging and mounting of the sensor element can generate offset signals which may change in time due to the change in heat dissipation of the sensor element. This influences the frequency response of the shear stress sensor. The MEMS-based shear stress sensor can have the following noise sources: thermal or white noise, shot noise, flicker noise and photon noise. The thermal noise is the movement of electrons due to the finite temperature difference leading to noise in the output voltage or current. Shot noise is due to the flow of charge carriers past different potential barrier sources in the electronic circuits. Flicker noise or $1/f$ noise is the low-frequency noise due to flow of charge carriers in discontinuous medium, i. e., resistors, transistors, thin films, etc. Photon noise is due to the fluctuation in the number of quanta or power reaching the photodiode or CCD element. Photon noise is strongly temperature dependent and can be reduced by effective cooling.

Future Directions for Research

Shear stress measurement plays an important role for characterization and control of both macro- and microscale flows. There are various existing techniques suitable for either steady state or instantaneous nature of the flow. The rapid development of MEMS manufacturing technology has immensely contributed to improvement in spatial and temporal resolution of shear stress sensors. Therefore, turbulent flow control has become feasible for many practical applications. However, the calibration and implementation issues of shear stress measurements are not completely established. Therefore, the implementation procedure for shear stress measurement is problem specific and requires complete understanding of the measurement principle. The existing shear stress measurement technologies have not been implemented over a wide range of microscale flow problems. Therefore, future research should concentrate on critical issues relevant to shear stress measurement in various microflow applications. This will contribute towards development of matured shear stress measurement techniques.

Definition

► Shockwaves are large-amplitude, nonlinear pressure waves produced in a supersonic field or flow. The fluid passing through this discontinuity undergoes a finite decrease in velocity accompanied by a marked increase in pressure, density, temperature and entropy.

Although the concept of ► microchannel has been in the field literature for some time now, a clear definition of it has not yet been enunciated. However, it is the general understanding that any channel that has a characteristic dimension is between 1 µm and 1 mm is considered to be a ► microchannel. Most of the microchannels discussed in the literature are manufactured through microfabrication techniques, but not exclusively.

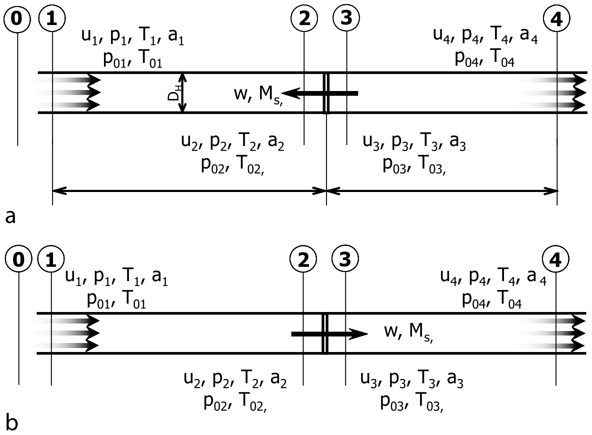
Overview

Since new and more complex microfabrication techniques became available, scientists have been trying to replicate at the microscale technologically more advanced systems and devices that have been available only at the large scale so far. During this process, it has been discovered that the laws of fluid mechanics and fluid dynamics do not necessarily scale linearly with the geometric dimensions. Although in the last ten years many questions have been answered regarding the behavior of fluid flow at the microscale, some phenomena still remain unclear. Among them is the phenomenon of ► shockwave propagation and compressibility effects inside a ► microchannel.

By its nature, the shockwave phenomenon happens in the microscale domain since the shockwave normal width is equal to a few mean free paths (less than a micrometer).

Basic Methodology

Estimates of pressure drops can be made using the traditional theory and correlations. However, accurate prediction of pressure drops in microchannels for non-slip flows is not possible [1]. For better prediction many models have been proposed [2]. Shockwave phenomena in microchannels have been investigated analytically, numerically, and experimental work is under way.



Shockwaves in Microchannels, Figure 1 One-dimensional model of a microchannel: (**a**) with shock traveling in the direction opposite to the flow; (**b**) with shock traveling in the direction of the flow

Knudsen Number

The ► Knudsen number Kn, defined as the ratio between the mean free path of the molecules and the characteristic length of the system, is often used to establish the domain level of the phenomenon and limits in the model application ranges. For $\mathrm{Kn} \gg 1$ the usual continuum modeling is valid. Satisfactory prediction of experimental results can be obtained until $\mathrm{Kn} = 0.3$, but the question is raised as to whether it is possible to further extend the continuum modeling accounting more correctly for surface phenomena like the reflection law, and the Knudsen layer, or whether the validity limit of the continuum approach is reached here [3].

Analytical Modeling

A one-dimensional mathematical model based on basic physical background has been created to investigate the efficiency of shockwave compression in microchannels. The model considers the entropy produced by a single normal shockwave that runs through the channel and by the wall friction due to the gas flow through the channel. Entry losses are also taken into consideration. Only heat transfer is neglected, following a recent study [4] that shows no significant effect of heat transfer on the compression efficiency in silicon microchannels.

Focusing on the phenomenon occurring inside a single channel, the normal shockwave is modeled by gas dynamics for one-dimensional flow [5]. The model has been presented with air as working fluid modeled as an ideal gas, and a friction coefficient that varies along the channel as a function of gas-dynamic conditions. The microchannel geometric characteristics are length ($2L$) and

hydraulic diameter (D_H, equal to 4 times the area divided by the perimeter of a section), shown in Fig. 1a. The model relates the efficiency of the compression process to the velocity, pressure, and temperature of the gas at the entrance of the channel (station 1: u_1, p_1, T_1), the pressure ratio across the shock Π_S, the friction coefficient f, and channel dimensions. In Fig. 1a, a shockwave is shown that moves in the opposite direction to the flow and is positioned in the middle of the channel. It can be shown that a snapshot evaluation at the mid position is a good representation of the overall results and does not affect the accuracy of the model. Friction is considered along the lengths L before and after the shock. The frictional effect is modeled as shear stress at the wall acting on a fluid with uniform properties over the cross-section.

One-Dimensional Flow with Friction

Using equations of one-dimensional compressible flow with friction, and knowing the conditions at station 1, the conditions at station 2, just before the arrival of the shockwave, can be obtained. Temperature and velocity at station 1 determine the speed of sound (Eq. (1)) and the Mach number (Eq. (2)):

$$a = \sqrt{\gamma \cdot R \cdot T} \tag{1}$$

$$\mathrm{M} = \frac{u}{a} \tag{2}$$

The Mach number at station 2 is found, by using the sonic condition as it would develop due to friction, from the state in station 1 through station 2, at the virtual distance from station 1 denoted with L_1^* (Eq. (3)), as can be derived from the momentum equation, expressing the shear stress in terms of friction coefficient and integrating between station 1 and the point where $\mathrm{M} = 1$ [5]:

$$L_1^* = \frac{D}{4 \cdot f}\left[\frac{1-\mathrm{M}_1^2}{\gamma \cdot \mathrm{M}_1^2} + \frac{\gamma+1}{2 \cdot \gamma} \cdot \ln\left(\frac{(\gamma+1)\cdot \mathrm{M}_1^2}{2+(\gamma-1)\cdot \mathrm{M}_1^2}\right)\right] \tag{3}$$

The classical theory of laminar flow relates the friction coefficient to be proportional to the Reynolds number:

$$f = \frac{64}{\mathrm{Re}} \tag{4}$$

The Reynolds number is dependent on density ρ, viscosity μ, velocity u, and hydraulic diameter (Eq. (5)):

$$\mathrm{Re} = \frac{\rho \cdot u \cdot D_H}{\mu} \tag{5}$$

Since the same sonic condition develops from the flow in station 1 and 2, the difference between the two virtual distances to sonic condition equals the distance L between both station 1 and 2:

$$L = L_1^* - L_2^* \tag{6}$$

Applying Eq. (3) to station 2 and substituting L_2^* from the Eq. (6), Eq. (3) can be solved for Mach number M_2. Pressure and temperature at station 2 then can be calculated with the continuity equation in adiabatic conditions, Eqs. (7) and (8), knowing M_2 and all conditions at station 1:

$$p_2 = p_1 \cdot \frac{\mathrm{M}_1}{\mathrm{M}_2} \cdot \sqrt{\frac{2+(\gamma-1)\cdot \mathrm{M}_1^2}{2+(\gamma-1)\cdot \mathrm{M}_2^2}} \tag{7}$$

$$T_2 = T_1 \cdot \frac{2+(\gamma-1)\cdot \mathrm{M}_1^2}{2+(\gamma-1)\cdot \mathrm{M}_2^2} \tag{8}$$

Jump Conditions Across a Moving Shock

Knowing T_2, the speed of sound a_2 (Eq. (1)) and then flow velocity u_2 can be calculated. Assuming that the distance between stations 2 and 3 is negligible, and knowing the pressure ratio across the shock $\Pi_S = p_3/p_2$, conditions at station 3 can be obtained by the normal shock relations (Eqs. (9) and (10)):

$$T_3 = T_2 \cdot \Pi_S \cdot \left(\frac{\frac{\gamma+1}{\gamma-1} + \Pi_S}{1 + \frac{\gamma+1}{\gamma-1} \cdot \Pi_S}\right) \tag{9}$$

From the three basic Euler equations, the Mach number of the shockwave, M_S, can be found:

$$\mathrm{M}_S = \sqrt{\frac{\gamma+1}{2\gamma} \cdot (\Pi_S - 1) + 1} \tag{10}$$

Further, the induced velocity of the flow behind the wave u_p can be calculated:

$$u_p = \frac{a_2}{\gamma} \cdot (\Pi_S - 1) \cdot \sqrt{\frac{\frac{2\gamma}{\gamma+1}}{\frac{\gamma-1}{\gamma+1} + \Pi_S}} \tag{11}$$

The velocity of the flow at station 3 is a vector sum of the initial velocity of the flow and the velocity induced by the moving shockwave:

$$\boldsymbol{u}_3 = \boldsymbol{u}_2 + \boldsymbol{u}_p \tag{12}$$

From station 3 to station 4, the same algorithm is applied as for the flow traveling from station 1 to station 2.

Since this is an unsteady process the total properties behind the shock at station 3 are different from the ones in front of the shock (station 2). The total pressure is calculated using the known properties of the induced mass motion instead of being directly calculated from the equation of state.

The isentropic efficiency of the compression process is defined as temperature difference for an isentropic process versus a real process:

$$\eta_C = \frac{\Delta T_S}{\Delta T} = \frac{\left(\frac{p_4}{p_1}\right)^{\frac{\gamma_{air}-1}{\gamma_{air}}} - 1}{\frac{T_4}{T_1} - 1} \tag{13}$$

Analytical Results

The model described has been applied to compressible air flow with Reynolds numbers in the range of 500 to 1500. These values were obtained using Eq. (5) that is also valid for shockwave propagation in a narrow channel [2]. Further, based on the analysis of gas flow characteristics in silicon microchannels [6], the friction coefficient f has been found to be approximately 0.04 for a Reynolds number of 500, while for Reynolds numbers greater than 1000, the friction coefficient becomes less than 0.005.

A variable friction coefficient is introduced dependent on Reynolds number and therefore indirectly dependent on viscosity and temperature. Using Eq. (13), the efficiency results for various entry temperatures and shock strengths have been calculated. For the reason that for a laminar flow at microscale the friction coefficient does not depend linearly on the Reynolds number [6], a second set of efficiencies for the same range of inlet temperatures has been presented using the experimentally obtained dependence of the friction coefficient on the Reynolds number. Both sets of efficiency results are represented in Fig. 2. The efficiencies obtained with the experimentally determined friction coefficient are about 10% higher than those obtained using the theoretical friction coefficient. For each pressure ratio across the shock, an optimum entry temperature can be found that results in the highest shockwave compression efficiency. Another observation that can be made is that the values of efficiency vary only a little with entry temperature, justifying the use of a constant friction coefficient determined for the inlet temperature. This effect is caused by the competing effects of the temperature in Eq. (3): higher temperature leads to lower Mach number for the same inlet velocity, but lower Reynolds number, thus higher friction coefficient. While the length/diameter ratio is an important parameter in shock tube design, its effect on the shock compression efficiency is not very significant over a wider range. However, at lower pressure ratios its effect is more considerable. For a shock strength $\Pi_S = 1.8$ the variation is only 3.3% for a diameter from $D_H = 30\,\mu m$ up to $100\,\mu m$ and a 1 mm channel length. Efficiency results are plotted in Fig. 3. The left graphs present the results versus length/diameter ratio with shock pressure ratio as parameter, while the graph on the right side is like a side view with the length/diameter ratio as parameter. On the right side the solid line connects the optimum pressure ratios for maximum efficiency for each length/diameter ratio. While in the application of the above described procedure the influence of heat transfer has been found negligible, under the presumption that shockwave motion at low Reynolds numbers is governed by convection as well as viscosity, another one-dimensional model that utilizes the Reynolds analogy for heat and momentum transfer could be applied to the phenomenon of shock and detonation attenuation in narrow channels [7].

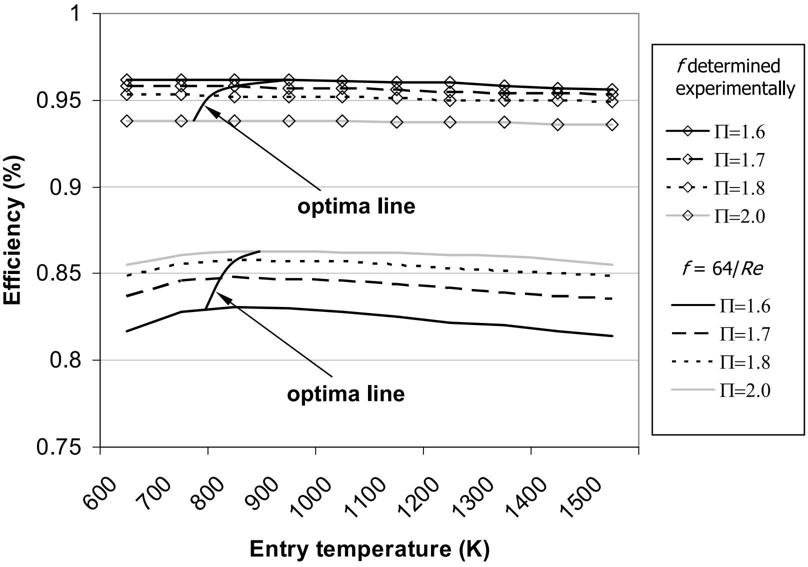
Numerical Modeling and Simulation

Numerical Model

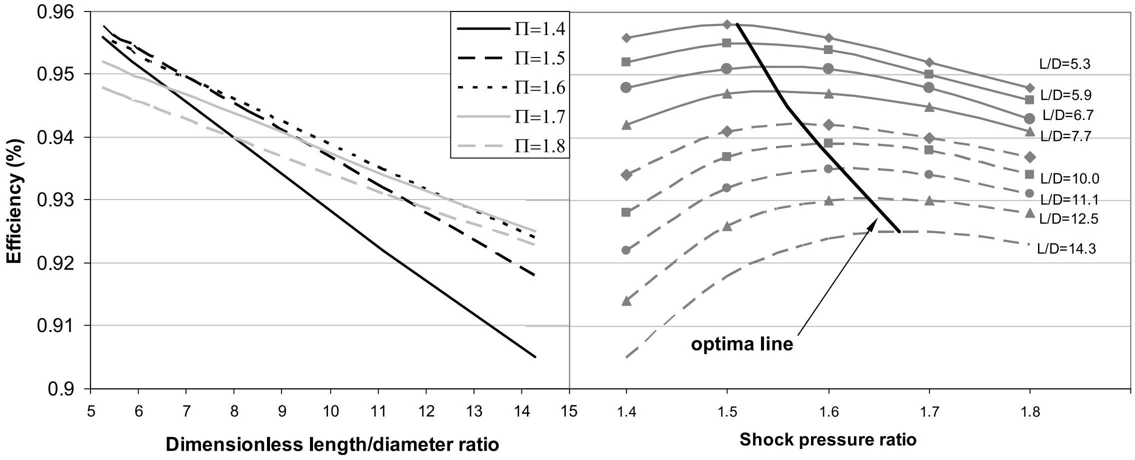
With the goal of simulating as best as possible the real-life conditions in a wave rotor channel (Fig. 4), a two-dimensional numerical model has been presented [8]. The channel modeled is 1 mm long and 76 μm wide and has a larger inlet duct (port) and opens into a larger outlet port. The mesh size in channels and inlet and outlet ports has been based on the results of a grid sensitivity study. A tetrahedral mesh is used with a 2 μm cell size for the channel and paved 10 μm cells for the inflow and outflow ports that sequence the flow through the channel. Air treated as a compressible ideal gas is used for modeling the flow.

Computational Fluid Dynamics (CFD) Results

The data trend of the above presented analytical study has been verified by computational fluid dynamics (CFD) analysis. Moreover, some microscale-specific effects could be seen: for the initial part of the process, the pressure drop is confined over a short distance (between stations 2 and 3 in Fig. 5a); as the shockwave travels further from the left to the right, the pressure gradient dissipates more and more continuously over a longer range. Instead of a well-defined shockwave, a set of compression waves can then be seen distributed over more than a half of the length of the channel (Fig. 5b). This effect has already been noted in experiments with microscale shock tubes [9], originating from the stronger influence of the viscous forces at low Reynolds numbers. In the den-



Shockwaves in Microchannels, Figure 2 Efficiency of shockwave compression process as a function of entry temperature for different shock strengths, and for a shock traveling in the opposite direction to the flow. Results obtained with analytical one-dimensional code



Shockwaves in Microchannels, Figure 3 Efficiency of shockwave compression process as function of microchannel length/diameter ratio for different shock strengths, and for a shock traveling in the direction of the flow. Results obtained with analytical one-dimensional code

sity contour plot (Fig. 6), the existence of the boundary layer can be seen clearly, behind the shockwave as soon as it has traveled about 20% of the channel length. Many more CFD simulations at the microscale exist and the numerical reproduction of the behavior of pressure-driven flows in microchannels has been obtained often [2, 10]. Some discrepancies have been found between numerical solutions of the Navier–Stokes equations and experimental data obtained in viscosity-dominated shock tube investigations. It was noticed that even using fine grid cells of a few micrometers, the solution of the Navier–Stokes equations still does not match experimental data of shockwave reflection transition over a wedge [2]. It has been pointed out that the solution of shockwave motion at low Reynolds numbers requires the finding of a two-dimensional unsteady solution of the Navier–Stokes equations and doubts are raised that the inclusion of transport phenomena as perturbations to a simple shock-tube flow would be adequate for a reliable flow description.

Numerical simulation might become a more efficient and economic way to analyze shock and flow phenomena at the microscale [2]. However, there is still a great need of experimental results to verify and support all the theoret-

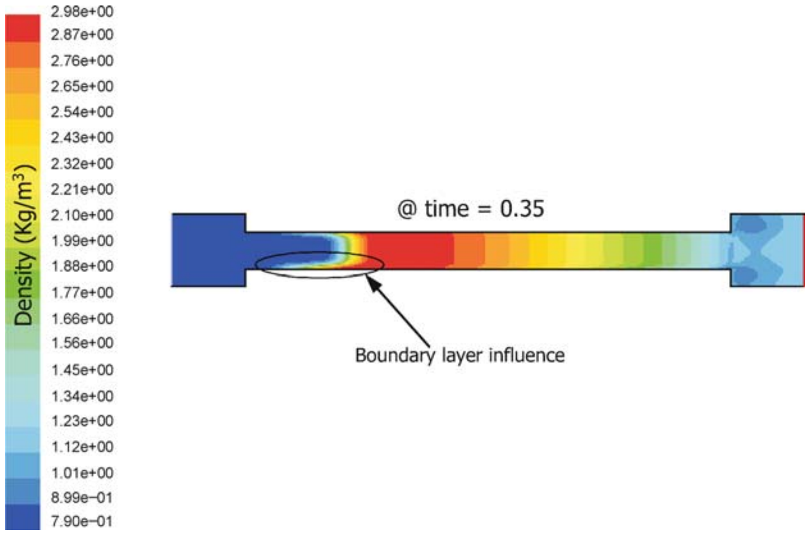
ical assumptions made in CFD and to establish reliable numerical models and schemes [2, 10].

Experimental Approach

Although the accuracy of present experiments is still not high enough to fully validate numerical models and solution schemes [2], more experimental investigations are needed in order to better understand the physics of shockwaves at the microscale. A good experiment will focus on trying to visualize the shock front, but a difficult task, besides obtaining good clarity, is recording the images. Although the geometric dimensions are scaled down, the shock velocities remain in the same high range; thus, the duration of shock travel is of the order of a microsecond for a channel length of 1 mm.

Despite the behavior of shockwave motion in large shock tubes at relatively high Reynolds numbers being extensively investigated in the 1950s and 1960s [2], little work has been done for low Reynolds number flows, especially at small scales. The experimental investigation of shock propagation in microchannels could provide valuable validation information on viscosity-dominated compressible flows. Two-dimensionality of the flow in channels is favorable for any validation effort. However, no shock visualization in microchannels has been published. Nevertheless, using the



Shockwaves in Microchannels, Figure 6 Density contours inside a microchannel. Time = 1 is when a pressure wave reached the end of the channel. Flow moving from left to right

Schlieren method for flow visualization to record the shock propagation has been successful down to a channel size of 3 mm × 3 mm cross-section and 42 mm length [11]. Investigations for microchannels are under way.

Single-Channel Experiment

Shockwave Visualization on 3 mm Wide Channels

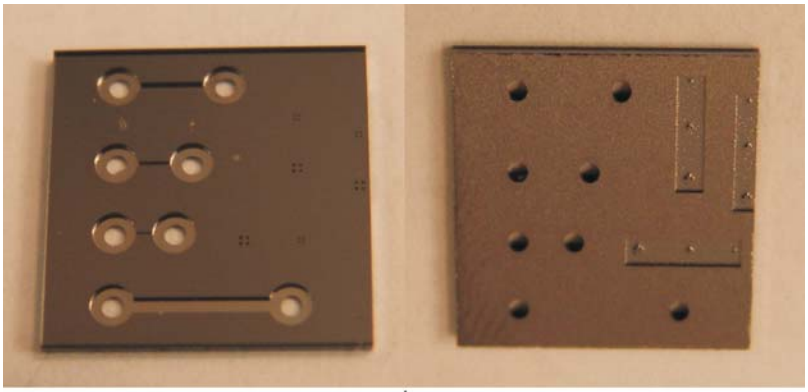
At the University of Tokyo, the Schlieren method and a high-speed camera have been used for capturing images of the flow of a traveling shockwave in channels of 3 mm × 3 mm cross-section and 42 mm and 168 mm length. The channels were closed at one end and high-pressure air (250 kPa) was supplied at the other end by means of rotating ports. The effect of the transient opening was neglected during preliminary calculations and it was observed that it does not affect the shock propagation during the experimental investigations. Shockwave propagation speed has been reported as 300–400 m/s in both tubes. Interestingly, no boundary layer effects on the shock propagation or shockwave dissipation were observed. The wall friction effect seemed not to play an important role in the shockwave behavior [11].

Microchannel Experiments in Preparation for 90–720 μm Wide Channels

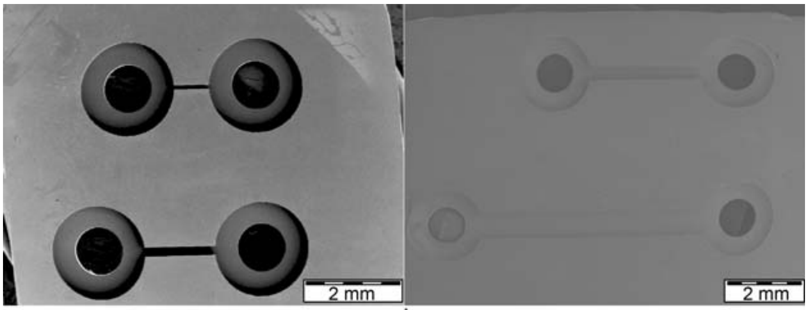
At Michigan State University a single-channel experiment has been developed to investigate the wave phenomenon. A set of similar channels have been designed in order to obtain more information on what the characteristic dimension is at which the shockwave behavior starts to deviate from macroscale theory. The channels have the same length/width ratio and same height; the length and width are varied (90 × 750 μm^2, 180 × 1500 μm^2, 360 × 3000 μm^2, 720 × 6000 μm^2), while the height is uniformly 360 mm. The channels are etched in a silicon wafer and closed on top with glass. The access ports are etched on the bottom side of the silicon wafer. Figure 7 shows photos of the silicon/glass microfabricated die. On the top side, the channels and the flow plenums can be observed, and on the bottom side, the access holes and the alignment marks can be seen. The quality of the geometry resulting from the microfabrication technique is impressive: even the smallest channel (90 μm in width) has crisp edges and a well-defined shape. Figure 8 shows SEM images of the four channels. In a first experiment with these micro-shock tubes, the channels are connected via access ports to stainless steel tubing (1.02 mm outer diameter) to a nitrogen supply tank. A quick release valve releases the nitrogen through the microchannel. Since the silicon wafer surface is highly reflective, reflection laser interferometry is used to capture the passing of the shockwave.

Microchannel Experiments in Preparation for 10 μm

A similar experiment is currently being designed at Sherbrooke University [12]. The goal is to build and test a true shock tube with two cavities filled with gases at different pressures, divided by a breakable membrane. The aspect ratio of the channel is 100 and a pressure ratio of 2 is planned for a Reynolds number of 100. These conditions could be achieved in a 5 mm diameter/500 mm long tube



Shockwaves in Microchannels, Figure 7 Silicon microchannels: (**a**) top view; (**b**) bottom view



Shockwaves in Microchannels, Figure 8 Different size channels visualized with SEM: (**a**) 90 μm and 180 μm wide channels; (**b**) 360 μm and 720 μm wide channels

with pressures of 1 mbar and 2 mbar, respectively. But the low pressures typically exclude the possibility for flow visualization or measurement. Therefore a more favorable solution is planned that will create the same hydrodynamic flow, using a micro-shock tube with a hydraulic diameter of 10 μm, operating at pressures close to atmospheric conditions.

The tube is created with a squared cross-section, 10 μm wide. The driver and driven section have equal lengths. The driver and driven sections are separated by a membrane, and the test section is pre-filled with the test gas during fabrication. The top side of the tube is made of a plate comprising direct-sensing piezoelectric gauges, used for timing the arrival of pressure waves.

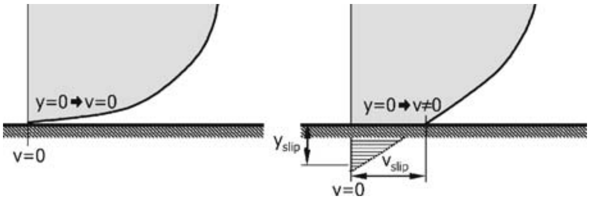
Key Research Findings

Microscale Flow Phenomena

The overall conclusion is that while the currently available experimental data suggest the presence of microscale phenomena, they do not unequivocally identify the effects [1, 13]. In general it is found that the boundary layer effects are dominant at and below the microscale resulting in rarefaction effects in gaseous flow. However, the no-slip boundary condition appears to hold true less and less with smaller scale. The slip flow effect is seen to result in less frictional pressure drop than the continuum model predicts. Further it is widely pointed out that sudden increases in pressure (due to a shockwave) dissipate gradually when propagating through a microchannel due to high hydraulic resistance.

Compressibility and Rarefaction Effect

With the dominant occurrence of boundary layer effects in microchannel flow, in gaseous flows considerable decrease in density is observed with increasing flow length due to viscous dissipation [14]. This is also referred to as the rarefaction effect. Compressibility and rarefaction effects have been studied in three-dimensional gas flow with Reynolds number varying from 0.0001 to 1.2 and pressure ratio varying from 1.5 to 5.0, with the Knudsen number varying from 0.001 to 0.06 [3]. It has been found that the



Shockwaves in Microchannels, Figure 9 Non-slip versus slip-flow wall velocity

pressure drop for compressible flows exhibits an unusual nonlinear behavior as compared to that for incompressible flows. Especially at high pressure ratio (or Reynolds number) the compressibility effect becomes dominant although the Mach number may still be very small. So typically Knudsen number increases from inlet to outlet for compressible microchannel flow.

Isothermal Effect

At the microscale the time scales associated with heat loss mechanisms reduce dramatically. However, the characteristic time scales for heat release, governed by the deflagration process, remain fairly independent of scale [9]. In long, non-insulated microchannels, an isothermal flow assumption has been found accurate for Mach numbers $\mathrm{M} \ll 1/\sqrt{\gamma}$, where γ is the specific heat ratio [14]. Values of laminar Nusselt number increase with the cross-sectional aspect ratio and the surface roughness [15].

Slip Flow

With scale in particular, changes in fluid–surface interactions, such as the wetting ability of the fluid, can affect the ability of the fluid to exchange momentum with the surface at the atomic scale, resulting in a slip velocity v_{slip} at the solid wall as shown in Fig. 9 [16]. The slip length y_{Slip} gives the imaginary location behind the wall where non-slip condition with zero flow speed $v = 0$ would be found. Slip flow has been reported for both liquid and gaseous flow. Especially at $\mathrm{Kn} < 0.1$, the effect of slip flow has been seen resulting in reduced pressure loss gradient and hence increased mass flow rate. Deviations from Poiseuille flow predictions are not related to turbulence when Re is too low but to deviations from the no-slip boundary conditions. Increase in the mass flow for given inlet and outlet pressures for microchannel flows has been based on a perturbation expansion of the Navier–Stokes equations with a first-order correction of wall slip [14]. More factors regarding non-continuum effect, compressibility effect, and surface effects are presented in [17].

Friction Factor

Discrepancy between the conventional theory and the microchannel measurements of friction factor f in gaseous flow has been attributed to compressibility [6]. In general it appears that $f\mathrm{Re}$ for compressible slip flow is less than that for the incompressible case [3]. In a comprehensive study of results of microscale single-phase internal flows [1], it has been found that the only definitive conclusion that can be reached from the currently available data is that gaseous slip flow data indicate an approximate 60% reduction in f compared to macroscale theory at the same Re (while for laminar non-slip water flow f appears to be approximately 20% higher than the theoretical predictions). The finding for compressible slip flow seems to be supported by a simple analytical correlation with the factor $c \approx 0.6 \pm 0.05$ [3]:

$$\frac{(f\mathrm{Re})_{\mathrm{slip}}}{(f\mathrm{Re})_{\mathrm{non-slip}}} = \frac{D_{\mathrm{h}}}{D_{\mathrm{h}} + c} \tag{14}$$

The currently available experimental data for other types of flows are inconclusive, as they appear both above and below the theoretical predictions (although data for each researcher are consistently either greater or less than theoretical values). In part, these differences may be attributed to roughness of the channels, to lack of well-controlled surface structures, and to uncertainty in the determination of channel dimensions. Some researchers estimate the entrance effects in determining the microchannel friction factor, while, much better, the measurements should be taken within the microchannel near the channel entrance and exit. Further, preliminarily it has been concluded that, regarding non-slip microchannel flows, f appears to increase with surface roughness and this effect seems to intensify with higher surface roughness.

For $\mathrm{Re} < 700$, global pressure drop has been shown to be proportional to Re. For $\mathrm{Re} > 700$, it deviates from the linear relationship with the deviation dependent on Re. Also it has been found that f increases with the cross-sectional aspect ratio and the surface roughness [15].

Critical Reynolds Number

There is an ongoing debate regarding the critical Reynolds number $\mathrm{R_{cr}}$ for microfluidics at which the transition from laminar to turbulent flow starts. The determination of $\mathrm{R_{cr}}$ depends very much on the method used. $\mathrm{R_{cr}}$ varies widely from 300 to 2200 with it being mostly between 1500 and 1800 [1, 13].

Entry Lengths and Boundary Layers

It is the case that most flow investigations at the microscale happen in the laminar flow regime with developing boundary layer (combined entry lengths). As for macroscale cases, the velocity entry length L_{E} is often simply calculated by

$$\frac{L_{\mathrm{E}}}{D_h} \approx 0.06\mathrm{Re} \tag{15}$$

However, also larger factors of 0.08 and 0.09 [9] have been found for microchannels. The thermal entry length L_{T} may be calculated by

$$\frac{L_{\mathrm{T}}}{D_h} \approx 0.05\mathrm{RePr} \tag{16}$$

where Pr is the Prandtl number, a measure of diffusivity.
When investigating the boundary layer thicknesses, the Euler equations lead to specific solutions. The thermal boundary layer thickness is

$$\delta_{\mathrm{T}}(x) = 3.6\sqrt{\frac{\alpha x}{\mathrm{u}_\infty}} \tag{17}$$

where x is the coordinate along the channel and u_∞ is the velocity of the free stream.
The Reynolds analogy between the flow field and the thermal field provides the relation between the velocity and thermal boundary layer thickness:

$$\frac{\delta_{\mathrm{T}}}{\delta} = 0.975\sqrt[3]{\mathrm{Pr}} \tag{18}$$

Shockwave Phenomena at the Microscale

Dominant viscous and wall effects appear to influence considerably shockwave behavior at the microscale. Sudden increase in pressure (due to a shockwave) vanishes gradually in time due to hydraulic resistance [18]. So, it has been observed that, subsequent to the arrival of the shocks, the pressure increases continuously which is not conventional shock tube behavior [8, 9]. Also the decaying amplitudes of the shocks indicate that dissipation plays an important role. Therefore when waves are generated and propagated into ducts of small dimensions, diffusive transport phenomena, commonly ignored at conventional scales, can no longer be neglected. Viscous stresses at the boundaries lead to the deformation of the wave fronts, and heat conduction with the wall no longer allows the flow to remain adiabatic; at certain scales, molecular diffusion and adsorption may also lead to important effects.
It has been reported that for a given wave Mach number at small scales, the resulting particle velocities are lower but the pressures are higher [9]. Also, it has been shown that at small scales, the weak wave solution is no longer sonic and isentropic but is isothermal and can be subsonic.
Further, a model has been introduced that predicts via molecular diffusion phenomena an isothermal bow at small scales and that the minimum wave velocity can be subsonic. A parameterization of the shear stresses and heat flux at the wall has led to new jump conditions [9].
Experiments with a miniature shock tube using low pressures to simulate the effects of small scale have shown qualitative agreement with the proposed model. The effects of scale are even more pronounced than what has been predicted by the model. Experimental and numerical investigations for incident shock Mach number of $\mathrm{M} = 1.2$ have shown significant viscous effects for channel heights below 4 mm even at atmospheric pressure. That shockwaves propagate more slowly at low pressures in a narrow channel has been confirmed, but they may propagate faster than in a wide channel because compression waves initiated from the entrance of the channel can strengthen the shockwave [2].

Micro-Shockwave Applications

Micro-Wave Rotors

The wave rotor is a pressure exchanger that uses the concept of direct energy transfer between fluids by waves. A basic wave rotor consists of a rotating drum with straight channels arranged around its axis. The drum lies between two end plates, each of which has a few ports or manifolds controlling the fluid flow through the channels. Figure 4 presents a schematic axial wave rotor drum and its end plates and inclusion in a microfabricated gas turbine. In the process of recent turbomachinery miniaturization it has been shown that a decrease of the overall thermal efficiency and output, and increase of losses are severe. While the wave rotor efficiency is based on the efficiency of the shockwave compression inside each channel, the influence of external losses can be minimal since the wave rotor itself is the only moving part and its rotation is only for the flow control. External losses are leakage, windage, friction in the bearings of the rotor, and if microfabricated losses due to sharp bends in the flow path to the rotor since rounded corners are difficult to obtain in the direction of etching. While all these losses also occur in turbomachinery, they can be lower in a wave rotor, since the compression process is only controlled but not determined by the rotational speed of the rotor. Therefore high efficiency can be obtained even at relative low rotational speed and relatively low flow speed, which implies less frictional losses as it becomes very important at small scale. It has been shown numerically that while the efficiency of a conven-

tional radial compressor drops to about 50% when scaled down to millimeter size, the efficiency of shockwave compression has values around 70%. Two effects support this favorable outcome: shockwave entropy production is independent of scale and wave rotors can work with relatively low flow speeds (while the compression is realized by shockwaves that travel at much higher speed than the flow speed).

The results of the previously described analysis show that the efficiency depends not only on pressure gain across the shockwave traveling through the wave rotor channel, but also on the friction coefficient for the channel geometry. According to the model, shorter wave rotor channels with larger diameter allow a higher compression efficiency of the wave rotor. The temperature at which the compression process is initiated also has a considerable influence: higher temperatures yield higher efficiencies. Analytical and numerical results suggest that a shockwave compression efficiency of 70–80% can be achieved in the channels. If the inlet temperature is high enough (about 1500 K), the efficiency is predicted to be even higher, up to 90%. Moreover, the wave rotor, due to its geometry, is ideal for microfabrication processes. Its mainly two-dimensional shape is easy to construct at the microscale, where most of the fabrication techniques rely on etching and deposition [4].

Shock Tube as Vaccine Delivery System

An unique form of powder delivery system, a biolistic system, has been developed [19]. This novel technology accelerates microparticles by a gas flow behind a traveling shockwave, so that they can attain sufficient momentum to penetrate the skin and thus achieve a pharmacological effect. One of the most recent developments is a mouse biolistic system, used in immunological studies. These studies require powdered vaccine to be delivered into the epidermis of the mouse with a narrow and highly controllable velocity distribution and a uniform spatial distribution. The preliminary results demonstrate the overall capability of a newly designed supersonic nozzle to deliver the particles to the skin targets with a more uniform velocity and spatial distribution. CFD has been utilized to characterize the complete operation of a prototype mouse biolistic system.

Micronozzles

The Mach number near the downstream position of a micronozzle's throat is lower than that in a conventional nozzle. In the divergent region of the micronozzle, there is a supersonic area instead of the shockwave that usually occurs in conventional-scale nozzles. Results of numerical simulations also show that the position of the sonic point moves away from the throat towards the outlet with a decrease in the size of the nozzle. This particular behavior is attributed to the higher viscous dissipation in micronozzles as compared to that in conventional-scale nozzles [20].

Future Directions for Research

Recent medical and industrial applications of shockwaves necessitate a better understanding of shockwave motion at low Reynolds numbers: for example, shock motion in very small tubes ($r < 1$ mm) and micrometer-size particles moving at a supersonic speed [2]. Along with this comes a clear need for additional experimental investigations over a wider Re range using microchannels with well-characterized dimensions and surface roughness and well-designed experimental methods in order to understand microscale single-phase internal fluid flow [1]. To enhance the accuracy, flow visualization may focus on a local region instead of the whole test section, and more sensitive and precise pressure transducers for measuring weak shockwaves at low initial pressures are necessary [2]. Wave rotors are a promising technology that uses unsteady waves in an instant self-cooled dynamic pressure exchange between fluids. For high-pressure, high-temperature topping cycles, it results in an engine overall pressure ratio and temperature increase which in turn generates higher efficiency and lower specific fuel consumption. Further applications are pressure wave-driven pumps. Most advanced embodiments are wave discs engines that do not need any other rotating parts beside the wave disc self. They appear to be superior in simplicity and power density [21].

Definition

Silicon micromachining concerns a process that involves the removal of silicon materials using wet chemical or dry plasma process in order to create 3-D silicon or non-silicon microstructures for making functional devices such as micro-sensors, micro-actuators, biochips, etc.

Overview

Silicon is a well-known single crystalline semiconductor material, which is widely used in integrated circuits (ICs). Silicon possesses excellent mechanical properties, which surpass stainless steel in yield strength and hardness with good mechanical stability. Silicon also has a high piezoresistance effect, whose resistivity changes when mechanical loads or stresses are applied to it. This makes silicon

a good candidate for various mechanical sensor applications. By combining micromachining technologies, its outstanding properties have made silicon a successful material not only for integrated circuits, but also for Micro-Electro-Mechanical Systems (MEMS), micro-fluidic components, optical devices, and other applications.

In general, silicon micromachining technologies can be classified as follows: wet bulk-micromachining, reactive ion etching (RIE), deep reactive ion etching (DRIE), surface micromachining, and laser micromachining. During the micromachining process, only the surface area, which will be etched away, is exposed to the etchants, such as wet chemicals or gases, while the rest of the silicon surface is protected by the so-called etching masking layer.

Silicon has a diamond cubic crystal structure. The Miller indices of the main crystallographic planes of silicon are (100), (110) and (111), respectively. In the wet bulk-micromachining, there are two silicon etching methods: isotropic (direction-independent) and anisotropic (direction-dependent) etching. Wet chemical etching solutions are used in this bulk silicon micromachining technology.

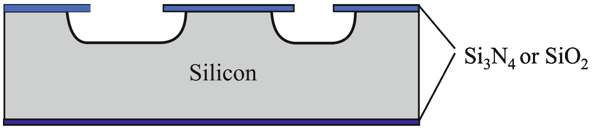
In the reactive ion etching, silicon is isotropically etched in plasma gases. Its silicon etch rate is relatively low and orientation-independent.

The deep reactive ion etching technology, also called Bosch process, uses the concept of alternate etch and passivation steps to achieve high aspect ratio (depth to width ratio of microchannel) silicon deep micromachining. In this process, silicon can be deeply micromachined, even through the whole wafer of few hundreds micrometers with aspect ratio as high as 30 to 1, without considering the wafer orientation.

Basic Methodology

Wet Silicon Bulk-Micromachining

This micromachining technique has been used for more than two decades and is the most popular fabrication technology for sensors such as pressure sensors and accelerometers [1]. In this bulk-micromachining, chemical etching solutions are used to shape the microstructures by the removal of a large amount of single crystalline silicon substrate. Thin films, acting either as etching mask materials or microstructure materials, are deposited/grown and patterned on the silicon substrate. KOH (Potassium Hydroxide), EDP (Ethylenediamine Pyrocatechol) or TMAH (Tetramethyl Ammonium Hydroxide) are commonly used as chemical etching solution for anisotropic micromachining of silicon materials, while the NHA ($HF-HNO_3-CH_3COOH$) solution performs the isotropic etching of silicon wafers. Thin films, such as SiO_2 and Si_3N_4 with a thickness ranging from few tens nanometers to few micrometers, are the common materials serving as etching mask layers, which can also be used as structure materials for sensors or actuators after silicon bulk-micromachining. The dielectric materials, SiO_2 and Si_3N_4, can be deposited either by low pressure chemical vapor deposition (LPCVD) or plasma-enhanced chemical vapor deposition (PECVD). Additionally, SiO_2 thin film can be also grown by thermal oxidation on the silicon substrate.



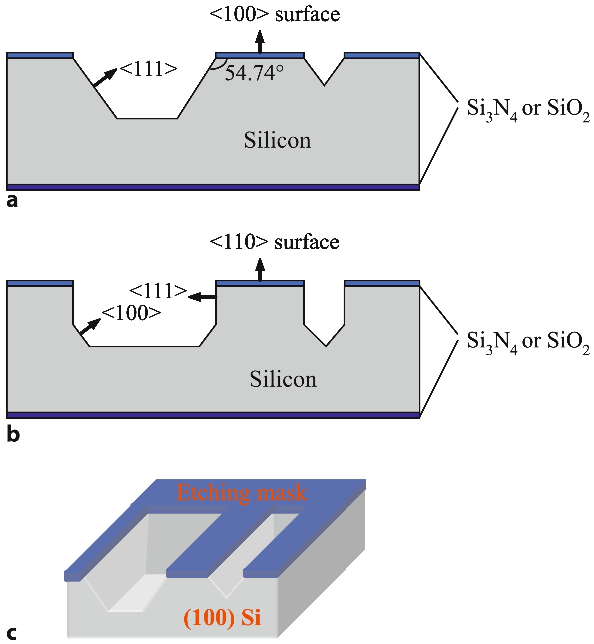
Silicon Micromachining, Figure 1 Schematic of cross sectional view of isotropically etched silicon microchannels using wet chemical etchants of NHA

Isotropic etchants etch in all crystallographic directions at the same rate; they usually are acidic, such as NHA, and lead to rounded isotropic features in single crystalline silicon as shown in Fig. 1. The basic chemical reaction equation is described as follows:

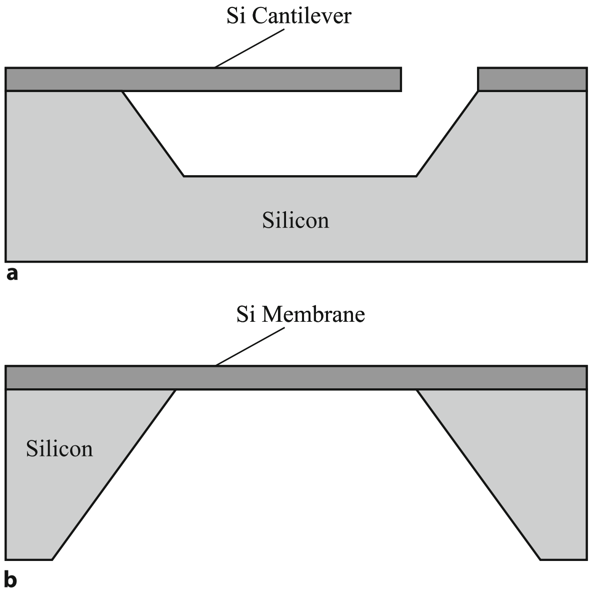
$$
\begin{aligned}
&Si + HNO_3 + 6HF \\
&\rightarrow H_2SiF_6 + HNO_2 + H_2O + H_2 \text{ (bubbles)}
\end{aligned}
$$

The etch rate can be as high as $5\,\mu m\,min^{-1}$ at room temperature, and is very temperature-dependent. At 50°C, the etch rate is increased to about $50\,\mu m\,min^{-1}$ [2].

Anisotropic etchants shape desired microstructures in single crystalline silicon material by etching much faster in one direction than the others. ► Anisotropic etching results in geometric shapes bounded by the slowest etching and perfectly defined crystallographic planes. By using KOH chemical etching solution, the etch rate in the <100> orientation is much higher than that in the <111> direction, up to 400:1. If holes, membranes, groove-type microchannels, pits, etc., have to be etched in silicon, then wafers are taken with surface orientation (100) and (110), depending on the required shape of the etched structures. Figure 2 shows some etch shapes in these two wafers. Parts of the wafers are covered with an etch mask, and the exposed areas are etched. For wafers of <100> surface orientation, etching proceeds along (100) planes, which intersects the surface along the mask edges. If the mask opening is a square with a side that is small compared to the etching depth, then a pyramidal pit is formed, which is defined by four (111) planes, i. e. it will virtually stop. The angle between the <100> and <111> directions is 54.74 degrees.



Silicon Micromachining, Figure 2 Schematic of cross sectional view of anisotropically etched microchannels (**a**) in (100) silicon, (**b**) in (110) and (**c**) of 3-D aerial view of anisotropically etched microchannels in (100) silicon using wet chemical etchants of KOH, EDP or TMAH



Silicon Micromachining, Figure 3 Schematic of cross sectional view of highly boron-doped silicon (**a**) cantilever, and (**b**) membrane. The anisotropic etching stops at the highly boron-doped (100) silicon layer by using wet chemical etchants of KOH, EDP or TMAH

In <110> wafers, the (111) planes are vertical, and deep trenches with high aspect ratio can be etched since silicon in the <111> direction will not be etched.

The commonly used anisotropic etchants are KOH, EDP and TMAH. KOH added with water is the most popular silicon anisotropic etchant. At 80 °C with 50 wt% KOH, the etch rate of (100) silicon can achieve 1.4 $\mu m\,min^{-1}$ with smooth silicon etching surface. The etching selectivity between (100) and (111) silicon is up to 400:1. However, the etching selectivity between Si and SiO_2 is not very good in KOH, as it etches SiO_2 too fast. So, SiO_2 is not a good choice as etching mask of silicon in KOH. The best candidate as etching mask is Si_3N_4. One disadvantage of KOH is its incompatibility with IC fabrication processes. Therefore, for MEMS with integrated circuits, the IC fabricated steps will be processed first and followed by the wet bulk-micromachining in KOH to create MEMS microstructures.

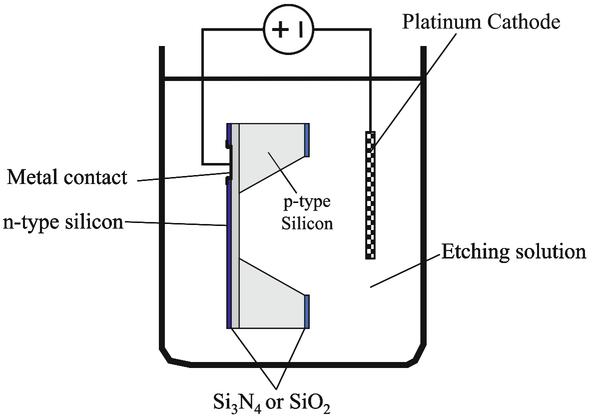
EDP etching solution doesn't contain sodium or potassium and therefore, it is IC compatible. EDP has also very high etching selectivity of 5000:1 between Si and SiO_2, which is a good etching mask for silicon etching. The etch rate can reach 1 $\mu m\,min^{-1}$ in EDP, however its etching selectivity of 35 to 1 between (100) and (111) silicon is relatively low. Furthermore, EDP contains pyrocatechol, which is described as a corrosive toxic.

TMAH is more compatible with CMOS IC processes than KOH and also neither toxic nor harmful. The etch rate of (100) silicon in TMAH can achieve about 0.7 $\mu m\,min^{-1}$, but its etching selectivity of (100)/(111) silicon is quite low, which is between 12.5 and 50.

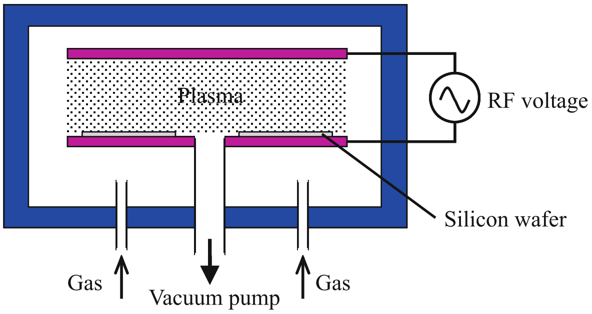
For some applications, especially for the microfluidic devices, the etched surface quality of micromachined microchannels is very important. In general, isotropic etching generates smooth etched surface. However, anisotropic etchants leave rough etched surface. A highly concentrated KOH is preferred to obtain a smooth surface. In some cases, a post polishing process after KOH etching can be adopted by using slight isotropic etching to obtain a smooth surface.

If silicon is highly doped, particularly with boron, then silicon will be etched very slowly by the previously mentioned wet chemical etchants such as KOH, EDP or TMAH. One can use ion-implanting or diffusing boron into silicon to form a thin etch-stop layer. Since non highly-doped silicon will be etched very fast, this thin etch-stop layer will stay as a free-standing membrane, bridge or cantilever, depending on its shape patterning, as illustrated in Fig. 3. Such dopant-dependent selective etching techniques have led to the development of pressure sensors, accelerometers and microphones [3] with great commercial success.

The most appropriate technique to make low-doped, single crystalline silicon membrane-type microstructures with



Silicon Micromachining, Figure 4 Schematic drawing of experimental set-up for electrochemical etching of p-type (100) silicon. The etching stops at p-type and n-type silicon interface



Silicon Micromachining, Figure 5 Schematic drawing of a typical reactive ion etching (RIE) system

well-controlled dimension and thickness is the electrochemical etch-stop on a diffusion or an epitaxial layer as shown in Fig. 4. In this silicon micromachining technique, a positive voltage is applied to one n-type side of a p-n junction of a wafer in an etch bath of a strong alkaline solution such as EDP or KOH. A platinum cathode is connected to the negative voltage and immersed in the etching solution. The etching proceeds as normal wet chemical etching until the exposed side of the p-n junction is completely etched away, which means that the etching stops exactly on the n-type silicon layer to release the diaphragm. In this case, only a low-doped layer is sufficient for the etch stop. Compared to the heavily-doped layer produced by purely chemical etching, silicon membranes micromachined by the electrochemical etching have much less mechanical stress.

Reactive Ion Etching of Silicon

In microelectronic fabrication processes, plasma etching is used to create the patterns of silicon-based thin films (silicon dioxide, silicon nitride, polysilicon). This etch process is performed in the vacuum chamber. By adding etch gases excited by radio frequency (RF) power, plasma is generated in the chamber, where silicon wafers are located. The exposed silicon surface is reacted with plasma gases and then removed layer by layer by this so-called reactive ion etching (RIE) technique. The schematic diagram of the RIE system is illustrated in Fig. 5. Since there is no wet chemical etching solution to be involved, this process is also called dry etching process. Assisted by the energetic plasma ions, fluorine gases, such as SF_6, CHF_3 and CF_4, are the etching gases for silicon-based thin films of SiO_2, Si_3N_4 and polysilicon, which are to be removed or patterned to form the desired shapes of microstructures.

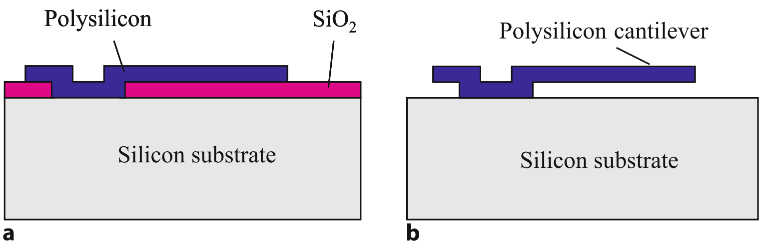
By adding small amount of O_2 gas, the etch rate can be accelerated. In general, in this approach, the etch rate is relatively small, and in the range of few nanometers to tens nanometers per minute. The RIE process is not applicable for bulk material micromachining and therefore, it is suitable only to etch thin films with thickness of few micrometers. However, RIE is a suitable process to etch shallow microchannels in silicon substrate with good etch depth control.

Silicon Surface Micromachining

In this technique, thin layers, such as polycrystalline silicon, SiO_2 and Si_3N_4, will be deposited on the silicon wafer, which serves as a supporting substrate and may contain integrated circuits. The silicon substrate is protected by the etch-resistant film, for example thermal silicon dioxide or LPCVD silicon nitride, grown or deposited on the silicon substrate. A sacrificial layer of low temperature oxide (LTO), phosphosilicate glass (PSG) or borophosphosilicate glass (BPSG) is then deposited and followed by the deposition of LPCVD polysilicon, which is used as microstructures, typically for comb-drive structures, and normally patterned by RIE or DRIE technology [4].

In this approach, the bulk silicon substrate is not etched away, but only the sacrificial layer between the silicon substrate and the polysilicon microstructures is removed by lateral under-etching using the selective wet etchant of HF or BOE. Such etching solutions do not have any etching effect on the polysilicon film. Figure 6 illustrates the process steps to fabricate a polysilicon cantilever.

The surface micromachining technique is a CMOS-compatible process and has some advantages over the bulk-micromachining one. The most popular microstructure is the so-called comb-drive structures as shown in Fig. 7. Several commercially available sensors with integrated circuit on chip have been developed by using



Silicon Micromachining, Figure 6 Fabrication steps of a polysilicon cantilever using surface micromachining. (**a**) Deposition of SiO_2 on silicon substrate, followed by polysilicon, whose shape is etched by DRIE or RIE, and (**b**) generation of polysilicon cantilever after removal of the sacrificial SiO_2

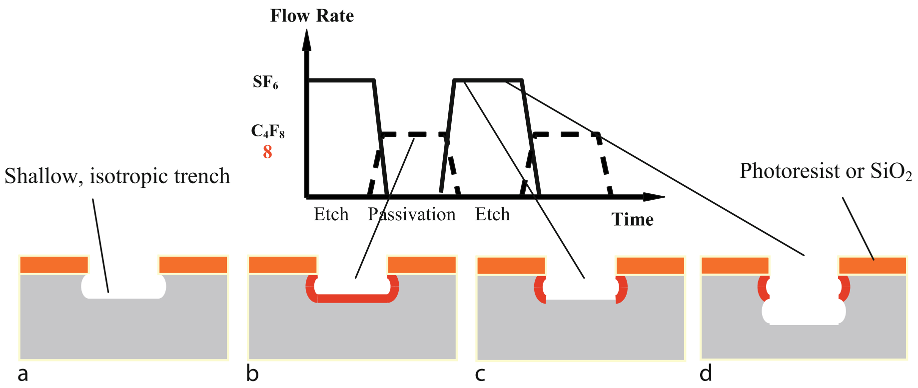
Silicon Micromachining, Figure 9 Scanning electron microscope (SEM) photograph of comb-drive structure in SOI (silicon-on-insulator) wafer fabricated using DRIE and surface micromachining

this technique such as accelerometers, gyroscopes, microphones, etc.

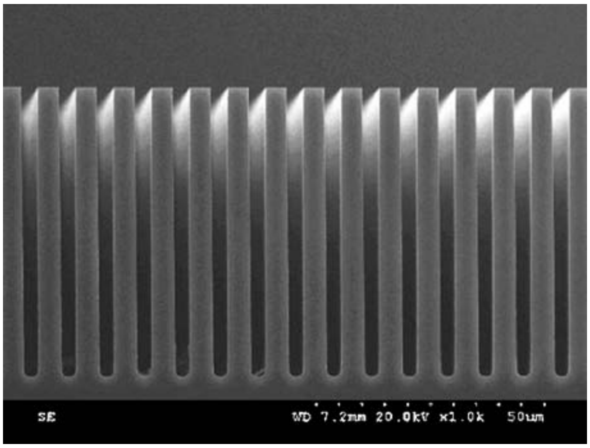
Instead of deposition of different thin films, silicon-on-insulator (SOI) micromachining may surpass the poly-Si surface micromachining technology for fabricating high performance devices. Figure 8 shows the process steps to fabricate a comb drive structure using SOI wafer. The single crystalline silicon device layer, whose thickness ranges from few to 100 μm, can be obtained by epi-silicon or fusion-bonding on a thin SiO_2 insulating layer. The top silicon device layer can be micromachined by RIE for thin layer and then followed by wet sacrificial etching of the buried SiO_2 layer by BOE for the structure release. Microstructures made from these single crystalline Si layers result in more reproducible and reliable sensors and other MEMS devices. Figure 9 presents a fabricated comb drive structure based on SOI surface micromachining.

Deep Reactive Ion Etching of Silicon

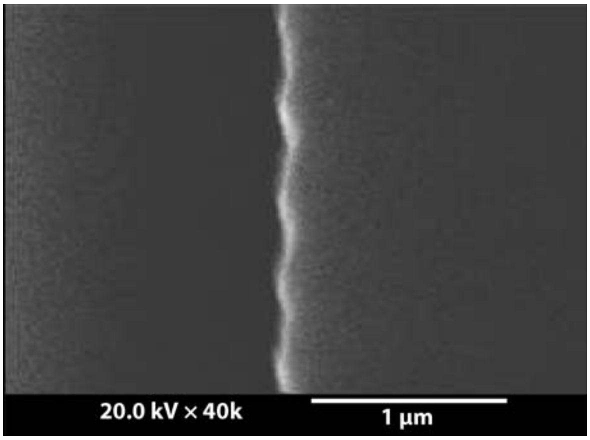
Microchannels and holes can be micromachined using wet chemical etching. However, as geometries of micro-device components get smaller, the requirement to etch silicon microchannels with vertical profile becomes important. An increase in aspect ratio for microstructures (for example microchannel) is desirable because more devices can be made from the same size of silicon substrate, and also lead to enhanced device characteristics.



Silicon Micromachining, Figure 10 Illustrations of deep reactive ion etching process by time-multiplexing scheme. (**a**) Silicon is isotropically etched using SF_6 etching gas, (**b**) Polymer is deposited on the trench sidewall and bottom using C_4F_8, (**c**) At the beginning of following etch cycle, the bottom polymer is removed by etching gas ions, (**d**) In the remaining etching cycle, silicon is then further isotropically etched using SF_6 etching gas, forming the scallop sidewall



Silicon Micromachining, Figure 11 Scanning electron microscope (SEM) photograph illustrating high aspect ratio and vertical silicon trenches etched by DRIE



Silicon Micromachining, Figure 12 Scanning electron microscope (SEM) photograph illustrating the DRIE etched silicon with sidewall scallops of 50 nm

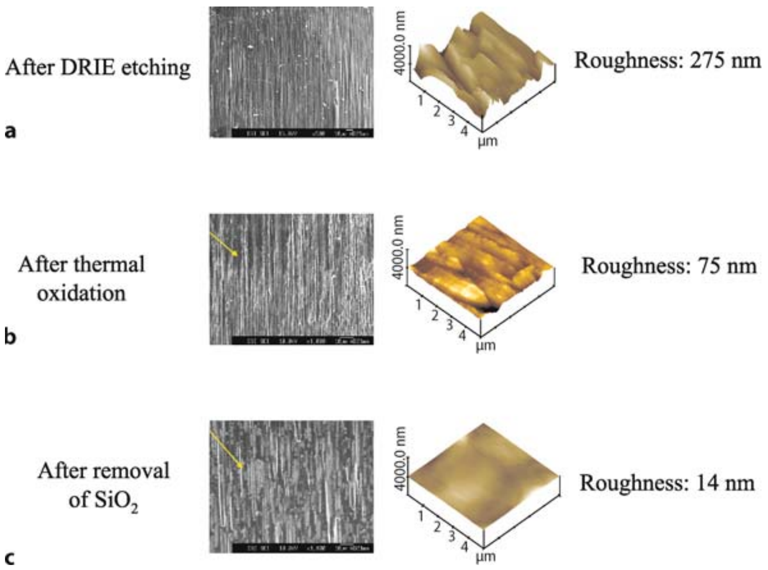
Laermer and Schilp of Robert Bosch GmbH originally invented a fluorine-based chemistry process [5], which maintains verticality (anisotropy), by using the concept of alternate etch and passivation steps, which is also called the time-multiplexed deep etching (TMDE) [6].

The TMDE technique utilizes an etching cycle flowing only SF_6 (steps b and d in Fig. 10), which is similar to the normal reactive ion etching process, and then switching to a sidewall passivating cycle using only C_4F_8 (step c in Fig. 10). During the subsequent etching cycle, the passivating film is preferentially removed only from the bottom of the trenches due to vertical ion bombardment, while preventing etching of the sidewalls, which are covered by the passivating layer.

To achieve a high etch rate, a high power inductively coupled plasma (ICP) source is used in the DRIE system. The etch rate can now reach up to $50\,\mu m\,min^{-1}$. The etching process is carried out at room temperature. Photoresist and SiO_2 can be used as etch mask with silicon etching selectivity up to 150:1 and 400:1, respectively. Compared to the wet chemical micromachining of silicon, the DRIE process is direction-independent. Any planar shapes of microstructures can be created while the wet anisotropic etching can only etch rectangle holes on (100) plane.

Key Research Findings

The aspect ratio of the microtrenches is defined as the ratio of the trench depth to the trench width. DRIE can easily reach an aspect ratio of 30. With special recipe and high plasma power, the highest aspect ratio can reach as high as 100 [7]. The smallest feature size is dependent of the patterning capability. Using the normal optical lithogra-



Silicon Micromachining, Figure 13 Scanning electron microscope (SEM) photographs and atomic force microscope (AFM) measurement results showing the improved surface roughness of DRIE etched silicon sidewall by thermal oxidation process, (**a**) after DRIE, (**b**) after thermal oxidation, and (**c**) after removal of oxide layer

phy, 2 µm high aspect ratio silicon beams can be deeply micromachined with almost vertical angle as shown in Fig. 11. Associated with the DRIE process, the etch rate is feature-size dependent, which leads to the RIE-lag effect. Smaller feature size results in a lower etch rate. Due to the nature of the time-multiplexing of etch-passivation process, rough wave-shaped features (called scallops) appear on the etched sidewall. The roughness is about 50 nm as observed in Fig. 12. However, if the etch depth is more than 200 µm, the sidewall is much rougher due to the micromasking effect of the passivation layer of polymer. The rough sidewall surface can be smoothed by the thermal oxidation and oxide removal as indicated in Fig. 13. Silicon material is not bio-compatible. The microchannels, which are micromachined by DRIE, RIE or wet chemical etching, can be coated with silicon oxide by the thermal oxidation process as shown in Fig. 14. For bio-chip applications [8], using silicon is not a cost-effective solution. However, one can use micromachined silicon structures as micro-molds for the polymer, PDMS or silicone replications. In this case, the sidewall of the small trenches needs to be coated with a special thin layer for easy demolding of microstructures [9].

Future Directions for Research

Silicon micromachining technology is important in the fabrication of micro- and nanofluidic chips, MEMS/NEMS and other miniaturized devices [10]. Deep reactive ion etching opens new research opportunities for high aspect ratio silicon-based micro- and nanostructures for various applications. The etch rate needs to be increased to reduce the process time and costs. Further study should be focused on smoothing rough sidewalls of DRIE etched silicon microchannels in order to reduce the fluidic resistance. Ultra high aspect ratio micromachining technology needs to be further developed to fabricate sili-

con nanostructures. Furthermore, a new challenge will be on how to use surface micromachining, which is a compatible process with integrated circuits, for the integrated micro- and nanofluidic applications.

Macromolecular transport; Active particle flows; Brownian dynamics

Definitions

Polymer chains are long flexible molecules usually associated with organic molecules such as DNA. Their transport is important to many medical screening applications and can be described using Monte Carlo or molecular dynamics approaches.

Overview

The motion of large molecules in microfluidic flows is important because the trajectories of particles in shear flows do not always follow the local flow field. Therefore, a knowledge of the fluid dynamics is not sufficient to completely describe the motion of the particles. When a suspended particle does not track the flow, the particle is said to be active as opposed to passive. The dynamics of active particles are particularly interesting in microfluidic devices because the molecules of polymer chains can approach – and even exceed – the characteristic lengths of the device. Consequently, the deviations between the particle/molecular motion and the fluid motion can be significant.

While active particle dynamics can address the motion of any suspended particle in a fluid, microfluidic researchers are usually interested in polymer chains because these structures in general do not follow the fluid flow, have a high degree of flexibility, and model important biological subsystems such as DNA and many types of proteins. If we want to track or manipulate different polymer chains in

a microfluidic system, we need to understand their dynamics relative to the fluid flow. However, not only will the bulk motion deviate from what the fluid is doing, but also their conformation or shape can change, which alters the transport properties. In other words, as polymer chains travel in a fluid system, the inherent flexibility of the chains allow them to bunch up, stretch out or tumble in the flow. As the shape of the chain changes, the fluid forces imposed on the chain will also change. As a result, the motion of a flexible chain will vary even if the flow field remains constant. For microfluidic systems designed to sequence or hybridize DNA, for example, the conformation can be as important as the trajectory of bulk motion of the molecule.

Basic Methodology

The adjective *macromolecular* is often used to describe transport of molecules in systems as opposed to transport within a molecule. This distinction can be important because some of the same methods can be used to treat both systems. Depending on the size of the system, two general methods could be used to describe molecular motion in a fluid.

1. Molecular dynamics is a fundamental approach that requires only the knowledge of forces between individual atoms. This approach is useful only for the smallest microfluidic systems because modern computational architectures can only handle a few million atoms and a single nanoliter of water contains over 10^{16} atoms.
2. Brownian dynamics approximates a molecule as a structure with limited degrees of freedom and with continuum forces. This approach is useful for multi-scale simulations, which are characteristic of the vast majority of microfluidic systems. With this approach we no longer have to simulate each individual atom, but approximate the force due to a large group of atoms.

Molecular Dynamics

Molecular motion can theoretically be described using molecular dynamics. In this context, molecular dynamics describes the motion of a molecule in a fluid by accurately characterizing the force between any two atoms in the system including the molecules of the surrounding fluid. All forces in the system are summed and Newton's law is applied to each atom to deduce its individual motion. The motion of the molecule is deduced from the motion of its constituent atoms. Because of its fundamental nature, a molecular dynamics approach is often considered ab initio or "from first principles", meaning that there are virtually no fitting parameters required to obtain a physical solution. Nevertheless, the force between atoms, or ►inter-atomic potential, arises from a variety of chemical interactions (Van der Walls' force, chemical bonding, electrostatic) and in general, is difficult to characterize. (Discussion of the different potential fields and their application is beyond the scope of this article, but it should be noted that inter-atomic potentials often contain approximations and non-physical fitting parameters, so the ab initio designation is not always appropriate.)

Applications for molecular dynamics in microfluidic systems include, for example, protein folding in solution, transport of amino acids in ion channels, and locally driven electro-osmotic flows with rigid particles. However, these applications do not involve the bulk motion of a fluid and are extremely small, specialized systems. In general, the systems that microfluidic researchers consider are multi-scale in that they require knowledge of the bulk fluid motion, far-field boundary conditions, interactions with other molecules, walls and fluid structures, and other experimental conditions. Consequently, the molecular dynamics approach is rarely feasible or even necessary for multi-scale systems. Instead, researchers and analysts rely on ►coarse-graining techniques to reduce the degrees of freedom, where tractable solutions are more accessible.

Coarse-Grained Models

By coarse-graining, the molecular system is discretized and treated as a bead/spring system or bead/rod system. In the case of the bead/spring system, the molecule is treated as a series of beads with mass and size connected by springs. In the case of the bead/rod model, the molecule is treated a series of massless beads connected by rigid rods. The bead/spring system is simpler, but can allow the molecule to cross, which is unphysical, and is susceptible to computationally unstable solutions. The bead/rod model is mathematically and computationally more difficult, but the motion is often more realistic. In either case, the discretization or the number of beads used to model the chain is somewhat arbitrary but is chosen so that the behavior of the chain in a flow matches observations of the motion of actual chains. In the case of DNA, each base pair could be treated as a bead, but even this level of coarse-graining is usually far too fine to yield reasonable computational times and unnecessary to achieve accurate results. Instead, most simulations use anywhere from 5 to 20 sections depending on the complexity of the flow and resulting motion of the molecule that needs to be captured. Besides the reduction in the problem size, another advantage of coarse-graining is that the forces on the beads or rods can be described by continuum mechanics instead of requiring inter-atomic potentials. The forces common to most simulations include the following.

Drag

Drag forces arise from the difference between a bead or rod's velocity $\dot{\boldsymbol{r}}_i$ and the local velocity field of the fluid $\boldsymbol{u}_i$, with the difference scaled by the drag coefficient ζ, giving $F_D = -\zeta(\dot{\boldsymbol{r}}_i, -\boldsymbol{u}_i)$.
The drag coefficient depends on the size of the bead. In the case of rods, the local flow field may not be uniform across the rod, which gives rise to moments on the object as well. Because the motion of a rod involves an additional angular acceleration, the computations are often more involved.

Internal

The internal forces for coarse-grained models can be considered elastic (bead/spring) or rigid (bead/rod). Regardless of the method, the force connecting adjacent beads does not represent inter-atomic forces, but merely constricts the distance between adjacent beads. In general, the effect of a shear flow is to stretch the molecule, so an attractive force is applied to keep the molecule intact. For the spring-like model, several non-linear forms of for the attractive force have been proposed. For more information about the types and physical basis for the mathematical form of these forces, the reader is referred to [1, 2]. Although the rigid model (bead-rod chains) introduces an added level of complexity due to constraints on the motion, the results obtained using the bead-rod model are more accurate for a fewer number of beads. Furthermore, for more complex situations such as electric field induced motion and obstacle navigation, the bead/rod formalism is often considered more robust.

Electrostatic

A myriad of conditions could give rise to non-uniform charge distributions in the fluid. For example, electroosmotic flows or solutions of electrolytes are often used to manipulate microfluidic flows. In these situations, the macromolecule may be subject to Coulomb forces. There is no general expression to account for these forces, but they will depend on the location and strength of the charge distribution in the fluid as well as along the molecule.

Image

The force of the wall is modeled as a steep potential near a physical barrier. The force is called an image potential because the magnitude is derived from a phantom particle that is placed on the perpendicular to the wall and the particle near the wall. The phantom particle is exactly the same as the particle being repulsed, and the repulsive force is the force between two neighboring particles (instead of the wall). This approach allows one to consider variations in forces that arise from the particles without having to treat the wall differently.

Brownian

All other forces are essentially continuum forces, i. e. they would be present for a large-scale strand of beads and are not specific to molecules. The Brownian force, on the other hand, is only present for very small objects. This force is the result of individual atoms and other molecules in the flow bumping into the macromolecule to change its conformation. In the continuum limit, enough momentum exchange occurs in all directions so that the net force is zero. For small objects, the net force is some non-zero randomly oriented force that goes to zero over long times. However, in some non-equilibrium situations such as near walls, the Brownian force can be non-uniform.

Hydrodynamic

Objects in the wake regions of other objects are known to experience different flow characteristics compared to the bulk motion of fluid. Therefore, some beads in a macromolecule do not sample the bulk fluid, but a modified version of the bulk fluid because of the proximity of other beads in the flow. A great deal of research has gone into developing techniques and approximations to attempt to include this effect with varying degrees of success. The difficulty lies in the attempt to invent a general solution to a problem that is dependent on geometry, discretization of the molecule and flow characteristics. Discussion of these details are beyond the scope of this article. Instead the reader is referred to [3].

Other External

Many other forces could conceivably be important in macromolecule flows. For example,

1. magnetic forces could arise when dealing with magnetized particles in conjunction with macromolecules, which is often done in drug delivery and targeting.
2. Gravitational forces may be important if transport occurs in a centrifuge.
3. Many experiments also track macromolecules with fluorescent dyes. If the dye molecule is of the order of the transported molecule, then the dye can introduce additional drag.
4. Hybridization of DNA can provide a force at the ends of the macromolecules that tether the molecule to a surface.
5. Van der Waals forces can arise between polar objects.

Once the forces acting on the molecule are known, two approaches can be used to solve for the dynamics behav-

ior of the particles. Boltzmann-based models (also called Fokker–Planck systems) can predict average quantities through calculation of a distribution function.

$$\begin{aligned}\frac{\partial f}{\partial t} &= \sum_i \left(m_1^{-1} p_1 \frac{\partial f}{\partial r_i} + F_j \frac{\partial f}{\partial p_i} \right) \\ &= \sum_i \sum_j \frac{\partial}{\partial p_i} \zeta_{ij} \left(m_j^{-1} p_j f + kT \frac{\partial f}{\partial p_j} \right).\end{aligned} \tag{1}$$

Moments of f result in an average displacement field. This approach has largely been supplanted by non-averaging techniques because of molecular individualism [3]. In other words, instead of calculating average displacements, the behavior of individual molecules are of more interest in modern macromolecule transport.

To determine specific molecular motions, the Langevin approach is relatively straightforward and involves integrating Newton's second law,

$$\sum_i F_{ij} = m_j \boldsymbol{a}_j = m_j \frac{\mathrm{d}^2 x_j}{\mathrm{d}t^2}\,, \tag{2}$$

over time to calculate the displacement (motion) of each bead. In equation 1, i indexes each force acting on a bead and j indexes the beads in the simulation. Tractable solutions to this motion are only possible when time is discretized into tiny steps. Over each time step, the forces and acceleration are assumed constant. The integration scheme varies with the discretization of the molecule and type and magnitude of the forcing functions that are present. However, most generally applicable schemes are second-order accurate and involve some leap-frog technique where velocities are calculated at the half-time step. The two primary difficulties are including the Brownian force and the hydrodynamic interactions because these two forces are not independent of the solution resulting in a non-linear system of equations. If we assume that the momentum relaxation is much faster than the position relaxation of the Brownian particles, then the resulting equations can be simplified with a diffusion tensor that represents the influence of the Brownian force on average displacement [1].

$$\langle \Delta r_i \rangle = \sum_j \left(\frac{\partial \mathrm{D}_{ij}^0}{\partial r_j} + \frac{\mathrm{D}_{ij}^0}{kT} F_j^0 \right) t\,, \tag{3}$$

where the summation index spans the particles in three-dimensional space. In the foregoing expression, time is assumed to be greater than the momentum relaxation, i. e. $t \gg \tau^0 = m\mathrm{D}/kT$. The Oseen tensor is often used for D_{ij} [2], but appropriate expression of this diffusion component is the subject of a great deal of research.

The prediction of molecular motion is only as good as the effective forces that act between beads or rods. In the case of rigid rods connected by rotating joints, Kramer's bead chain rod system is the prevailing model. In this approach, the total length of the polymer is fixed, which may not be physically realistic in many cases. Yet, this model prevents the molecular strand from crossing itself, which is also physically unrealistic. The displacement of the beads is usually predicted from an optimization using the inter-bead distance as an internal constraint. For the bead-spring models, several different forms of inter-bead potentials have been used. The simplest model has a linear spring between each bead. This model tends to allow too much displacement, so an inverse Langevin model is used to stiffen the spring for larger displacements, which can be approximated as

$$F_j = \frac{Gr_i}{1 - (\frac{r}{r_0})^2} \tag{4}$$

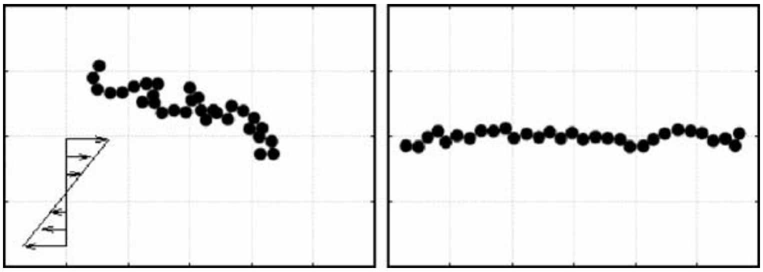
where G is the spring constant and r_0 is the relaxed molecule length. For DNA molecules, a worm-like chain model has proven remarkably successful, which has several forms that can be useful.

Key Research Findings

Research in macromolecular transport using Brownian dynamics is either fundamental in that a parameterized class of fluid flow conditions is considered, or a particular experiment is modeled with well-known geometric and fluid conditions.

In the study of molecular transport and conformation in simple flows, results suggest that the motion is not very simple. Many polymers have fairly complex shapes when in a quiescent fluid. They can be coiled, straight, curved or a combination of different shapes as seen in Fig 1. This tendency is important when discussing transport in a ▶ shear flow. Both simulations and experiments produce molecular shapes described as coils, dumbbell, linked, half dumbbell, straight and folded, all in a single longitudinal shear flow. Moreover, for varying flow parameters, the shape can transition between the different forms, and the transition is unpredictable. Similarly, in linear shear flows, the motion can be characterized as longitudinal (perpendicular to the shear direction), tumbling, or globular. Transition between flows can occur without changing flow parameters. The transition rate, however, is usually governed by the strength of the shear.

S



Simulating Migration of Polymer Chains, Methods, Figure 1 Conformation of a 30-bead chain in a linear shear flow at different times. The chain shown will exhibit a periodic tumbling motion if observed for long periods of time

These results suggest that control of a single polymer chain in a flow is difficult because of the unpredictability of any specific molecule. However, we are usually interested in the motion of a large number of molecules in a micro-fluidic system. Therefore, statistics are collected on a single molecule given a variety of initial conditions, for example. Then predictions about the average behavior of certain types of molecules in certain types of flows can be made.

The non-dimensional Weissenberg number ($\mathrm{Wi} = \dot{\gamma}\lambda$) is defined as the product of fluid strain rate ($\dot{\gamma}$) and the longest relaxation time of the polymer chain (λ). This number provides an approximation to the ratio of ability of the flow to stretch the polymer chain divided by the tendency of the chain to resist stretching. For large Wi, the flow generally results in stretching of the molecule; for small Wi, the molecule's conformation is dominated by Brownian motion.

Other studies of polymer transport focus on how long molecules behave in a complex flow in the presence of obstacles. For example, one group has examined how DNA migrates through a field of posts where the strands straddle the obstacle. Simulations of this type are useful to help predict the resident time of DNA in a particular region. This might be important to researchers who are using micro-fluidic chambers to produce chemical reactions with DNA, for example.

Future Directions for Research

Two research direction emerge from existing studies and needs in the community. (1) Fundamental studies focus on the physics governing the relationship between the forces acting on the beads. (2) Applied studies focus on how molecules behave in different systems.

In terms of fundamental studies, modeling of polymer chains is still in its infancy. Although there are plenty of instances where experiments and simulation converge, there is no general purpose, all-encompassing simulation approach that works universally. The primary difficulty arises from resolving the relative strengths of each force acting on the molecule. In isolation, each force can be described mathematically with a good deal of rigor. However, the relative magnitude of each force relies on difficult to characterize free parameters. Therefore, simulations still rely on experiments to provide data for accurate simulations. A first-principles simulation is simply not possible yet. Consequently, much of the current research is devoted to refining the force models to include more physics in simulations.

In terms of applied studies, different configurations are constantly being addressed to help analyze specific experimental studies and to help provide ranges for the free parameters associated with the forces.

To address both of these concerns, the following areas are suggested as immediate research areas where substantial contributions can be made.

Complex Flows

Most fundamental simulations examine simple flow situations such as elongation and linear shear flows. These flows appear in many micro-fluidic structures, and include a wide range of effects that molecules might experience. In addition, the flow solution is simple and can be reliably produced in the lab. Therefore, there is continued need to investigate these configurations. However, these simple flows do not represent all situations seen in modern micro-fluidic devices. For example, stagnation point flow into a stationary wall, flow around corners and flow mixing are all complex phenomena that affect polymer chain transport and conformation.

Overlap Models

Although the bead spring model appears adequate for many situations, more complex flows can cause interaction of a molecule with itself. For bead-spring models, this can be treated by introducing strong, short-range potentials. Because of the large gradients, however, simula-

tions are prone to exaggerated motion when non-adjacent beads approach each other. The bead-rod model attempts to account for the interaction by preventing the coarse-grained model of the chain from crossing itself. This approach can be relatively complex and a universally agreed upon approach has not been established.

Wall Interaction

Typically a wall is modeled with an image potential. In this case, a virtual particle that is located at the mirror location to the real particle provides an interaction potential. As such there is often an artificial buffer that prevents the bead from contacting the wall and migration away from surfaces is possible. Even though these interaction potentials have a short range, they can be strong to prevent beads from penetrating walls. As a result, time stepping becomes crucial, and too large of a time step can result in physically unrealistic motion. New methods to treat this artifact are needed to provide transport in confined channels.

DNA Hybridization

In the case of DNA transport, the researcher is often interested in hybridization, which is a reaction that changes the characteristics of the chain or causes additional forces. Motion in the presence of interaction particles is complex and has not received much attention.

Analysis of individual cell contents

Definition

►Chemical cytometry is a class of highly sensitive analytical techniques for the analysis of the chemical contents of single cells. These techniques enable the detection and identification of cell constituents including oligonucleotides, small molecules, and proteins, as well as providing means to monitor the effects of biochemical and enzymatic reactions.

►Capillary electrophoresis is an analytical technique used to separate chemicals in solution as a function of their charge and size. Samples are injected into a capillary, a high electric field is applied, and the analytes migrate to the end of the column, where they are detected.

S

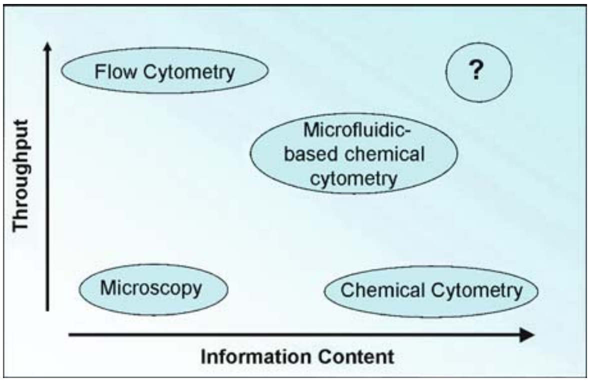
Overview

The cell is a complex biochemical factory, capable of proliferation, differentiation and communication. The cell also interacts with its microenvironment, comprised of other cells, tissue matrix and interstitial vascular, lymphatic and non-biological compartments. Yet most of what is known about the correlation between behavior, function and genotype of biological cells comes from *average* measurements of cell populations. While useful, these studies are unfortunately incapable of assessing the response and interaction of individual cells within a heterogeneous population. As an illustration, a recent study [1] of hormone-induced maturation of unfertilized eggs (oocytes) as a function of enzyme activation was evaluated both based on populations and individual cells. The population data suggested a *graded* relationship between

the hormone (progesterone) concentration and enzyme activation while the single cell data revealed a sharp *all-or-nothing* switch. The single cell analysis approach can in fact provide not only complementary information but rather reveal the actual functional interaction of biomolecules thus assisting in understanding complex biological systems on the cellular and tissue structural basis. This kind of biological insight is required to understand complex systems such as tissues, organs and even complete organisms. While it is obvious that this type of work is useful, single cell studies are much more complicated and time-consuming than their population counterparts; in fact, single cell analyses push the boundaries of conventional techniques.

Several single cell analysis techniques have been developed, which may be classified in terms of information content (# of elements capable of being studied simultaneously) and throughput (# of cells studied in a given time) – this is illustrated in Fig. 1. The simplest and most widely used forms of single cell analysis are fluorescence microscopy and flow cytometry. In microscopy, fluorescence from small molecule reporters, immunochemical labels, or transfected fluorescent proteins within cells is observed with subcellular localization. While this technique enables the measurement of time-dependent changes in response to stimuli of individual cells as well as cell-cell interaction studies, it is an inherently low-throughput method if used with high magnification. Conversely, flow cytometry is a high-throughput technique that can be used to analyze up to several tens of thousands of cells per second but is limited in the type of assays for which it can be used and does not provide subcellular resolution. Multiple wavelength analysis schemes have been developed, but the number of parameters which can be measured simultaneously is intrinsically limited by the finite spectral bandwidth of the detectors and the increasing complexity of using multiple fluorophores, excitation sources, and/or detectors. These two techniques therefore are classified in the region of low information content space in Fig. 1.

In order to achieve a more comprehensive analysis of individual cells, methods that incorporate chemical separations have been developed to increase the number of parameters capable of being studied simultaneously. These techniques, termed *chemical cytometry* by Dovichi and coworkers [2] are used to detect and identify various components of single cells such as oligonucleotides, small molecules and proteins, as well as to monitor enzyme activity. Capillary electrophoresis (CE), laser-induced fluorescence (LIF), and electrochemistry are the tools which are used in chemical cytometry; this chapter deals with capillary electrophoresis implemented in microfluidic devices.



Single Cell Analysis in Microfluidic Devices, Figure 1 Chart comparing single cell bioanalytical techniques in terms of information content and throughput

CE-based chemical cytometry can be used to evaluate many cell constituents simultaneously, and is thus, as shown in Fig. 1, categorized as a high information content technique. This comes at a cost, however, as the cell injection schemes and use of a single capillary makes the technique extremely low-throughput. Ideally, the contents of hundreds of cells could be individually analyzed for statistical evaluation of the heterogeneity of a population; in practice, however, the arduous and time-consuming nature of chemical cytometry typically limits it to a few cells (i. e., < 10) per analysis.

In recent years, microfluidics has become a popular technology for applications in the life sciences. The continued development of new microfabrication techniques has permitted the integration and scaling down of several bioanalytical procedures into a single device, from which emerged the concept of Lab-on-a-Chip or micro total analysis system (μTAS). Microfluidic devices have several advantages over conventional bioanalytical techniques: low reagent and power consumption, low cost, and the potential for mass production and massively parallel scale analysis. As illustrated in Fig. 1, the application of microfluidics to chemical cytometry may result in a solution to the low-throughput problem of capillary-based chemical cytometry techniques, forming a new class of methods with high-throughput and information content. Several good reviews have been recently published covering the potential of microfluidics for applications involving cells [3, 4]. Microfluidics has been applied to microscopy, flow cytometry, and chemical cytometry, among others. As microscopy and flow cytometry are discussed in detail in other chapters in the *Encylopedia* (► flow cytometer lab-on-chip devices, ► detection using confocal microscopy), we focus here on chemical cytometry. In what follows, we discuss the state-of-the-field and

challenges remaining to be solved in the areas of fabrication, cell selection/transportation, cell lysis/treatment, and analysis, from the standpoint of microfluidic method development for high-throughput chemical cytometry.

Basic Methodology

Fabrication Considerations

There are many well-established microfabrication techniques which can be used to construct microfluidic devices (▶ microfabrication techniques). Each has strengths and weaknesses, but the choice of fabrication technique ultimately depends on cost, availability of the facility, and most importantly, on compatibility with the desired application. This is especially important for chemical cytometry, where the fabrication process must be versatile enough to form devices capable of implementing the many necessary functions. Key considerations for fabrication of chemical cytometry include material, integration, and macro-to-micro interface.

Material

The materials used for the fabrication of most microfluidic chips include glass, silicon, quartz, and plastics (▶ materials used in microfluidic devices) In addition to cost and optical, electrical and physical properties, careful consideration must be given to the surface chemistry of the material (▶ methods for surface modifications). In fact, surface chemistry plays a major role in chemical cytometry, as protein adsorption to the channel walls can degrade the separation performance and make the electroosmotic flow unreproducible.

Integration of Multiple Components

The functionality and versatility of microfluidic devices for chemical cytometry requires the combination of several cell manipulation, processing, and analysis steps. These techniques, discussed in detail in the next section, rely on device components such as microstructures, optical windows, electrodes, embedded waveguides, and valves and pumps; each of which must be miniaturized and integrated on a single microfluidic platform (please refer to the following chapters ▶ fabrication of 3D microfluidic structures, ▶ on-chip waveguide, ▶ pneumatic valves, ▶ thermomechanical valves, ▶ thermopneumatic valves). Integrating multiple components on a single device dramatically increases the complexity of the final product and introduces compatibility problems in the various integrated functions. For example, surfaces designed to promote or prevent cell adhesion (for cell manipulation) are often different than surfaces best suited for electrophoretic separations. These engineering challenges are a bottleneck in the development of multifunctional microfluidic devices and must be addressed for the development of high-throughput chemical cytometry.

Macro-to-Micro Interface

A key concern for all microfluidic devices is the macro-to-micro interface. The complexity of the interface depends on the number of integrated functions (see ▶ packaging (including wire bonding)).

Cell Manipulation and Transportation

One of the most critical steps in single cell analysis is selection of predetermined individual cells and transportation through the device (▶ techniques for manipulating cells, ▶ microfluidic sample manipulation). The manipulation and transport techniques used for chemical cytometry should be multiplexed, have the potential for automation, and, depending on the assay, should have minimal biological or chemical impact on the cell(s) to be transported. Techniques fitting this description include cell sorting and integrated flow cytometry (▶ cell sorting, optophoresis for cell sorting, ▶ flow cytometer lab-on-chip devices). Several micromanipulation techniques based on mechanical, electrical and optical means have been developed for cell-based assays in microfluidic devices.

Mechanical Manipulation

While micromanipulators and micropipettes are routinely used for in vitro fertilization studies, they are bulky, suffer from low throughput and are not amenable to integration with a sealed microfluidic device. Other mechanical manipulation techniques include microfilters, dams, and *sandbag* structures. We note that these techniques are often used to capture, dock or sort many cells simultaneously without specificity and thus are limited in their use for single cell analysis where selecting a particular cell is a key goal.

Electrical Manipulation

The electric charge or polarity of cells (and cell contents) may also be used for manipulation and transportation within microfluidic devices. In contrast to mechanical methods, the use of electric field based approaches such as electrokinetics and dielectrophoresis are well-suited for microfluidics as they permit flexibility, controllability, automation and high-throughput capability. We note, however, that these kinds of techniques can produce undesired biological stress such as protein migration and clustering within the cells and in high fields, cells may

even lyse (i. e., die). For more information, please refer to the following *Encyclopedia* chapters: ► dielectrophoretic motions of particles and cells, ► electrokinetic motion of cells and non-conductive particles, ► AC dielectrophoresis Lab-on-a-Chip devices.

Optical Manipulation

Optical micromanipulation techniques use lasers to apply piconewton forces on micron sized particles, and have been demonstrated to be useful for cell transportation in microchannels. One of the most popular optical techniques is ► optical *trapping* (or optical/laser tweezers), which is implemented by focusing a laser to a diffraction-limited spot by a high numerical aperture (N.A.) microscope objective. Although optical trapping can be used to select particular cells accurately, its slow translational speeds (20 – 30 μm/sec) [5] makes it a low-throughput cell manipulation technique. We note that some have used diffractive optical elements (DOEs) and spatial light modulators to create multiple *optical traps* simultaneously, thus improving throughput [6]. These techniques are described further in ► optical tweezers for manipulating cells and particles. Another alternative in optical manipulation is laser-guided direct writing, in which a weakly collimated or converging beam pushes cells to desired locations [7]. This technique has been used to transport cells at 88 μm/s over several millimeters. A similar transportation technique was developed using evanescent waves from integrated waveguides to manipulate micron size particles [8]. While these two techniques suffer from lack of cell selectivity, they could potentially be automated to increase throughput in chemical cytometry by strategically positioning the integrated waveguides within the microfluidic device.

Cell Lysis/Treatment

In conventional population cell-based assays, sample preparation involves several steps, including lysis, filtration of non-solubilized cellular material, labeling of the analytes of interest, and sample purification. However, to prevent dilution of the extremely small samples in single cell analysis, filtration and purification are not typically integrated in chemical cytometry methods. This section briefly describes the various cell lysis techniques which have been implemented in microfluidics; for more detail, please see ► on-chip cell lysis.

In CE-based chemical cytometry, the quality of the information is ultimately determined by the manner in which the cells are lysed and their contents injected into the capillary. The technique employed to perform this task must be carefully designed to enable high quality, reproducible electrophoretic separations. Dilution of the contents of the cell prior to application of the electric field must be reduced to maximize sensitivity and resolution of the separated analytes. Lysis should occur in a manner such that the biochemical contents of the cell are not altered, for example, by the activity of proteases that are usually kept partitioned away from free cellular proteins. The technique must also address capillary clogging issues which result from the presence of insoluble cell debris. Finally, the lysis technique must be able to function in parallel for high-throughput applications. There are three categories of cell lysis techniques: electrical, mechanical and chemical lysis.

Electrical Lysis

When a large electric field is applied across a cell, the transmembrane potential is disrupted and pores are formed on the surface of the membrane. This phenomenon is called ► electroporation and is often used for gene transfection. As conventionally implemented, the process is reversible, and when the electric field is terminated, the pores close. The phenomenon can also be used to cause permanent disruption of the membrane, effectively lysing the cell. There have been several reports on the use of electrical lysis techniques in microfluidic devices [9–11]. Of particular interest, fast lysis of individual cells (∼ 33 ms) by electrical pulses for chemical cytometry was demonstrated in a microfluidic platform [12]. These extremely rapid lysis methods which minimize unwanted effects of slow lysis (that may bias the results) make these techniques favorable for protein analysis when compared to chemical lysis techniques. One drawback of electrical lysis is that much of the cell membrane, subcellular structures and the nucleus may remain intact and thus can clog the channe or adhere to the surface, affecting the separation and limiting the capacity for re-use.

Mechanical Lysis

Typical lysis techniques based on mechanical forces such as sonication and bead milling are not amenable for integration in a microfluidic device; however, in recent work, cells were lysed in microchannels by mechanical shearing on nanostructured filter-like *nano-knives* [13]. This method had the additional advantage of aiding subsequent analysis steps by filtering out cellular debris thus preventing clogging and sample fouling.

Chemical Lysis

The most common macro-scale cell lysis methods make use of chemical agents; as a result, several research groups have used similar techniques to lyse cells in microfluidic

devices [14–16]. While detergents such as sodium dodecyl sulfate (SDS) permit a greater number of proteins to be analyzed due to the capacity to solubilize membrane proteins and lipids, chemical lysis reaction times are relatively slow (tens of seconds). Therefore, this technique may not be ideal for applications in which desired biological events take place on time scales of seconds or less (e. g., metabolite concentrations can change by a factor of 10 within 1 s [17]) or when diffusion of the cellular content within the microfluidic chip structure can not be suppressed.

Analysis

While an array of analytical techniques has been developed to study various aspects of cells (please see ▶ cell assays in microfluidics), this chapter is focused on chemical cytometry. As mentioned above, chemical cytometry refers to methods in which intracellular constituents of a single cell are analyzed by means of a chemical separation. Such methods typically employ capillary electrophoresis for separations, combined with laser induced fluorescence (LIF) or amperometry for detection. We refer readers to other chapters for detailed descriptions of other methods used to evaluate contents of cells (▶ patch–clamp measurements on-chip, ▶ mass spectrometry on chip device).

In capillary-based chemical cytometry, a cell is injected into a capillary, where it is lysed, and then its contents are separated by electrophoresis. The separating contents are detected at or near the end of the capillary, as the analytes migrate past the detection zone. Microfluidic devices are well-suited to replace capillaries for chemical cytometry. The channel dimensions (5 – 100 μm) and planar geometry allow for very efficient dissipation of Joule heat produced from large electric field gradients. The capacity to apply high fields (e. g., 500 – 1000 V/cm) dramatically reduces separation time and minimizes band diffusion. Most importantly, the small channel dimensions can handle injection volumes ranging from nanoliters to hundreds of femtoliters [18], and thus results in minimal dilution of sample.

The level of expression of protein species within a single cell ranges between several millions to under 10 copies, requiring that extremely sensitive detection techniques be employed. LIF is particularly well suited for this task as it is capable of achieving mass concentration detection limits of a few tens of molecules and even single-molecule detection [19]. Amperometry has also been used frequently due to its high sensitivity. A more detailed look at these two techniques can be found elsewhere (▶ fluorescence measurements, ▶ amperometric techniques).

Key Research Findings

Over the past few years, several groups have attempted to integrate all of the critical processes for chemical cytometry on a single mirofluidic plattform. Various combinations of cell manipulation, cell lysis, and analysis strategies were used to obtain high content information with the goal of maintaining analysis in a high-throughput format. Some methods were optimized for analysis of small molecules and proteins, while others were developed for genetic assays, evaluating DNA or RNA content.

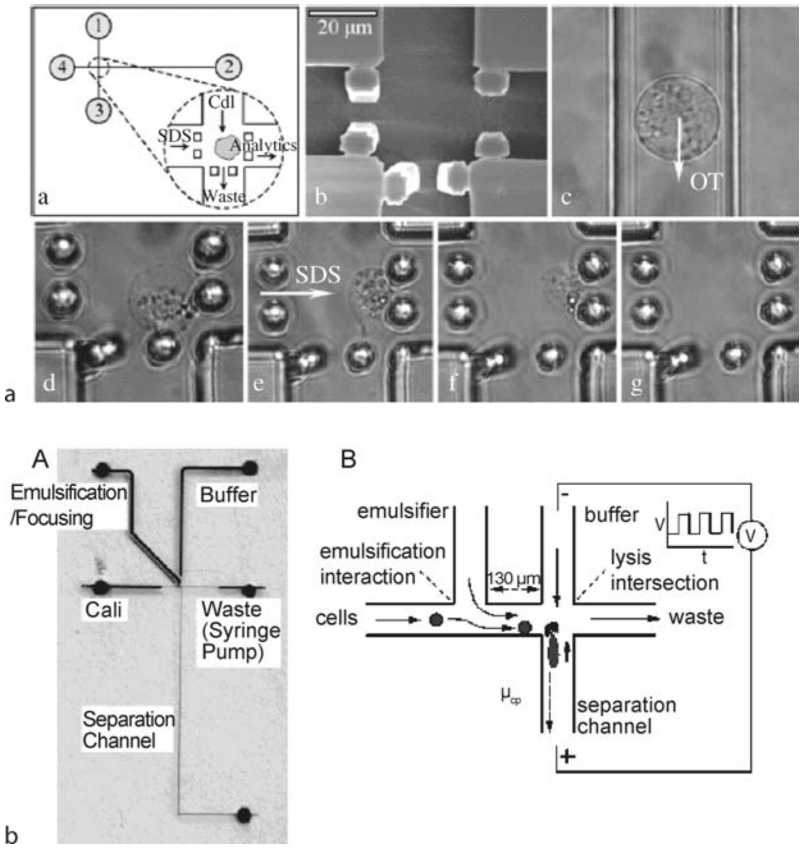
Protein or Small Molecule Analysis

Fang and coworkers [9] developed a glass microfluidic chemical cytometry device with a simple cross-shaped channel design. Derivatized glutathione (GSH) in single human erythrocyte cells was separated and detected by LIF. Cells were transported from the reservoir to the T-junction by hydrodynamic flow, which was controlled by adjusting the amount of liquid in the four reservoirs; fine positioning was performed by applying a series of voltages to *dock* the cell. Once positioned, each cell was electrokinetically lysed. This technique yielded a throughput of approximately 15 cells/h.

Hellmich et al. [20] designed a PDMS device comprising a cross-junction integrated with other micro-scale features as shown in Fig. 2a. GFP-transfected insect cells were selected and transported to the intersection using optical tweezers. After positioning, the cells were lysed with SDS; the microstructures acted as a physical cell trap, preventing the cell from moving away during the process. After each cell was lysed, fluorescently labeled contents (amino acids and proteins) were separated by electrophoresis and detected with LIF.

McClain et al. [12] also developed a microfluidic device that integrated cell handling, lysis and electrophoresis, as shown in Fig. 2b. The device was evaluated with T-cells loaded with fluorogenic dyes which were separated and detected by LIF. Cell transport and lysis were accomplished using electric fields. In order to reduce Joule heating, lysis was effected by superimposing AC fields on the DC fields used for separations. This technique enabled separation to be maintained throughout the process; lysis was completed within 33 ms and a throughput of 7 – 12 cells/min was achieved with a separation efficiency ranging from 2300 to 4000 theoretical plates.

As an alternative to using AC fields, to prevent excessive Joule heating, Wang et al. [21] designed a microfluidic device with channels having variable cross-sections which modulated the local electric field strengths. Chinese hamster ovary cells labeled with calcein AM were used to

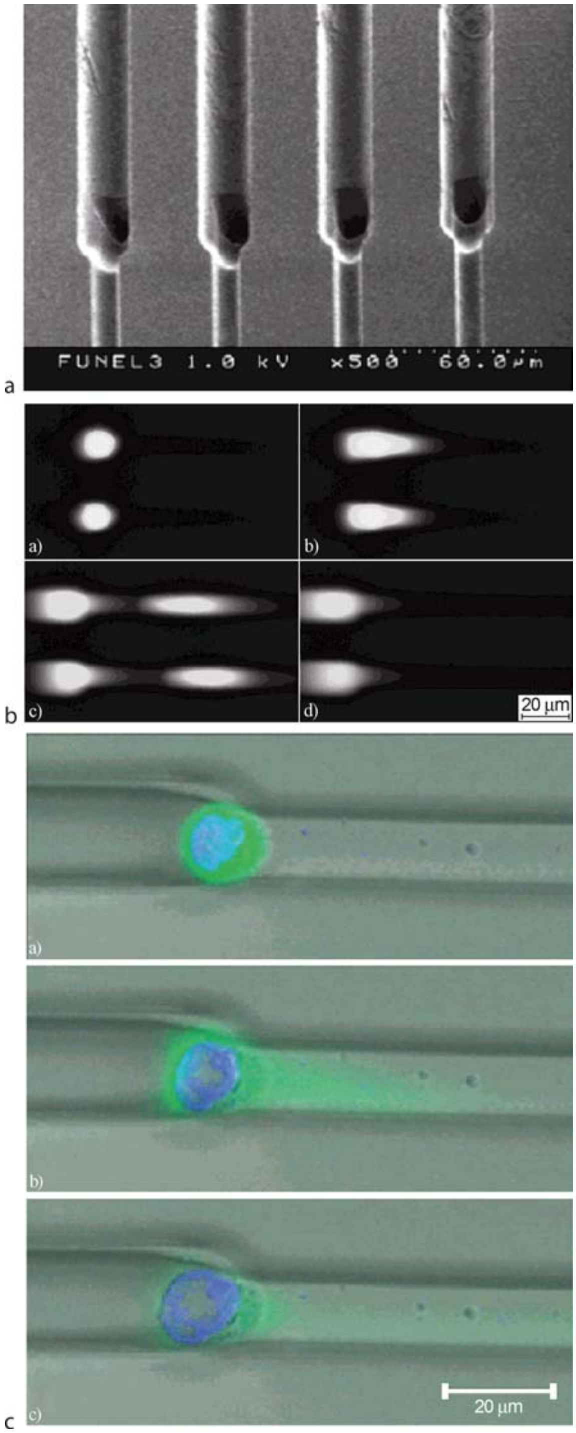


Single Cell Analysis in Microfluidic Devices, Figure 2 (**a**) PDMS single-cell microfluidic device with T-junction and integrated cell trap, formed from micron-sized posts. The cell is transported with optical tweezers (OT) to the intersection, followed by the delivery of the surfactant, SDS, to lyse the cell. (Image reproduced from [20].) (**b**) Design for high-throughput chemical cytometry; this method uses a combination of AC and DC electric fields for cell lysis and electrophoresis. (Image reproduced from [12])

test the device. The cells were driven to the T-junction by hydrodynamic flow generated by a syringe pump. Once at the junction, the cells were lysed and the contents were separated by electrophoresis and detected.

To increase throughput and eliminate sample cross-contamination, which is common when analyzing cells sequentially, Munce et al. [22] developed a microfluidic device with four parallel CE channels. Calcein-labeled acute myloid leukemia cells were selected and transported with optical tweezers to injector structures at the entrance of each channel, as shown in Fig. 3a. Once loaded, the cells were lysed by the combined action of an applied electric field and the reduction in channel cross-section (Fig. 3b). The injector design also enabled stepwise lysis of the cell, shown in Fig. 3c, where only the cyctoplasmic material (containing calcein AM in green) was injected into the capillary while the nucleus (stained blue with Hoechst 33342) remained in the injector structure. This selective lysis is especially useful to separate the cytoplasm from the nucleus and finally the membrane particularly if protein signalling is the focus of the application. The injector structures also prevented extracellular debris from entering the channels. Once loaded in the capillary, the analytes were separated and detected with LIF. The throughput was estimated to be 24 cells/h; however, this could be increased with additional separation channels.

Wu et al. [23] designed a PDMS microfluidic device for chemical cytometry, consisting of integrated valves which formed a reaction chamber and a picopipette for reagent delivery. The system, depicted in Fig. 4a, allows for individual cells to first be isolated in a closed chamber, and then be combined with an aliquot of lysis and fluoresecent derivatization reagents, delivered by the picopipette. After lysis and derivatization, the valves are opened and voltage is applied to separate the derivatized amino acids. Figure 4b shows an electropherogram collected from a single Jurkat T cell compared to one generated from a population of cells with off-column lysis and derivatization. With the pneumatic valves, 70-picoliter reaction chamber, and



Single Cell Analysis in Microfluidic Devices, Figure 3 (**a**) Four parallel laser-etched injector structures in PMMA. picopipette, this device simultaneously addresses the problems of fluid control and reagent delivery without affecting sample dilution. This system could also be implemented in parallel to increase throughput.

As an alternative to LIF, Xia et al. [24] used amperometry to detect the contents of single wheat callus cells. In this work, cells were transported electrokinetically to a double T-junction, and docked, after which they were lysed by a DC electric field. Ascorbic acid and other analytes were separated by electrophoresis and detected by means of an amperometric detector.

DNA Analysis

A study of doxorubicin-induced apoptosis (programmed cell death) in individual cardiomyoctes was performed using a microfluidic device created by Horky and coworkers [25]. Apoptotic DNA fragments from individual cells were electrophoretically separated and detected by LIF. The device consisted of a simple cross channel design; cells were injected into the device and transported by pressure-driven flow by application of a vacuum. Cell lysis was achieved by activating an electric field across the T-junction, which was filled with a 2% solution of linear polyacrylamide.

Quake and coworkers [16] developed a PDMS microfluidic device (shown in Fig. 4c) for nucleic acid purification from a small number of bacterial or mammalian cells. This multilayer device contained fluidic channels and a system of membrane-actuated pneumatic valves and pumps, which enabled precise control of buffers, lysis agents and cell solution, and also allowed for parallel processing. Bacterial cells, dilution buffer and lysis buffer are first introduced into the chip and then transferred into the rotary mixer. Once mixed, the lysate is flushed over a DNA affinity column and drained. The DNA is recovered from the chip with an elution buffer for further analysis. We note that this is the only microfluidic chemical cytometry device to use a separation method other than solution-phase electrophoresis (i. e., solid phase extraction).

Future Directions for Research

This chapter has outlined the challenges inherent in chemical cytometry, i. e., the separation and detection of the contents of a single cell. Microfluidics is a promising technology in the goal of developing high-throughput chemical cytometry techniques, which require robust and repeatable means for cell transportation, lysis and analysis applied in parallel (or very rapidly in series). The current methods have established proof-of-principle; however, much work remains to be done, especially related to scaling up for parallel analysis.

Definition

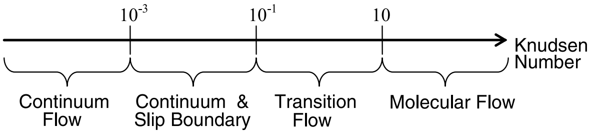
When gases are at low pressures, or are flowing in small geometries, the interaction of the gas molecules with the wall becomes as frequent as intermolecular collisions. This type of flow is known as rarefied gas flow. Typically, macrochannel boundary conditions, gas velocity and temperature that are applied to fluid flow and heat transfer equations are equivalent to the corresponding wall values. In contrast, these conditions do not hold for rarefied gas flow in microchannels. The Knudsen number (Kn) is used to represent the rarefaction effects. It is the ratio of the molecular mean free path to the characteristic dimension of the flow (i. e., the channel hydraulic diameter). The mean free path is defined as the average distance traveled by a molecule before colliding with another molecule. As Kn takes higher values, due to a higher molecular mean free path by reduced pressure or a smaller flow dimension, rarefaction effects become more significant. Kn is an important parameter to explain the surface effects in gaseous flows in microchannels in determining the pressure drop and the heat transfer coefficient. The continuum flow assumption will only be valid when $Kn < 10^{-3}$. As Kn increases, the flow enters the slip flow regime ($10^{-3} < Kn < 10^{-1}$), transition flow regime ($10^{-1} < Kn < 10$) and eventually the free-molecular flow regime ($Kn > 10$). These four regimes are illustrated in Fig. 1.



Single-Phase Gaseous Flow, Figure 1 Flow regimes identified by the Knudsen number

Overview

Gaseous flow in micro- and minichannels has been extensively investigated, and it is very important in microdevice development and design. Although several contradictory results have been published related to pressure drop and heat transfer coefficients, a few experiments were also performed to verify the theoretical results and some arguments are also made to explain those discrepancies.

Continuum Regime

The velocity, density, pressure and other properties of a fluid are all defined at every point in space and time and the solutions of fluid flow in the continuum regime are obtained by using the Navier–Stokes equations. For incompressible flow with constant properties we have the following.

Conservation of mass:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{v}) = 0 \tag{1}$$

Conservation of linear momentum:

$$\rho \left(\frac{\partial \boldsymbol{v}}{\partial t} + \boldsymbol{v} \cdot \nabla \boldsymbol{v} \right) = \rho g - \nabla p + \mu \nabla^2 v \tag{2}$$

Conservation of energy:

$$\rho c\left(\frac{\partial T}{\partial t}+\boldsymbol{v}\cdot\nabla T\right)=k\nabla^2 T+\Phi \tag{3}$$

where $\boldsymbol{v}, t, p, T, \mu, k, c, g$ and ρ are velocity, time, pressure, temperature, viscosity, thermal conductivity, specific heat, gravity and density respectively.

The fluid velocity and temperature in this regime are equivalent to the corresponding wall conditions. The boundary layer approximations for a two-dimensional fluid flow in Cartesian coordinates (x, y) are given as

$$u \gg v\,, \qquad \frac{\partial u}{\partial y} \gg \frac{\partial u}{\partial x}, \frac{\partial v}{\partial x}, \frac{\partial v}{\partial y} \tag{4a}$$

$$\frac{\partial T}{\partial y} \gg \frac{\partial T}{\partial x} \tag{4b}$$

The Nusselt number (Nu) for laminar, fully developed flow is constant and independent of the Reynolds number (Re), the Prandtl number (Pr) and the axial location of the channel.

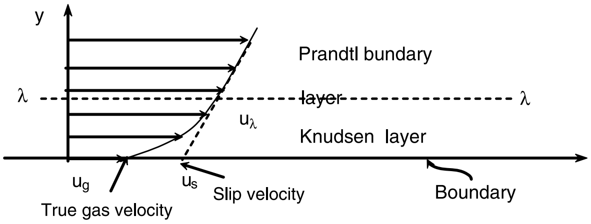
Slip Flow Regime

The current standing on the study of gaseous slip flow in microchannels stipulates that, although the continuum assumption is no longer valid within the slip region, Navier–Stokes equations are still applicable with some boundary modifications. The continuum model will apply at the core of the flow and a modified molecular/continuum boundary condition at the boundaries. That is, the Navier–Stokes equations are applicable except in the layer next to the surface. The commonly used slip boundary conditions are called Maxwellian boundary conditions. Since they are first order in accuracy, other extended boundary conditions are proposed in [1]. In the Knudsen layer, the layer one mean free path away from the boundary, the Maxwellian velocity slip boundary condition approximates the true gas velocity at the boundary by the velocity that the molecules would have if a linear velocity gradient existed, as shown in Fig. 2. In other words, the magnitude of the slip is calculated from the velocity gradient evaluated at $y = \lambda$.

The first-order approximation to the velocity slip within the Knudsen layer is given by

$$u_{\mathrm{s}} = \frac{2-F_{\mathrm{m}}}{F_{\mathrm{m}}}\lambda\frac{\mathrm{d}u}{\mathrm{d}y} \tag{5}$$

Another characteristic of rarefied gas flow is that there is a finite difference between the fluid temperature at the wall and the wall temperature. The temperature jump is first proposed to be



Single-Phase Gaseous Flow, Figure 2 Schematic of the first-order slip velocity approximation

$$T_{\mathrm{s}} - T_{\mathrm{w}} = c_{\mathrm{jump}}\frac{\partial T}{\partial y} \tag{6}$$

The thermal accommodation coefficient is defined as

$$F_{\mathrm{T}} = \frac{Q_{\mathrm{i}}-Q_{\mathrm{r}}}{Q_{\mathrm{i}}-Q_{\mathrm{w}}}$$

where Q_{i} is the energy of the impinging stream, Q_{r} is the energy carried by the reflected molecules and Q_{w} is the energy of the molecules leaving the surface at the wall temperature. F_{T} can be defined as the fraction of molecules reflected by the wall that accommodated their energy to the wall temperature. Let us assume that the temperature of the approaching molecules is T_{s}. The energy difference of these molecules can be written as the summation of the kinetic energy, internal energy and contribution of the incoming molecules to the conduction minus the energy of the outgoing molecules at the wall temperature as

$$Q_{\mathrm{i}} - Q_{\mathrm{w}} = \frac{c_{\mathrm{v}}\left(T_{\mathrm{s}}-T_{\mathrm{w}}\right)(\gamma+1)P}{2\sqrt{2\pi RT}} + \frac{1}{2}k\frac{\partial T}{\partial y} \tag{7}$$

where $R = c_{\mathrm{p}} - c_{\mathrm{v}}$ and $\gamma = c_{\mathrm{p}}/c_{\mathrm{v}}$.

The net energy carried to the surface, $Q_{\mathrm{i}} - Q_{\mathrm{r}}$, is equal to the heat flux at the wall

$$Q_{\mathrm{i}} - Q_{\mathrm{r}} = k\frac{\partial T}{\partial y}\,. \tag{8}$$

Therefore the temperature jump in Eq. (7) is derived to be [2]

$$T_{\mathrm{s}} - T_{\mathrm{w}} = \frac{2-F_T}{F_T}\,\frac{2\gamma}{\gamma+1}\,\frac{\lambda}{\mathrm{Pr}}\,\frac{\partial T}{\partial y} \tag{9}$$

Equation (9) gives the first-order approximation to the temperature jump, and it is assumed that the temperature gradient at the wall is the same as that at $y = \lambda$. The same

S

approach is applied to obtain the second-order velocity slip equation [1]. This results in

$$\theta_s - \theta_w = \frac{2 - F_T}{F_T} \frac{2\gamma}{\gamma + 1} \frac{\mathrm{Kn}}{\mathrm{Pr}\,(1 - a\mathrm{Kn})} \left(\frac{\partial \theta}{\partial \eta} \right)_0 \tag{10}$$

where $\theta = T/T_{\text{reference}}$ and a is a variable.

The gaseous flow heat transfer problem in the slip flow region is solved both analytically and numerically. Larrode et al. [2] solved the problem for micro-circular tubes with constant wall temperatures. Beskok et al. [3] presented computational results in the slip flow region for Knudsen number less than 0.3. Yu and Ameel [4] studied laminar, fully developed slip flow forced convection heat transfer in rectangular microchannels by applying a modified generalized integral transform. The compressibility effects in the slip flow were included in [5, 6] and the results agreed with previous experimental results. It was found that compressibility is significant for high Re and rarefaction is significant for low Re. Exact, analytical solutions for flows in circular, rectangular and parallel plate microchannels were given by Tunc and Bayazitoglu [7, 8]. The neglected frictional heating effects in low-velocity gaseous flows of macrochannel flows are found to be significant for microchannel flows. Bayazitoglu and Kakac [9] reviewed the flow regimes, and Bayazitoglu et al. [10] reviewed mathematical solutions to gaseous slip flows.

Slip Flow Nusselt Number for Different Geometries

The steady-state heat convection between two parallel plates and in circular, rectangular and annular channels with uniform heat flux and uniform temperature boundary conditions including the viscous heat generation for thermally developing and fully developed conditions are solved. Both constant wall temperature and constant heat flux boundary conditions are considered. The velocity and the temperature distributions are derived from the momentum and energy equations by using the proper slip flow boundary conditions. To have a better understanding of the viscous heating effects, the following parameter to combine the effects of the Brinkman number (Br) and the Graetz number (Gz) is used:

$$\frac{\mathrm{Br}}{\mathrm{Gz}} = \frac{\nu u_m}{c_p \left(T_0 - T_s\right)} \frac{L}{D^2} \tag{11}$$

Using the integral transform method, Yu and Ameel [4] solved for Nu for flow in a rectangular microchannel subject to the constant temperature and slip flow boundary conditions. They did not include viscous dissipation in the work, but they included variable thermal accommodation coefficients. Similar to [7], they concluded that Kn, Pr, aspect ratio, velocity slip and temperature jump can all cause Nu to deviate from the conventional value. Overall it is found that the heat transfer coefficient is strongly influenced by variation of Kn.

Transition and Free-Molecular Flow Regime

As the flow enters the transition flow regime and continues into the free-molecular flow regime, Kn becomes significant enough that the molecular approach has to be utilized. Thus, the Boltzmann equation

$$\frac{\partial f}{\partial t} + v_i \frac{\partial f}{\partial x_i} + F_i \frac{\partial f}{\partial \xi_i} = Q\,(f,f) \tag{12}$$

should be considered to fulfill the atomic level of studies of the gaseous flows in the transition regime. The Boltzmann equation denotes v_i as the velocity, F_i as the forcing function and f as the particle velocity distribution function in space, while $Q(f,f)$ describes the intermolecular collisions. The density can be obtained by integrating f over time and space. The integration of the product of the density and the velocity will provide the mass velocity. The Maxwellian distribution is the simplest distribution as it is the zeroth-order approximation of the Boltzmann equation.

The Boltzmann equation is solved by the particulate methods, molecular dynamics (MD), the direct simulation Monte Carlo (DSMC) method or by deriving higher order fluid dynamics approximations beyond Navier–Stokes, which are the Burnett equations. The Burnett equation

$$f = f^{(0)} + \mathrm{Kn} f^{(1)} + \mathrm{Kn} f^{(2)} + \cdots \tag{13}$$

is the first three terms of the Champan–Enskog equation. The simplified Boltzmann equation can be solved using the lattice Boltzmann method (LBM) for the distributed function on a regular lattice. Being a deterministic approach, the MD method simulation may require a very large domain for gaseous flows while the DSMC is a stochastic approach and is simulated more efficiently for gaseous flows. When $\mathrm{Kn} = 0.06 - 1.1$, the flow is called transition flow and the continuum assumption becomes invalid; the DSMC method also requires a large number of particles, which makes it expensive in terms of computational time and memory requirements.

Another mechanism that may affect the velocity profile in a microchannel is thermal creep. It is a molecular transport phenomenon that occurs when two isopressure containers at different temperatures are connected by a channel whose diameter is close to the gaseous mean free path. Under this condition, gaseous molecules start to flow from the cooler

container to the hotter container. Thus, a positive temperature gradient along the flow direction tends to increase the mass flow rate while a negative temperature gradient tends to reduce the mass flow rate. The inclusion of the thermal creep effect in the slip boundary condition is given in by the following formula:

$$u_s = \frac{2 - F_m}{F_m} \mathrm{Kn} \frac{\partial u}{\partial \eta} + \frac{3}{2\pi} (\gamma - 1)\, \mathrm{Kn}^2 \mathrm{Re} \frac{\partial \theta}{\partial \zeta} \tag{14}$$

The large surface-to-volume ratio in microchannels tends to enhance several factors that are neglected in macroscale flow and heat transfer, such as surface friction, compressibility, surface roughness, viscosity, channel surface geometry, surface electrostatic charges, axial wall heat conduction and measurement errors. Certainly more experimental measurements would be necessary to resolve the various discrepancies.

Smoluchowski Equation

Definition

The Smoluchowski equation is used to relate average flow (v_{av}) velocity to electric field strength (E_z) in electroosmotic flows. Under the conditions of a thin double layer or a large channel height (i. e a plug-like or constant velocity profile), it can be expressed as follows:

$$v_{av} = \frac{(\varepsilon_0 \varepsilon_r)\zeta}{\mu} E_z\,, \tag{1}$$

where ε_0 and ε_r are the electrical permittivity of a vacuum and the relative dielectric constant, respectively. Zeta potential is represented by ζ, and μ is the solution viscosity. The proportionality constant $(\varepsilon\zeta/\mu)$ is often referred to as the electroosmotic mobility.

SNP on Chip – Micro- and Nanofluidics for Single Nucleotide Polymorphism Discrimination

David Erickson
Sibley School of Mechanical and Aerospace Engineering, Cornell University, Ithaca, NY, USA
de54@cornell.edu

Synonyms

Nucleic acid detection

Definition

Single Nucleotide Polymorphisms (SNPs) are single base pair differences in individuals where the less common variant occurs in only a small portion of the total population. Detection of these SNPs is proving to be a useful technique for the diagnosis of a variety of genetic diseases and disorders. In this article microfluidics based techniques for SNP discrimination are explored.

Overview

Single Nucleotide Polymorphisms

Single Nucleotide Polymorphisms (SNPs) are single base pair differences in DNA amongst individuals where the less common variant occurs in at least 1% of the total population [1]. The decoding of the human genome has given us access to more than 3 million SNPs (roughly 1 every 100 – 300 bases) and opened up exciting new capabilities for associating individual SNPs, haplotypes and linkage disequilibrium with disease states and pharmacological responses. The first of these associations represents the simplest of cases, where the SNP alleles are the actual sequence variants that result in differences in gene function (by inducing sequence errors in the expressed protein or the exons it contains) or regulation (as a result of the SNP occurring within a promoter region). In general however the vast majority of SNPs fall into one of the latter two categories in that they do not contribute directly to disease states, but can serve as genetic markers that can be used to find functional SNPs as a result of associations between the two. In such cases many SNPs (in exons, introns and other non coding regions) may all be associated with a disease state or phenotype though only a single one may have a direct effect.

To make good use of SNPs for finding genes related to disease and studying their function, for genotyping them in many individuals, for finding their frequencies in pooled samples and for discerning haplotypes, better and cheaper technological methods are needed for discovering SNPs. At present the technology is not yet cheap enough for studies that would genotype thousands of individuals for hundreds of thousands of SNPs across the genome in order to see which variants are most closely associated with a disease phenotype [2]. The purpose of this article will be to introduce some of the ways micro- and nanofluidic technology is making progress towards addressing this issue. The first *Basic Methodology* section will introduce some of the existing chip based techniques for interrogating SNPs with a focus on surface phase hybridization techniques as being the most commercially viable. The *Key Research Directions* section will then describe how these techniques are being implements in microfluidic formats. In the final section a discussion regarding how these technologies can or should be extended to handle future analytical needs will be provided.

Basic Methodology

Techniques for SNP Screening

All allele-specific SNP discrimination techniques suitable for high throughput genetic analysis can be categorized as either being either primer extension, oligonucleotide ligation, invasive cleavage or hybridization based [3]. There are numerous variants on the primer extension technique however all are based on the ability of DNA polymerase to incorporate specific deoxyribonucleotides that are complementary to the sequence of the template DNA [4]. An entire class of techniques based on electrophoretic separation have also been developed and include: heteroduplex analysis (HA), single-strand conformation polymorphism (SSCP), denaturing gradient gel electrophoresis (DGGE), temperature gradient gel electrophoresis (TGGE), allele-specific PCR amplification and ligase chain reaction/ligase detection reaction (LCR/LDR).

Next generation SNP discrimination techniques should…

1. Have high throughput capabilities, enabling multiplexing of both interrogated SNPs and (less importantly) patient samples on the same device.
2. Minimize the total amount of time and handling required to perform a multiplexed reaction.
3. Enable either disposability or reusability functionality.
4. Be sufficiently sensitive to so as to work with raw, unamplified samples.

SNP on Chip – Micro- and Nanofluidics for Single Nucleotide Polymorphism Discrimination, Figure 1 Requirements for next generation Single Nucleotide Polymorphism Screening Technologies. A technique which meets the above requirements is required to perform the large scale population screening studies

Of all these, the technique that has shown the most commercial promise has been surface phase DNA microarray technologies, involving large-scale DNA sequence detection based on hybridization between complementary DNA sequences on a solid support. In recent years a number of DNA microarray and DNA chip type devices have been developed and commercialized (examples include LabCard by ACLARA Bio Sciences, GeneChip by Affymetrix, NanoChip by Nanogen). Such devices enable parallel DNA or RNA analysis to be carried out in a format that typically includes some functional microfluidic technology which serves to increase the rate at which targets are delivered to the region of interest (either by increasing the probability of target-surface collisions through physical confinement near the probesite or direct electro-active attraction). Though broadly useful to study a number of different target: probe binding systems, such chips are commonly used gene expression analysis or Single Nucleotide Polymorphism (SNP) discrimination applications.

Such high throughput DNA microarray technologies can simplify SNP analysis, but most methods require several hours for hybridization (due to diffusion-limited reaction kinetics) and complicated washing steps demanding strict temperature and buffer salt-content control. In addition, microarray hybridization and washing manipulation is conducted on centimeter-scale glass substrates thereby requiring that large quantities of DNA target sample be used. While numerous techniques have been identified for amplifying the signal, recently even to the point where SNP identification can be performed without the need for target amplification (via PCR), such processes require complex and, often, expensive labeling steps. The main difficulty with such devices however relates to the infrastructure/sensitivity tradeoff whereby either a large expensive tabletop optical apparatus (often con focal) is used to perform ultra-sensitive detection or a smaller footprint (though still relatively large) laser scanner is used to perform much more rapid analysis however the detection sensitivity is significantly lower. Such post-reaction scanning systems typically also lack the ability to monitor reaction kinetics. Based on these limitations the requirements outlined in Fig. 1 are proposed as requirements for next generation SNP discrimination techniques. These conditions will be revisited in the *Future Directions* section of this article.

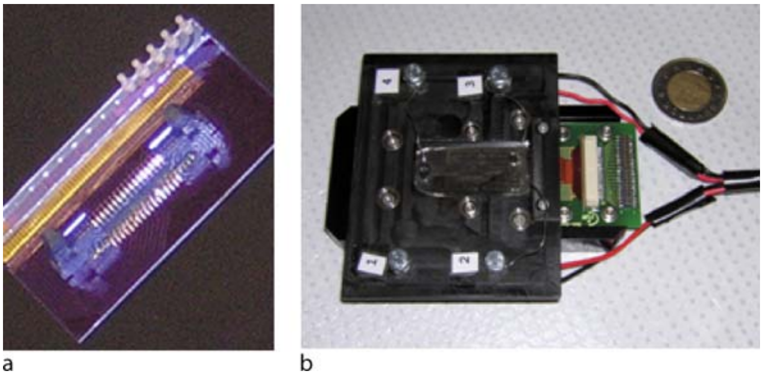
Key Research Findings

As mentioned above, this section will review the state of the art in microfluidics based SNP discrimination with the goal of providing as broad of an overview of the existing technology as possible. As this review by necessity is somewhat cursory, it will be followed up with a more detailed description of a particular *electrokinetically based* on-chip SNP discrimination technique. The overall thrust of this section will be to determine to what degree exiting microfluidic technology can be used to address the next generation needs described in Fig. 1.

State of the Art in Integrated Microfluidic Devices for Single Nucleotide Polymorphism Discrimination

As described throughout this encyclopedia, microfluidic (Lab-on-a-Chip) technologies enable processing small liquid volumes in a rapid and controlled manner which has proven especially useful for analysis in life sciences. In the early 2000's several researcher groups began to investigate the integration of multiple microfluidic-based technologies into single microscale platforms with the goal of developing integrated technologies for performing nucleic acid analysis. Designs included paramagnetic or glass bead based devices, poly(methylmethacrylate) (PMMA) chips exploiting universal zip code arrays and polycarbonate (PC) chips designed to be credit card sized all of which proved successful in accelerating and automating detection of hybridization events (see Erickson and Li [5] for a more comprehensive review of these devices).

Commonly, a necessity for obtaining maximum discrimination between fully matched target: probe complexes

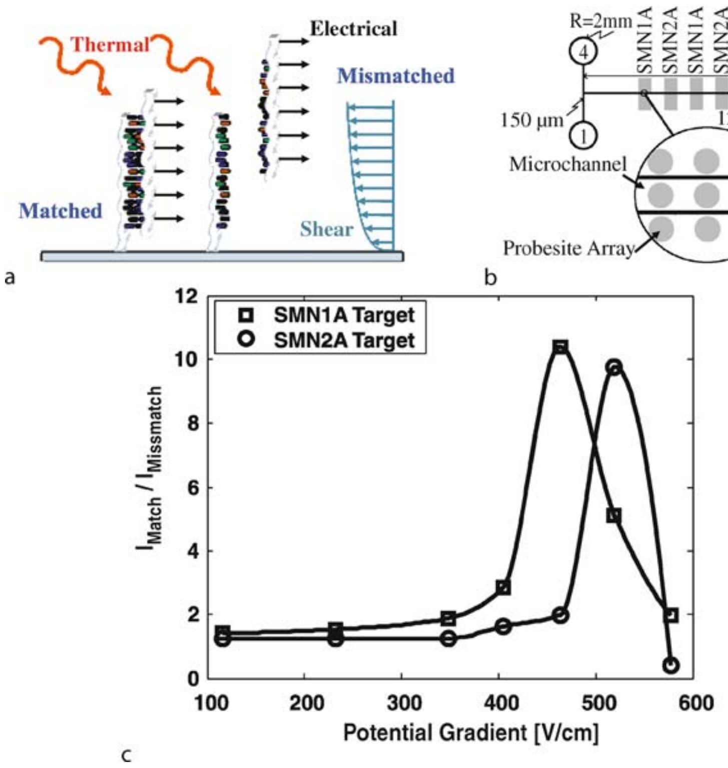


SNP on Chip – Micro- and Nanofluidics for Single Nucleotide Polymorphism Discrimination, Figure 2 Integrated Microfluidic Devices for (**a**) Parallel Polymerase Chain Reaction and (**b**) DNA hybridization (from [5])

and those containing a single-base base pair mismatch in a microfluidic chip is accurate control of the thermal conditions at the reaction site (whether it be in solution or at a surface). This has been largely accomplished through the integration of external heaters and thermal sensors (e. g. RTDs) on chip thereby adding an additional level of device complexity to that required for simple hybridization detection. Figure 2 illustrates recently developed devices for PCR (Fig. 2a) and surface phase DNA hybridization (Fig. 2b) which incorporate such functionality. PCR amplification was one of the first on-chip applications which required this type of control. In what were some of the first prominent examples Kopp, deMello and Manz [6] used a copper heating block for continuous-flow PCR in a microfluidic channel, while others such as Lao et al. [7] used high thermal conductivity silicon-based devices to achieve precise temperature control and rapid cooling in cycling based device. As for devices specifically devices for SNP detection, Buch et al. [8] reported a TGGE method based on the presence of a controllable temperature gradient on a polymer microfluidic chip. Platforms for high-throughput on-chip temperature gradient assays were also developed by Mao et al. [9] who demonstrated discrimination of fully complementary DNA strands from those containing a single T–G or C–A mismatch. This was also done using SYBR Green I intercalating dye and was reported for parallel and combinatorial measurements. As described above these devices required the incorporation of temperature control units, external heaters and thermal sensors on the microfluidic chips making it possible to control and rapidly change the temperature in order to produce spatial temperature gradients. In a recent work, Blazej et al. [10] developed what they terms a *microfabricated bioprocessor* which integrated all three steps involved in Sanger sequencing (namely thermal cycling, sample purification, and capillary electrophoresis). Using this device they demonstrated a 99% read accuracy over 556 bases. The device presented in that work represents one of the most integrated microfluidic systems developed at time of publication incorporating such elements as pneumatic microvalves and electrokinetic flow control elements and low dispersion turns in addition to thermal control and monitoring elements. Of note is that in the majority of these devices, hydrodynamic pumping techniques have been relied upon for performing the majority of the primary transport operations (the exception of course being those which rely on an electrophoresis step).

Electrokinetically Based Single Nucleotide Polymorphism Discrimination

On the length scales relevant to microfluidic devices, fluid flow and species transport can be accomplished using numerous different techniques, a few of which include: traditional pressure driven (pneumatic) flow, electrokinetic transport, buoancy, magnetohydrodynamics, capillarity, electrowetting and thermocapillarity (see Stone et al. [11] for a comprehensive overview). While electrokinetic means can greatly simplify species transport in microfluidic systems (see the section ▶electroosmotic flow), an effect commonly considered a significant drawback is the internal heat generation caused by current flow through the buffer solution. To maintain uniform and controlled system temperatures required for SNP discrimination, devices must have the ability to rapidly reject this heat to the surroundings. This problem is enhanced as a result of the recent shift towards low cost polymeric microfluidic systems (which will be discussed in greater detail in the final section) fabricated from such low thermal conductivity polymeric materials as poly(dimethsiloxane) (PDMS) and poly(methylmethacrylate) (PMMA) as opposed to tra-



SNP on Chip – Micro- and Nanofluidics for Single Nucleotide Polymorphism Discrimination, Figure 3 Electrokinetically based SNP discrimination technique (**a**) Schematic describing electrokinetically based SNP discrimination technique applying an electrokinetic driving potential allows for precise manipulation of the thermal (through Joule heating), shear (through electroosmotic flow) and electrical (through electrophoresis) forces enabling the SNP to be discriminated. (**b**) H-type channel structure probesite layout for electrokinetically-based single nucleotide polymorphism discrimination. Peak represents point where ratio of match intensity to mismatch intensity is greatest

ditional materials such as glass or silicon. The primary attractiveness of these materials is that they tend to involve simpler and significantly less expensive manufacturing techniques while still being amenable to surface modification and probe functionalization. The low thermal conductivities inherent in these materials (0.18 W/mK for PDMS which is an order of magnitude lower than that of glass) retards the rejection of internally generated heat during electroosmosis.

As mentioned above we have recently developed a novel on-chip electrokinetically-based microfluidic technique for SNP discrimination (see Erickson et al. [12] for details). The traditional advantages in terms of flow and sample handling afforded by electrokinetic transport described in the electroosmotic flow section of the article were extended to include thermal control through on-line manipulation of the Joule heating conditions. Precise control of the thermal, shear and electrical conditions at the probe sites were shown to enable discrimination of single-base-mismatch SNP sample targets on the chip by exploiting differences in denaturation energetics. This technique is expanded on in this article as it uniquely demonstrates how detailed understanding of fluid dynamics and thermal transport on the micro- and nanoscales can be exploited to control reaction specificity without the need for incorporating additional device functionality.

A schematic of the discrimination technique is shown in Fig. 3. As can be seen under standard conditions (or at low applied voltage) both the fully matched hybrid and that with a single base pair mismatch remain hybridized making discrimination difficult. Applying an electrokinetic driving potential allows for manipulation of the thermal (through Joule heating), shear (through electroosmotic flow) and electrical (through electrophoresis) forces above the microarray. To demonstrate the clinical utility of the technique, the detection of single base pair mutations in

the survival motor neuron gene, associated with the childhood disease Spinal Muscular Atrophy, was performed. Specifically the technique was applied to the detection of the common C→T mutation in the SMN1 gene resulting in what is known as SMN2 (and is found in all SMA patients). Such mutations lead to the loss of alphamotor neurons and subsequently the wasting of voluntary muscles.

To determine the optimal conditions for SNP discrimination, a series of incrementally increasing voltages were applied during the discrimination step, ranging from 100 V/cm to 600 V/cm within the hybridization array. Figure 3c compares the florescence intensity of the matched probe sites with that of the mismatched probe sites for both SMN1A and SMN2A targets. While the intensity ratios remained constant at lower voltages, a clear optimum in the discrimination existed for each different target:probe complex, at 460 V/cm and 525 V/cm, respectively. The difference in the optimal potential gradient between these two cases can be attributed to the slightly larger change in the thermodynamic stability associated with the SMN1A:SMN2 hybrid.

Future Directions for Research

In the preceding two sections an overview of microfluidics based SNP discrimination technology has been presented and thus when defining future directions for research it makes sense to compare these devices with each of the needs as expressed in Fig. 1. Continuing the theme from above here we focus more on technology development rather than clinical applications (for more details on the latter of these readers are referred to Motsinger et al. [13].

The first condition for next generation technology outlined in Fig. 1 relates to the development of highly multiplexed devices that enable simultaneous screening of multiple samples against multiple SNPs. While most of the surface phase binding based chips described above have generally targeted a small number of specific SNPs for demonstrative purposes, the extension to the kind of parallelity used in microarray formats is relatively easy. This is as a result of the numerous microfluidic technologies have been developed for dispersing samples over relatively large interrogation areas and the well developed detection/scoring infrastructure. Devices which rely on what have classically been more serial technologies (e. g. capillary electrophoresis) can have many analytical advantages over binding assays (such as enabling Sanger-type sequencing as discussed above) but are likely to face parallelity roadblocks in the future unless more cost-effective multiplexing technologies can be developed.

The second requirement for next generation technologies pertains to minimizing the time and handling required to perform a complete assay. Great advances have been made along these lines in the past 2 – 3 years largely thanks to the development of multi-layer soft lithography [14]. This technology has enabled the incorporation of pneumatic pumps, valves and other flow control elements on chip with relative ease. Given that, much of the effort in the field is therefore directed towards pushing the analytical technology upstream towards processing real patient samples or at least minimizing the number of manual processing steps. Almost inevitably however incorporation of additional on-chip functionality increases the final cost-per-chip and thus a trade off has to be made between how much manual processing the customer is willing to tolerate in order to keep total device costs down. In a research environment, where tests are likely to be conducted by a technician or graduate student with a relatively sophisticated level of expertise, this tolerance level is likely to be relatively high. For point of care applications the requirements are much more stringent.

The third condition relates to disposability or reusability of devices. In general disposability is so ingrained in the medical community that even if washing technologies were developed to the point that the potential for cross contamination could be effectively eliminated, it seems unlikely that reusable devices are likely to have a significant commercial impact. As alluded to above this suggests that development efforts should be focused on polymer devices, where device fabrication can be done using relatively simple and inexpensive casting or hot embossing techniques. This simplification of the fabrication steps tends to conflict with the requirements mentioned above for the basic thermal control (that facilitates SNP discrimination) let alone some of the desired additional upstream functionality. Since fabrication technology is reasonably well developed, research directed towards the development of techniques that can perform the desired analytical operations without the need for additional on-chip functionality (such as the electrokinetic SNP discrimination technique described above) is certainly warranted.

Most of the existing technologies discussed above require some sort of upstream PCR amplification step to bring the target concentration up to detectable levels. This step requires additional time, more functionality to be incorporated onto a chip and limits the degree of multiplexing. For the reasons discussed above therefore it would be desirable if this step could be eliminated in favor of sensor systems which have sufficient sensitivity and specificity to detect relatively minute quantities of a target in its unamplified state. Achieving this task in a multiplexed format requires research that takes an overall systems view

of device development looking at the coupling of sensitivity, specificity, transport and repeatability in the context of a whole device, as opposed to a component view as is commonly done at present.

Soda-Lime Glass

Synonyms

Sodium glass; Sodium silicate glass

Definition

Soda-lime glass is the kind of glass which is most widely used for various purposes. Soda-lime glass is a multicomponent mixture of SiO2 (72.8%), Na_2O (13.7%), CaO (8.8%), MgO (4.0%) and small amounts of Fe_2O_3 (0.12%) and Al_2O_3 (0.1%). Adding sodium carbonate lowers the melting point of the glass, thus lowering the energy required to heat it, but also making it soluble in water. Calcium carbonate or calcium oxide are added to counter this.

Sol–Gel Technique

DOMINIC S. PETERSON
Chemistry Division, Los Alamos National Laboratory, Los Alamos, NM, USA
DominicP@lanl.gov

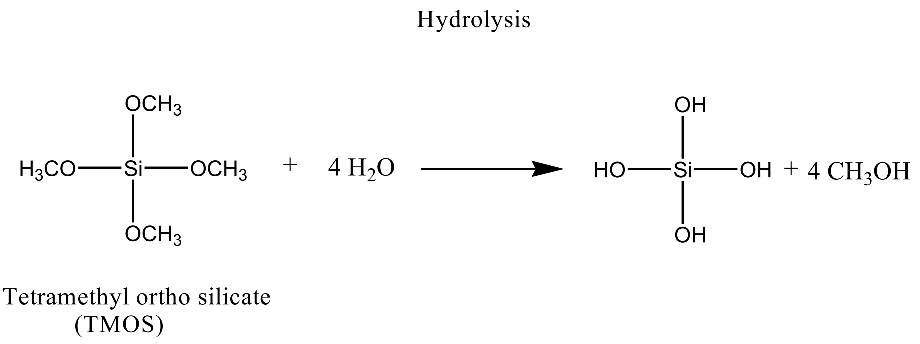
Definition

The sol–gel synthetic technique is used to fabricate a porous structure composed of transition metal alkoxides. These structures most commonly utilize a siloxane (Si – O) to form the backbone structure. The synthesis of these sol–gels involves a hydrolysis of a silicone monomer followed by the condensation of the silica into a porous structure with a 3-dimensional networked structure. The physical structures of these sol–gels can be tailored to produce structures with a wide range of useful properties and the chemical surface chemistry can be modified to produce various surface interactions.

Overview

Sol–gel chemistry is a versatile tool that can be used to produce organic and inorganic hybrid materials that have properties that can be difficult to obtain from only inorganic or organic synthetic approaches. The synthetic approach involves the polycondensation of sol–gel active molecules to form a macromolecular network structure.

S



Sol–Gel Technique, Figure 1 Hydrolysis of tetramethyl ortho silicate to silanol

Basic Methodology

The synthesis of a sol–gel follows three primary steps [1]. First, the transition metal monomers are hydrolyzed to form a tetrahydroxy alkoxide. Because most sol–gels are formed from silica monomers the remainder of the discussion will focus on silica sol–gels. The hydrolysis step for silica sol–gels typically involves the use of either tetramethyl ortho silicate (TMOS) or tetraethyl ortho silicate (TEOS). The side product of the reaction is the corresponding alcohol (Fig. 1).

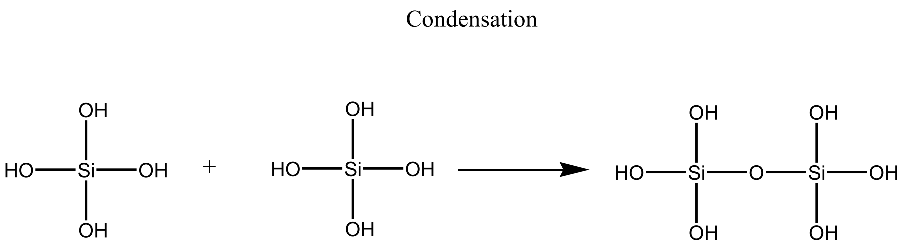
Once the tetrahydroxy silane has been formed, the silica will condense to form larger silica molecules and oligiomers (Fig. 2). This formation of the sol (or small colloidal silica particles) can be controlled to produce particles that have a particular size or size distribution.

Once the sol has been formed, they will cross-link to form a gel structure. This formation of a gel from the sol gives the materials the name sol–gel (Fig. 3). This crosslinking is achieved through a poly-condensation step. This step is the same as the condensation step, except that is results in a structure that is highly crosslinked. The size and amount of cross linking is dependant on the pH of the system and also the presence (and amount of) any other alkyl groups in the silica monomers ($-\mathrm{Si}-\mathrm{OR}$). It should also be noted that a wide range of chemical functionalities can be incorporated into the eventual sol–gel by the use of monomers that have useful alkyl groups incorporated into the structure. Alternatively, it is possible to modify the sol–gel after it has been formed by the condensation of a functional silane onto the sol–gel surface.

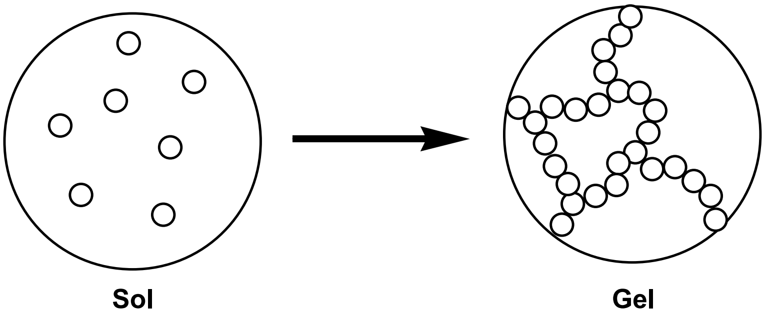
The relative rates of reaction between the hydrolysis, condensation, and polycondensation directly affect the type and quality of sol–gel produced. For instance, in base catalyzed sol–gel synthesis, the rate of the hydrolysis reaction is much slower than the polycondensation step, which tends to form a polymeric structure that is highly branched with relatively large particles. In contrast, in acid-catalyzed sol–gel synthesis the rate of the hydrolysis reaction is much faster than the polycondensation step, which favors the formation of linear polymers. This also tends to form much smaller particles that the gel is composed of, which results in materials with much higher porosities and higher surface areas than is formed with sol–gels formed in base-catalyzed reactions. Therefore acid-catalyzed synthesis tends to produce materials that have properties that are preferable for microfluidic applications.

Another process that is essential to the properties of the sol–gel produced is aging. When the gel that is formed is maintained in liquid its structure and properties continue to change after the gel has been formed. There are three processes that continue to change the properties of the sol–gel during aging. These include polycondensation, syneresis, and coarsening. Polycondensation reactions continue to occur within the gel as long as silanol groups are close enough to one another to react with one another. This continues to increase the connectivity within the gel network. Syneresis is the shrinkage of the gel and the expulsion of liquid from the pores of the gel. This shrinkage is attributed to the formation of new bridging siloxane bonds through condensation, which causes the gel to contract. The amount of shrinkage will increase with higher concentrations of silica in the gel and at higher temperatures. Coarsening is the decrease in surface area through dissolution and reprecipitation of dissolved material within the gel network. Due to the solution microenvironment, this precipitation of material is irreversible. The overall aging process is affected by several parameters including time, pH, temperature, and inclusion of organic solvents in the gel system. Through the control of the aging process it is possible to produce sol–gels with specific porous structure including the particular surface area that is needed for specific applications.

The preparation of sol–gels is a simple and straightforward process. Because the precursor sol has a low viscosity, it



Sol–Gel Technique, Figure 2 Condensation of two silanols into a dimer



Sol–Gel Technique, Figure 3 Schematic of conversion of the sol into a gel structure

is easy to place it into any mold (including a microfluidic channel) and then form the gel. The primary limitation on the mold is that it needs to avoid adhesion of the sol solution, and it must not lead to the formation of bubbles during filling or during the gelation process.

Key Research Findings

In the past decade there has been intense interest in the use of sol–gels for use in microfluidic and nanofluidic applications. The most widespread use of sol–gels in microfluidic systems has been for capillary electrochromatography (CEC). CEC is a separation technique in which an electrical potential is applied across a capillary (containing a packing material) and the ionic functionalities generates bulk flow through the capillary through electroosmosis. The separation of non-ionic analytes can then be achieved as the analytes will partition between the mobile phase and the packing stationary phase. Sol–gels have provided an excellent method to make CEC columns, as they are simple to prepare within the capillary and they easily crosslink with the silica surfaces of the capillary, thus immobilizing them. Furthermore, in addition to using functionalized silica monomers in the preparation of a CEC sol–gel column, it is also possible to modify the silica surface with functionalized siloxanes. This enables the column to have higher thermal and solvent stability. The sol–gel process for preparing CEC columns enables the surface chemistry to be controlled and the selectivity of the column to separate different compounds can be adjusted for specific applications.

There are two types of preparation that are used to make CEC columns [2]. The first approach involves fully filling the capillary with the sol–gel solution. This method produces a sol–gel that fully fills the capillary, and thus produces the maximum amount of surface area for separation processes. However, fully filling the column with a sol–gel leads to a higher rate of bubble formation under the high voltage conditions utilized for CEC separations. The preparation of filled CEC sol–gel columns involves pre-treating the capillary, preparing the sol and filling the capillary with the sol-solution. After this, the gel step is performed and the sol–gel is formed in situ. After the sol–gel is formed there is typically a rinsing step that is used to remove un-reacted sol and to fill the column with a solution that is more suitable for electrophoretic operations. The other approach to sol–gel columns is the preparation of open tubular columns in which the sol–gel is coated on the interior surface of the capillary. The greatest difficulty in preparing open tubular is in preparing sol–gel coatings which are relatively thick, stable, reliable, and reproducible. There have been many examples of sol–gel CEC columns, and they have been shown to enable separations that have high efficiency and are quite reproducible.

The preparation of open tubular CEC sol–gel columns first involves the pre-treatment of the capillary and the prepa-

ration of the sol. The gel step for open tubular columns is allowed to proceed for only a short period of time (i. e. 20 min). This short time allows the gel to begin to form, typically silanol containing groups will began to react with other silanols in the immediate vicinity. This includes the sol reacting with the silanol groups at the surface of the silica capillary. When the non-reacted sol is rinsed out of the capillary all of the sol–gel that is not covalently attached to the wall of the capillary will be rinsed out. This will leave a layer of the sol–gel on the interior of the capillary.

While the use of sol–gels in capillaries has been extensive, their use in microchannels on chips has been more limited, due to the difficulty of fabricating sol–gels within the chip materials. The primary difficulty is in preparing the sol–gel in the region of the chip that it is needed, while excluding it from the areas where it is not needed. One method that has been introduced to fabricate the sol–gel in a particular area of a chip is to use a photoinitiation step to cause the gelation to form in a specific area [3]. This process first involves preparing a sol from a siloxane containing an organic monomer, such as a methacrylate. Once the sol had been prepared it was placed into a UV transparent capillary or chip. The organic functionalities on the sol was then reacted utilizing a UV active initiator under a UV lamp, which causes the sol to become crosslinked through the organic functional linker. Because this reaction is activated using light it is possible to cause the sol to polymerize only in a specific region of interest. The unreacted sol is then rinsed out of the channel. This approach allows the sol–gel to be placed into a very specific portion of the chip or capillary with no residual sol–gel remaining in other portions of the channel. The primary disadvantage to this approach is that it requires that the sol–gel that is fabricated be imparted with very specific organic functionalities in order to enable the photopolymerization step to proceed with high efficiency.

Another approach that has been used to introduce a sol–gel functionality into a microchip has been to either imbed the sol–gel into the microchip or to coat a microchip channel with a sol–gel. The method to imbed sol–gel functionality into a chip involved to preparing a PDMS chip with silica nanoparticles homogeneously distributed throughout the PDMS [4]. This approach produced a chip that was more hydrophilic than normal PDMS. In addition, when these chips were used for capillary electrophoresis analysis, the electroosmotic flow was much higher than in other PDMS chips.

Another application to which sol–gels have been applied is in assays involving various biocatalytic reactions. It has been demonstrated several times that proteins can be easily immobilized within a sol–gel and then used for a variety of applications. Once the proteins are incorporated into the sol–gel structure they still retain their enzymatic activity. This enables a wide array of enzymatic reactors to be prepared including oxidases, lipases, and proteases. Enzymes and even whole cells can be incorporated into the gels to enable flow-through reactors to be simply constructed. The incorporation of proteins into a sol–gels can also be combined with CEC separations to enable the separation of enantiomers.

Sol–gels with encapsulated enzymes have been demonstrated for high throughput screening of catalytic activity [5]. This involved fabricating an array of sol–gel microstructures on a glass slide. This was accomplished by using a PDMS template and then synthesizing the sol–gel with the active enzyme on top of the glass slide. The enzyme kinetics of the encapsulated proteins can then be studied in detail by changing the concentrations of substrate and inhibitor and using different temperatures. This enables rapid detailed analysis of the behavior of the enzyme. The activity of the immobilized enzyme was similar to the free enzyme, which demonstrates that the activity is maintained even in the sol–gel matrix. Each microwell requires only 50 μg of enzyme. These assays have been demonstrated with dozens of enzymes, which further demonstrates the robustness of the method.

In addition to microwell bioreactors for screening of enzymatic activity, enzymes have also been encapsulated into sol–gels for flow-through systems. For instance, trypsin has been fabricated into a sol–gel on a microchip to form a device that performs both digestion and separation on the same device [6]. Because of the proteolytic activity of the trypsin, proteins that are passed through the device are digested into consistuent peptide fragments. The amount of trypsin that was incorporated into the sol–gel was varied between 0.1% and 10% depending on the size of the analyte that needed to be digested and thus the amount of activity that was needed to adequately digest the sample. For sample introduction the driving force for introducing the analyte to the bioreactor was electroosmotic flow. Once the protein was digested it was then separated using the same electrophoretic forces that are used to introduce the protein to the bioreactor. Because the protein will be digested into fragments of different sizes, the different fragments (which are charged) will migrate at different speeds and be separated in the microchip. The overall time that was required for the digestion of the protein and the subsequent separation is much faster than other methods have been.

Protein encapsulation has also been used to prepare sol–gel columns for CEC separations [7]. This involved incorporating a proteins that has a chiral center such as bovine serum albumin or ovomucoid. Because these proteins have a chiral center it is possible to use the hybrid

protein/sol–gel column to separate enantiomers. In these separations, the amount of protein that was encapsulated was critically important in resolving the enantiomers, and protein concentrations generally needed to be above 5%. Even at these levels, the total amount of protein loaded was in the range of tens of micrograms.

Pre-concentration of analytes is another application that sol–gel materials have been applied to. Pre-concentration steps are critical in microfluidic analytical systems because the small volumes used require that the concentration be relatively high to allow analytes to be detected. The pre-concentration step typically involves loading the analyte onto the sol–gel in one solvent or solution. The analytes are later released from the sol–gel utilizing another solvent in which the analyte is more soluble than the sol–gel. A wide variety of functional interactions can be utilized to pre-concentrate an analyte. These can include ion-exchange, hydrophobic, and hydrophilic interactions. One major difficulty of these types of pre-concentrators is that it is very difficult to change solvents from one to the other in a microfluidic system. Also, the loading and release solvents must be miscible, which limits the solvents that may be used for pre-concentration operations. An example of sol–gels being used for pre-concentration is in the enrichment of DNA [8]. This process involves first adsorption of the DNA onto the silica in the presence of a salt. The containments are then washed off using an alcohol/water solution, and finally the DNA is eluted utilizing a buffer solution. The DNA that is eluted is suitable for further PCR amplification, which adds to the utility of the process.

Sol–gels can also be used for more than one application at the same time. For instance, it has been shown that a sol–gel column can be produced that enables both pre-concentration and separation of amino acids [9]. The column was prepared with a quaternary ammonium functionality, which gives the sol–gel a positive charge. This unique functionality in the sol–gel enabled amino acids to be preconcentrated and separated on the column with high enrichment and efficiency. Furthermore, the use of a positively charged surface for the silica surface enables the electroosmotic flow to be reversed to that which is normally observed in silica capillaries. This enables specialized separations to be performed on the sol–gel CEC column compared to that which would be normally achievable.

Future Directions for Research

Sol–gel technology is a very mature technique with a wide variety of methods that are known and are widely used. However, there are many opportunities that still exist to expand the sol–gel technique to microfluidic applications. One of the most important areas of future research involve developing microfluidic systems that incorporate multiple functionalities. For instance, a device for proteomic determinations may involve a sol–gel bioreactor to digest proteins, a sol–gel pre-concentrator to enrich the peptide fragments, and a CEC separation phase to separate the peptides prior to detection. Incorporating multiple functionalities will require several additional difficulties to be overcome. In addition to placing the sol–gel in a specific portion of a microchip it will be necessary to prepare multiple columns on a chip without adversely affecting the structure or functionality of the other sol–gel devices on the chip. This may be accomplished by using multiple interconnected channels and placing each sol–gel into its channel individually. It may also require some careful selection of the sol–gels to be prepared so that the preparation can be achieved while not disturbing the other devices. The other area that is ripe for further research is to utilize sol–gels for other functional devices in microfluidics. This could involve making electrokinetic pumps from sol–gels, which would involve fabricating sol–gels with high ionic loading so that a current can be used to cause the sol–gel to act as a pump with no moving parts. It has been demonstrated that a variety of biological proteins can be easily encapsulated into sol–gels. This should be expanded so that other functionalities can be included in microfluidic devices. Other pre-concentration approaches could also be fabricated using sol–gels. Pre-concentration will be a critically important step in microfluidics since the concentrations required for detection is relatively large. It should be possible to make pre-concentrators that would release the anaytes in response to other stimuli, such as heat or light, which would simplify the injection of the analytes into the system.

Synonyms

Spectral analysis; Spectral approximation

Definition

Spectral methods are a class of techniques used in applied mathematics and scientific computing to numerically solve certain differential equations using the method of weighted residuals. In spectral methods, the solution is approximated as an expansion in terms of spectral basis functions. Here, the basis functions are infinitely differentiable *global* (non-local) functions defined over a whole domain, e.g. trigonometric functions, Chebyshev polynomials, Legendre polynomials and so on, making the spectral methods different from the finite-element and finite-difference methods. Spectral methods have an excellent property of very high spatial accuracy for well-behaved problems and, thus, they are appropriate for the numerical simulation of accurately predicting flows with a broad range of dynamically significant scales of motion.

Overview

Spectral methods are used to numerically solve boundary value, eigen-value and time-dependent problems and these methods involve a completely different approach from finite-element and finite-difference methods. In spectral methods, instead of representing a function by its values at grid points, one would approximate the function by a series expansion in terms of spectral basis functions as follows (in the case of one-dimensional problem):

$$u(x) \approx u_N(x) = \sum_{n=0}^{N} a_n \phi_n(x) , \tag{1}$$

where $u(x)$ and $u_N(x)$ denote respectively a function and its approximation, and $\phi_n(x)$ and a_n respectively the nth basis function and its corresponding coefficient. N is the degree of the series expansion. The basis functions are infinitely differentiable non-local functions defined over a whole domain. In addition, they should have a lot of appropriate properties, such as easy computation, rapid convergence and completeness (A basis set is said to be *complete* for a given class of functions if all the functions within the class can be represented to arbitrary high accuracy as a sum of a sufficiently large number of basis functions) [1]. The typical examples are the trigonometric functions and Chebyshev and Legendre polynomials. The trigonometric functions, or Fourier series, are used for the periodic boundary conditions, whereas the Chebyshev and Legendre polynomials are used for the Dirichlet conditions. It means that the coefficient, a_n, influences the function, $u_N(x)$, and its derivative, $du_N(x)/dx$, over a whole domain and, thus, spectral methods are completely *global*. Note that finite-element and finite-difference methods are local because the function value at a grid point has influence only near that point.

When the spectral series (1) is substituted into the differential equation

$$Lu(x) \equiv f(x) , \tag{2}$$

where L is the differential operator, the result is the so-called residual function defined as;

$$R(x; a_0, a_1, \ldots, a_N) \equiv Lu_N(x) - f(x) . \tag{3}$$

Since the residual function, $R(x; a_n)$, is identically equal to zero for the exact solution, the ultimate goal in spectral methods is to choose the spectral coefficients, a_n $(n = 0, 1, \ldots, N)$, so that the residual function is minimized. The different kinds of spectral methods differ mainly in the minimization strategies.

The basis functions, $\phi_n(x)(n = 0, 1, \ldots, N)$, should be already determined such that each of them satisfies the corresponding boundary condition. Here, the application of the *method of weighted residuals* [2] determines the coefficients, a_n, by imposing the $(N + 1)$ conditions

$$(w_i, R[x; a_0, a_1, \ldots, a_N]) = 0 , \quad i = 0, 1, \ldots, N \tag{4}$$

for some suitable test functions, $w_i(x)$. The inner product for any two functions, $u(x)$ and $v(x)$, is defined as

$$(u, v) \equiv \int_{\Omega} \rho(x)u(x)v(x)\,dx \tag{5}$$

for a given non-negative weight function, $\rho(x)$, where Ω denotes the whole domain.

There are two basic types of spectral methods: *pseudospectral* methods and *Galerkin* methods. In pseudospectral methods, or spectral collocation methods, the test function is given as

$$w_i(x) \equiv \delta(x - x_i) , \tag{6}$$

where x_i is each collocation point and $\delta(x)$ the Dirac delta-function (1 for $x = 0$ and 0 otherwise). The substitution of Eq. (6) into Eq. (4) results in the algebraic equations

$$R(x_i; a_0, a_1, \ldots, a_N) = Lu_N(x_i) - f(x_i) = 0 , \quad i = 0, 1, \ldots, N \tag{7}$$

at the collocation points.

S

In the Galerkin method, on the other hand, the test function is given as

$$w_i(x) \equiv \phi_i(x) . \tag{8}$$

This choice of test function is successful because any well-chosen set of basis functions would have all the properties desired by weighting functions, including linear independence and completeness. The main difference between pseudospectral and Galerkin methods is as follows. In pseudospectral methods, some of the calculations are carried out in terms of the spectral coefficients, a_n, and some in terms of the values of $u(x)$ at certain grid points, whereas, in Galerkin methods, all the computations are carried out in terms of the spectral coefficients, a_n.

Micro and nanoflows involve a relatively broad range of dynamically significant scales of motion. Thus, highly accurate numerical methods are required for exactly capturing these dynamics. High spatial accuracy is achieved by spectral methods, which thus may be very effective in simulating micro and nanoflows. However, most micro and nanoflows involve complex wall-bounded geometries, that is the flow geometry is complex or particular regions need to be resolved. Note that spectral methods cannot be readily applied to such cases without any special treatment.

Spectral domain-decomposition methods are suggested as an efficient way of resolving the limitation of conventional spectral methods. The basic idea behind the methods is to partition the whole domain into several subdomains, and then to simultaneously solve the differential equations in each subdomain and appropriate matching conditions on each interface. These methods have very attractive features, such as rapid convergence, geometric flexibility, and suitability to parallel implementation. Thus, they are appropriate when particular regions need to be resolved or when flows in complex geometries are to be simulated.

In general, two classes of spectral domain-decomposition methods have been proposed in the literature: *patching* methods and *variational* methods. The difference is in the way how the interface conditions are imposed. To solve second-order partial differential equations as an example, the interface condition is typically enforced by requiring that the solution and its first normal derivative be continuous on each interface. In patching methods, the continuity conditions on each interface are discretized by enforcing them at selected points, and thus are satisfied exactly by any approximation. In variational methods, on the other hand, the continuity conditions are enforced implicitly or variationally with differential equations at all points, including all the subdomains and interfaces.

Patching methods are based on spectral collocation methods first developed by Orzag [4]. They are useful in exploiting the efficiency of spectral collocation methods. On the other hand, the spectral element methods first developed by Patera [5] are a kind of variational methods. These methods are a high-order weighted residual technique that combines the accuracy and rapid convergence of spectral methods with the generality and geometric flexibility of finite-element methods.

Basic Methodology

Pseudospectral and Galerkin Methods

In order to simply explain the basic principle behind spectral methods, consider one-dimensional linear Helmholtz equation as an example:

$$Lu(x) = -\frac{d^2u(x)}{dx^2} + \lambda u(x) = f(x) \quad \text{in } \Omega , \tag{9}$$

where λ is a non-negative constant. The same basic principle can be readily extended to more complex differential equations and more-dimensional problems.

The function, $u(x)$, in Eq. (9) can be approximately written as a series expansion in terms of spectral basis functions, $\phi_n(x)$, as in Eq. (1). When the spectral series (1) is substituted into Eq. (9), the resultant residual function can be written as

$$\begin{aligned} R(x; a_0, a_1, \ldots, a_N) &= Lu_N(x) - f(x) \\ &= \left(-\frac{d^2u_N}{dx^2} + \lambda u_N\right) - f . \end{aligned} \tag{10}$$

Since the residual is zero if $u_N(x)$ is the exact solution of Eq. (9), it follows that the goal of all numerical methods is to choose the undetermined coefficients, a_n, so as to make $R(x; a_n)$ as small as possible. The different kinds of spectral methods differ mainly in the minimization strategies. There are two basic types of spectral methods: pseudospectral methods and Galerkin methods.

In pseudospectral methods, the following $(N+1)$ algebraic equations are derived from Eq. (7):

$$\begin{aligned} &R(x_i; a_0, a_1, \ldots, a_N) = Lu_N(x_i) - f(x_i) \\ &= \left(-\frac{d^2u_N(x_i)}{dx^2} + \lambda u_N(x_i)\right) - f(x_i) = 0 , \\ &i = 0, 1, \ldots, N . \end{aligned} \tag{11}$$

In other words, pseudospectral methods define the 'minimization' of the residuals as 'zero at a set of $(N+1)$ collocation points, x_i'.

In the special case where the differential operator, L, is linear, Eq. (11) converts the differential Eq. (9) into the following linear matrix problem:

$$\bar{L}\bar{a} = \bar{f}\,, \tag{12}$$

where the elements of the matrices are

$$\begin{aligned} \bar{L})_{in} &= L[\phi_n(x_i)] = \left(-\frac{\mathrm{d}^2\phi_n(x_i)}{\mathrm{d}x^2} + \lambda\phi_n(x_i)\right), \\ \bar{a})_n &= a_n\,, \\ \bar{f})_i &= f(x_i)\,. \end{aligned} \tag{13}$$

Thus the inth element of the matrix, $\bar{L})_{in}$, is the approximate value of the differential operator, L, of the nth basis function (where n is the column index) evaluated at the ith collocation point (where i is the row index). If L is a nonlinear operator, on the other hand, then the algebraic Eqs. (11) are nonlinear, too. In such a case, they should be solved by iteration methods such as the Newton–Raphson method.

The alternatives to pseudospectral methods are Galerkin methods. Galerkin methods distribute the residual so that the expansion of the residual function as a series of the basis functions, $\phi_n(x)$, contains no component with respect to the test function, $\phi_i(x)$ $(i = 0, 1, \ldots, N)$. The combination of Eqs. (4) and (8) gives the following $(N+1)$ algebraic equations:

$$\begin{aligned} &(\phi_i, R\,[x; a_0, a_1, \ldots, a_N]) \\ &\quad = \int_\Omega \rho(x)\phi_i(x)\left(-\frac{\mathrm{d}^2u_N(x)}{\mathrm{d}x^2} + \lambda u_N(x) - f(x)\right)\mathrm{d}x \\ &\quad = 0\,, \\ &\quad i = 0, 1, \ldots, N\,. \end{aligned} \tag{14}$$

In the special case where L is a linear operator, Galerkin methods give the linear matrix problem

$$\tilde{L}\tilde{a} = \tilde{f}\,, \tag{15}$$

where the elements of the matrices are

$$\begin{aligned} \tilde{L})_{in} &= (\phi_i, L\phi_n) \\ &= \int_\Omega \rho(x)\phi_i(x)\left(-\frac{\mathrm{d}^2\phi_n(x)}{\mathrm{d}x^2} + \lambda\phi_n(x)\right)\mathrm{d}x\,, \\ \tilde{a})_n &= a_n\,, \\ \tilde{f})_i &= (\phi_i, f) = \int_\Omega \rho(x)\phi_i(x)f(x)\,\mathrm{d}x\,. \end{aligned} \tag{16}$$

In some cases, the orthogonality of the spectral basis-function set may be important because the coefficients of the expansion of an arbitrary function, $u(x)$, in terms of an orthogonal basis function set are given as

$$u(x) = \sum_{n=0}^{\infty} u_n(x)\phi_n(x)\,, \quad u_n = (u, \phi_n)/(\phi_n, \phi_n)\,. \tag{17}$$

If L is a nonlinear operator, then the algebraic Eqs. (14) are nonlinear, too.

Pseudospectral and Galerkin methods are very different in appearance. However, pseudospectral methods are efficient only if the collocation points are distributed so that the residual is not merely zero at the collocation points themselves but also very small everywhere in between. It turns out that, for all the canonical basis sets, the optimum choice of collocation points is to employ the Gaussian quadrature points which are used to evaluate the integral inner product associated with the basis set [1, 3]. From this, one could show that Galerkin and pseudospectral methods are equivalent if the integrals are evaluated by $(N+1)$-point Gaussian quadrature.

To summarize, pseudospectral algorithms are easier to program. On the other hand, Galerkin methods are more accurate for small N and are easier to understand and manipulate for theoretical purposes such as perturbation theory. Perhaps Galerkin methods are more robust for difficult problems. For numerical purposes, however, there is not much to choose between them [1].

S

Choice of Basis Function Set (Fourier Series and Chebyshev Polynomials)

When the solution has spatially periodic boundary conditions, one uses the following Fourier series as a basis func-

tion set:

$$u(x) = a_0 + \sum_{n=1}^{\infty} a_n \cos(nx) + \sum_{n=1}^{\infty} b_n \sin(nx)\,,$$
$$x \in [-\pi, \pi]\,,$$
$$a_0 = \frac{1}{2\pi}\int_{-\pi}^{\pi} u(x)\,\mathrm{d}x\,, \tag{18}$$
$$a_n = \frac{1}{\pi}\int_{-\pi}^{\pi} u(x)\cos(nx)\,\mathrm{d}x\,,$$
$$b_n = \frac{1}{\pi}\int_{-\pi}^{\pi} u(x)\sin(nx)\,\mathrm{d}x\,.$$

Since each Fourier term is individually periodic with a period 2π, the solution, $u(x)$, automatically satisfies the periodic conditions, independent of the spectral coefficients, a_n and b_n.

On the other hand, if the domain is finite, but the function is not periodic, for example $u(\pm 1) = 0$, the Chebyshev polynomials are best. The Chebyshev polynomials of degree n are defined as

$$T_n(x) = \cos[n \arccos(x)]\,. \tag{19}$$

It can also be calculated directly via the following three-term recurrence relation:

$$T_0(x) \equiv 1\,,$$
$$T_1(x) \equiv x\,, \tag{20}$$
$$T_{n+1}(x) = 2xT_n(x) - T_{n-1}(x), \quad n \geq 1\,.$$

To impose the Dirichlet boundary conditions, $u(\pm 1) = 0$, one defines the spectral basis functions to be linear combinations of the Chebyshev polynomials, which vanish at the boundaries, such as

$$\phi_{2n}(x) = T_{2n}(x) - 1\,,$$
$$\phi_{2n+1}(x) = T_{2n+1}(x) - x\,, \quad n = 1, 2, \ldots \tag{21}$$

The fact that $\phi_n(\pm 1) = 0$ for each n follows from the trigonometric definition of the Chebyshev polynomials, which implies $T_n(\pm 1) = (\pm 1)^n$.

There are many exceptions: the basis set can be generally determined by the flow geometry and boundary conditions. Therefore, the interested readers may refer to the literature for more details.

Spectral Domain-Decomposition Methods

Most of spectral methods have been developed paying attention to simple geometries and, thus, one would suffer from many difficulties in applying them to more complex geometries. Recently, there have been a number of developments on the use of spectral schemes in more complex geometries, for example the advent of spectral domain-decomposition methods. The basic idea behind these methods is to partition the whole domain into several subdomains, and then to simultaneously solve differential equations in each subdomain and appropriate matching conditions on each interface. In general, two classes of spectral domain-decomposition methods have been proposed in the literature: patching methods and variational methods.

In order to simply explain the basic principle of patching and variational methods, consider one-dimensional linear Helmholtz equation subject to zero Dirichlet boundary condition as follows:

$$Lu(x) = -\frac{\mathrm{d}^2 u(x)}{\mathrm{d}x^2} + \lambda u(x) = f(x) \qquad \text{in } \Omega \tag{22}$$
$$u(x) = 0 \qquad \text{on } \partial\Omega \tag{23}$$

where $\partial\Omega$ is the boundary of the whole domain.

Patching Methods

Patching methods [1, 3], first developed by Orzag [4], are useful in exploiting the efficiency of spectral collocation methods. Suppose that the whole domain, Ω, is decomposed into M subdomains, Ω_s $(s = 1, \ldots, M)$. N_s denotes the degree of polynomials used to approximate $u(x)$ in the sth subdomain, and $N \equiv N_1 + N_2 + \ldots + N_M$ is the total number of degrees of plynomials in the whole domain. The numerical solution is denoted by $u^N(x)$, while $u_s(x)$ indicates the *restriction* of the numerical solution to the sth subdomain.

In patching methods, the Helmholtz equation and the corresponding boundary condition are satisfied in each subdomain as follows:

$$Lu_s(x_i^s) - f(x_i^s) = \left(-\frac{\mathrm{d}^2 u_s(x_i^s)}{\mathrm{d}x^2} + \lambda u_s(x_i^s)\right)$$
$$- f(x_i^s) = 0 \quad \text{in } \Omega_s\,,$$
$$i = 0, 1, \ldots, N_s\,, \quad s = 1, 2, \ldots, M \tag{24}$$
$$u_s = 0 \quad \text{on } \partial\Omega \cap \Omega_s\,. \tag{25}$$

On the other hand, the solution and its first normal derivative should be continuous across the interface:

$$u_s = u_{s+1} \quad \text{on } \Gamma_s\,, \tag{26}$$

$$\frac{\mathrm{d}u_s}{\mathrm{d}x} = \frac{\mathrm{d}u_{s+1}}{\mathrm{d}x} \quad \text{on } \Gamma_s\,, \tag{27}$$

where Γ_s $[s = 1, 2, \ldots, (M-1)]$ denotes the interface between two adjacent subdomains, $\Gamma_s = \Omega_s \cap \Omega_{s+1}$. If the order of a certain differential equation is d (≥ 2), the solution and all the normal derivatives less than d should be continuous across the interface.

To summarize, in patching methods, the algebraic equations (24) are solved, together with the boundary condition (25), in each subdomain and simultaneously the interface matching conditions (26) and (27) are satisfied on each interface. The same principle can be readily extended to more-dimensional problems.

Variational Methods

Variational methods [3] are a class of high-order weighted residual techniques that combines the high spatial accuracy and rapid convergence of spectral methods with the generality and geometric flexibility of finite-element methods. Consider a variational method on Ω for one-dimensional Helmholtz Eq. (22). A variational formulation of this problem is that $u(x)$ should be the solution to

$$\int_\Omega \left(-\frac{\mathrm{d}^2 u(x)}{\mathrm{d}x^2} + \lambda u(x) \right) \phi_i(x)\,\mathrm{d}x = \int_\Omega f(x)\phi_i(x)\,\mathrm{d}x\,. \tag{28}$$

Equation (28) can be converted into another form, using integration-by-parts and zero natural boundary condition:

$$\int_\Omega \left(\frac{\mathrm{d}u(x)}{\mathrm{d}x}\frac{\mathrm{d}\phi_i(x)}{\mathrm{d}x} + \lambda u(x)\phi_i(x) \right) \mathrm{d}x = \int_\Omega f(x)\phi_i(x)\,\mathrm{d}x\,, \tag{29}$$

where $\phi_i(x)$ is the trial (or test) function which vanishes on $\partial\Omega$ and which is integrable over Ω together with its first derivative. In addition, it is a continuous function of piecewise polynomials defined on the decomposition of the whole domain, Ω. The solution to the Eq. (29) is approximated by a function $u^N(x)$ satisfying

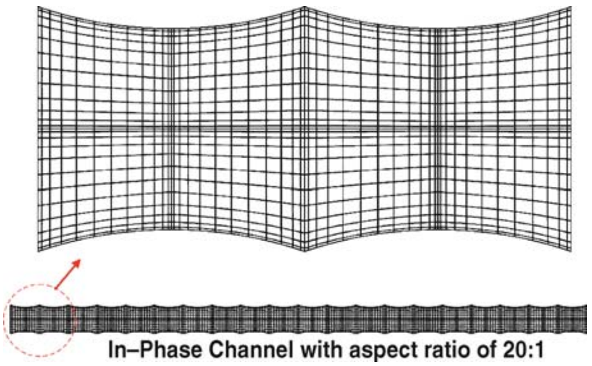
$$\sum_{s=1}^{M} \int_{\Omega_s} \left(\frac{\mathrm{d}u_s^N}{\mathrm{d}x}\frac{\mathrm{d}\phi_i}{\mathrm{d}x} + \lambda u_s^N \phi_i \right) \mathrm{d}x = \sum_{s=1}^{M} \langle f, \phi_i \rangle_s\,. \tag{30}$$

For each s, $\langle f, \phi_i \rangle_s$ is a convenient approximation of the integral, $\int_{\Omega_s} f\phi_i\,\mathrm{d}x$. Equation (30) is a variational formulation with trial and test functions which are continuous across the interface (element boundary).

Key Research Findings

Since micro and nanoflows involve very low Reynolds numbers, the convection effects may be neglected in simple geometries. However, in complex geometries with abrupt turns the effects are substantial [6] and, thus, more accurate and efficient numerical schemes such as spectral methods may be necessary in handling such flows. Up to now, there have been a vast number of numerical studies on micro and nanofluidics. Therefore, few conspicuous numerical studies using spectral methods have been performed, except Karniadakis' research group.

Karniadakis and Beskok [6] developed a code *μFlow* with implementation of spectral element methods. They employed both the Navier–Stokes (incompressible and compressible) and energy equations in order to compute the relative effects of compressibility and rarefaction in gas micro flow simulations. In addition, they also considered the velocity slip, temperature jump, and thermal creeping boundary conditions in the code *μFlow*. The spatial discretization of *μFlow* was based on spectral element methods, which are similar to the *hp* version of finite-element methods. A typical mesh for simulation of flow in a rough micro channel with different types of roughness is shown in Fig. 1. The two-dimensional domain is broken up into elements, similar to finite elements, but each element employs high-order interpolants based on Legendre polynomials. The N points that determine the interpolant correspond to the maxima locations of the Legendre polynomials and the end-points. For smooth solutions, the spatial discretization error decays exponentially to zero (spectral or p-convergence). This means that if we dou-



Spectral Methods, Figure 1 A typical mesh in a rough micro channel for the spectral element method [6]

S

ble N, the error would decay by two orders of magnitude. This is a much faster decay than in standard second-order methods which yield an error reduction by a factor of only four. In MEMS simulations, spectral element methods can be used efficiently by exploiting the dual path of convergence allowed by the method. For example, in regions of geometric complexity, a finite element-like discretization (low N and small size elements) can be employed, whereas in regions of homogeneous geometry with steep gradients, a spectral-like discretization (high N and large size elements) can be employed. In particular, the boundary conditions for MEMS flows, either for gases (Knudsen effects) or liquids (electrokinetic effects), can be resolved very accurately.

Future Directions for Research

Spectral methods have been a promising tool for simulating micro and nanoflows as well as macro flows because they have excellent properties of high spatial accuracy and rapid convergence. Therefore, they can capture a broad range of dynamically significant scales of motion very effectively.

Up to now, a vast number of studies on micro and nanofluidics have been performed based on the theoretical, numerical and experimental approaches. For the numerical analysis, however, finite-volume or finite-difference schemes have been mostly used. In the future, spectral methods will contribute more to the studies on micro and nanoflucids that require numerical methods with high spatial accuracy, for example electrokinetic and capillary effects.

Spectrophotometric Analysis

Synonyms

Spectrophotometry; Spectrophotometric measurement; Spectral analysis

Definition

The spectrophotometric analysis is the study of the interaction of electromagnetic radiation with chemical compounds. This analytical technique can be used to determine the structure of a new compound, identify a specific compound, determine the activity of a specific enzyme and determine the concentration and/or amount of a particular compound in body fluids samples. It is the one of the most commonly used analytical techniques for body fluids analysis in clinical diagnosis.

Spectrophotometric analysis by optical absorption is based on the absorption of electromagnetic radiation that is proportional to the amount of the element, ion, compound or molecule being analyzed in the sample. Absorbance detection is covered under a separate title.

Definition

The verb *to sputter* originates from *sputare* (latin, to emit saliva with noise). Sputtering is the ejection of atoms from a surface following bombardment by suitably energetic atomic particles. Typically, these bombarding particles are ions generated by an electrical discharge in a low pressure gas. This process can be utilized as a thin film deposition technique by allowing atoms sputtered from a target to impinge on a substrate. The process is widely used to deposit films less than one micrometer thick for microelectronic component fabrication, the formation of optical coatings and the production of decorative parts.

Overview

The process of sputtering was first reported by W. R. Grove in 1852. He observed the formation of metallic deposits on the inner wall of a glass discharge tube during an investigation into the electrical conductivity of gases using direct current (DC) glow discharges. This observation has led to the development of an extremely versatile thin film deposition technique that is utilized in numerous different fields. A vast range of different materials can be deposited using sputtering, including: pure metals, alloys, semiconductors and insulators. The deposition process can also be used for the formation of films with novel properties in terms of stoichiometry and crystalline orientation. In addition to deposition, sputtering can also be used for etching, surface cleaning and for surface layer analysis.

Sputtering has been used for many years to produce the chromium coated ▶ photomasks that are often used in the production of glass microdevices. Recently, sputtering has become a common technique for the deposition of thin films in microfluidic and nanofluidic devices. For most applications, it is used as a convenient means for the production of patterned electrodes. However, as will be shown below, sputtering can be used to achieve far more than this. In the not so distant future it is likely that the enormous versatility of this technique will be exploited for the fabrication of miniaturized fluidic devices with greatly enhanced functionality that would be difficult or impossible to produce by other means.

The sputtering process is governed by a range of different parameters. These parameters can be manipulated to alter the properties of the deposited film. In DC sputtering systems, the maximum energy (E) of the atoms ejected from the target is determined by the applied voltage. Accelerating a singly charged ion through a potential difference of 1 V imparts a kinetic energy of 1 eV to the ion. For a given voltage atoms are sputtered from the target with a broad distribution of energies. The sputtered atoms impinge on the substrate with maximal energies that are typically 100 times greater than those achieved during film deposition by evaporation. The applied voltage also governs a parameter called the ▶ sputter yield (S), which is the number of target atoms removed divided by the number of incident ions. For applied voltages below a certain threshold value, the ions have insufficient energy to overcome the surface binding energy (U_0) of the target material and so atoms are not ejected. This threshold level usually occurs between 0 and 100 eV. For ion energies between 100 eV and 1000 eV, atoms are ejected from the target and the *sputter yield* increases with increasing applied voltage. For ion energies within this range, the *sputter yield* can be estimated by assuming energy transfer occurs by binary collisions:

$$S = \frac{3\alpha}{4\pi^2} \cdot \frac{4m_\mathrm{i} \cdot m_\mathrm{t}}{(m_\mathrm{i} + m_\mathrm{t})^2} \cdot \frac{E}{U_0} \quad (1)$$

where m_i and m_t are the masses of the incident ion and the target atom, respectively; α is a function of the ratio $m_\mathrm{t}/m_\mathrm{i}$. This increases from 0.17 for $m_\mathrm{t}/m_\mathrm{i} = 0.1$ to 0.28 for $m_\mathrm{t}/m_\mathrm{i} = 1$ to 1.4 for $m_\mathrm{t}/m_\mathrm{i} = 10$.

For ion energies greater than 1000 eV, the probability of ions being implanted into the surface of the target becomes significant. The *sputter yield* no longer increases linearly with increasing ion energy. Eventually, the *sputter yield* becomes almost constant and at very high energies it begins to fall as ▶ ion implantation becomes the dominant process. As a consequence of this, in DC systems, applied voltages between 100 V and 1000 V are most widely used for the sputter deposition of thin films.

The rate of sputtering is determined primarily by the sputter current density. For most systems, this is generally between 0.1 and 10 mA/cm^2. Increasing the current density increases the rate of deposition. However, a faster rate of arrival of material on the surface of the substrate means that there is less time for the occurrence of processes such as surface diffusion and agglomeration on existing growth sites or nucleation with other growth sites.

The rate of sputtering and the properties of the deposited film are also significantly influenced by the sputter gas type and pressure. In most instances, it is not desirable for the sputter gas to react with the target and so noble gases tend to be used. Xenon and Krypton have larger atomic masses than Argon and generally give higher *sputter yields*. However, Argon is most often used as it is cheaper and more readily available.

The gas pressure dictates the average distance the sputtered atoms travel before they interact with gas atoms. This is called the mean free path (λ) and it is inversely proportional to the gas pressure. A short mean free path means that the sputtered atoms will be subjected to many collisions with gas atoms before being deposited on the substrate. This can affect the porosity of the deposited film and also its crystallinity and surface morphology. Hence, it is often desirable to sputter at low pressure, so that λ is as large as possible. For simple DC gas discharge systems (Fig. 1), relatively high pressures are used, typically 30 to 120 mTorr. This is because it is difficult to maintain the gas discharge at lower pressures. DC ► magnetron systems (Fig. 2) can be operated at lower pressures (10^{-5} to 10^{-3} Torr) since the magnetic fields around the target increase the number of collisions between electrons and neutral sputter gas atoms. Sometimes, a reactive gas such as oxygen or nitrogen is added to the sputter gas, so that oxide or nitride films can be deposited.

Not surprisingly, different target materials sputter at different rates. Periodicity is observed when *sputter yields* are plotted against target atomic number. This is related to the surface binding energy (U_0) of the target materials. For the transition metals, *sputter yields* increase between Ti and Cu; then decrease sharply. *Sputter yields* increase again between Zr and Ag before decreasing to another minimum at Hf. Yields increase once more, reaching another maximum at Au. Hence, Cu, Ag and Au are the transition metals that sputter most readily. The orientation and crystal structure of the target relative to the incident sputter ions can also affect the *sputter yield* and the angular distribution of sputtered atoms. *Sputter yields* tend to increase with increasing angle of incidence reaching a maximum between 60° and 80° from the target normal. For larger angles of incidence, the *sputter yield* decreases rapidly. At the optimal angle of incidence, the target atoms are sputtered predominantly in the forward direction with the maximum of their distribution occurring between 10 and 30° from the target normal. If the target is made of a monocrystalline material, then the angular dependence and *sputter yield* will vary according to the orientation of the crystallographic planes relative to the angle of incidence. This is because the surface binding energy (U_0) varies slightly in accordance with the ► anisotropy of the crystal structure.

Different metals sputter at different rates. However, when an alloy target is sputtered, the deposited film develops the same composition as the target material, as long as the target temperature is below that required for thermal diffusion. This is because the faster ejection of one element leads to the enrichment of the target's surface with elements that have lower sputter rates. Hence, differences in sputter rates are counteracted and the deposited film obtains the same stoichiometry as the target.

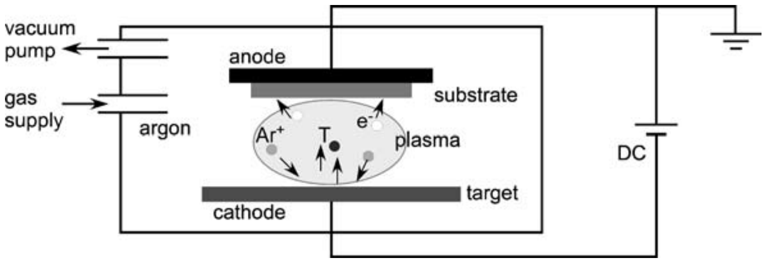
DC systems cannot be used to sputter insulating targets. This is because an electrical discharge in such a system would result in the charging up of the target. Therefore, radio frequency (RF) excitation is used to sputter insulating targets. RF excitation reverses the surface polarity of the target typically at a rate of 13 MHz, and this prevents the target from becoming charged.

The distance between the target and the substrate dictates the mean number of collisions that occur once the sputtered atoms leave the target and travel through the sputter gas to the substrate. Varying this distance can influence the porosity, crystallinity and surface morphology of the deposited film.

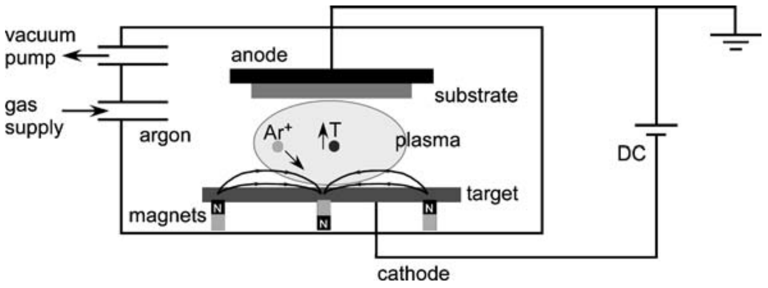
Film adhesion is strongly dependent on the cleanliness of the substrate, the chemical nature of the substrate relative to the film and the surface morphology of the substrate. Surface contaminants may increase or decrease adhesion, depending on how they influence the adsorption energy of the deposited material. Often it is desirable to have a very clean surface and so sputter cleaning of the substrate is performed prior to film deposition. Certain metals do not adhere well to substrates such as glass. Adhesion can be improved by increasing the kinetic energy of the incident atoms or by increasing the number of nucleation sites on the substrate. Alternatively, an adhesion layer could be applied to the substrate prior to deposition. For example, chromium is frequently used as an adhesion layer for the deposition of gold onto glass.

During sputtering, the substrate is bombarded by a wide range of species. Some of these species are charged. Hence the properties of the deposited film can be influenced by applying a ► bias voltage to the substrate. This is typically between ±100 V and it is used to repel or attract electrons or ions. Substrate biasing can exert a great influence on the physical and electrical properties of the deposited film, including: dielectric constant, porosity, surface morphology, hardness and etch resistance. The polarity and magnitude of the optimal *bias voltage* will depend on the target and substrate materials and the desired properties of the deposited film.

As with most vacuum deposition techniques, film growth on the substrate occurs according to the sequence: atom arrival and physical adsorption, migration on the surface



Sputtering for Film Deposition, Figure 1 Schematic of a DC sputtering system



Sputtering for Film Deposition, Figure 2 Schematic of a DC *magnetron*; a magnetic field is generated by an assembly of magnets beneath the target. This lead to the confinement of electrons in the immediate vicinity of the target

Sputtering for Film Deposition, Table 1 Advantages and Disadvantages for film deposition using sputtering.

Advantages of Sputtering	Disadvantages of Sputtering
– no melting of target material required – deposited film has same stoichiometry as target material – sputtering does not require evaporation, can sputter materials with high evaporation temperature – versatility (type of materials, instrumental parameters) – formation of novel materials possible – long target lifetime – simple DC systems can be built easily from primitive materials	– vacuum required – many variables to optimize, complexity to produce high quality films – dedicated instruments are expensive and require cleanroom facilities – contamination (increased porosity, pinholes, gas incorporation into film) – often slower than other methods

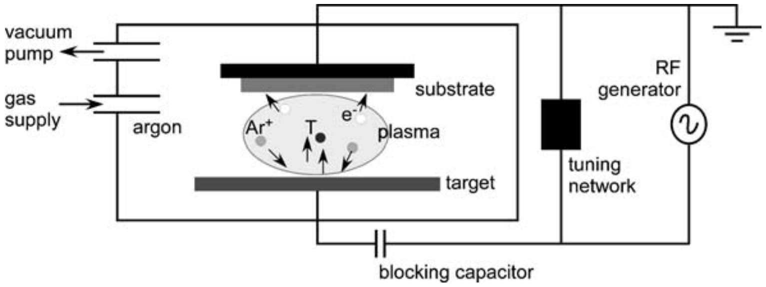
or re-evaporation, formation of atom pairs, nucleation of islands, island growth, coalescence and finally continuous film formation. Clearly, the temperature and crystallinity of the substrate will have a significant effect on the growth behavior of the film. Higher substrate temperatures impart higher mobilities to the atoms on the surface. This leads to larger grain sizes and smoother films. Hence, in many sputtering systems, the substrate is placed on a heated stage. However, the sputtering process itself can lead to significant substrate heating. Excessive heating is undesirable and so substrate cooling may be necessary. The use of polycrystalline substrates will generally lead to the formation of a polycrystalline film. However, if a monocrystalline substrate is used at a suitable temperature, then it is possible to form an ► epitaxial film. Substrates may also be chosen with specific crystallographic orientations so that deposited films acquire particular orientations.

The advantages and disadvantages of sputtering for film deposition are summarized in Table 1.

Basic Methodology

The simplest of sputtering systems is the DC gas discharge diode as shown in Fig. 1. This apparatus consists of a vacuum chamber containing two planar electrodes. One electrode is the cathode, to which the target is connected. This is usually water cooled to prevent it from over-heating. The substrate to be sputtered is placed onto the other electrode, which forms the anode. This may also be water cooled if necessary.

Prior to sputtering, the chamber is evacuated to remove as much oxygen and moisture as is possible. The level of vacuum that is achieved will depend on the effectiveness of the pumping system and the desired quality of the



Sputtering for Film Deposition, Figure 3 The principle of a radio frequency (RF) sputtering system

sputtered film. For high quality film production, the pre-sputtering vacuum should be in the region of 10^{-7} Torr. Once this has been achieved, sputter gas (typically Argon) is admitted to the chamber to raise the pressure to between 30 and 120 mTorr. A high voltage is applied to the electrodes and an electrical gas discharge is initiated. Generally, a constant current power supply is used so that the sputter current can be adequately controlled. The spacing between the target and the substrate is usually set at about 10 cm and the sputter current is adjusted to deposit a film at a suitable rate. Deposition rates are usually between 10 and 200 nm per minute, although this will vary significantly depending on the target material.

The main advantage of DC diode sputtering systems is that they can be extremely simple and can be constructed at low cost using readily available components [1] However, the quality of the films deposited with such systems is relatively poor. This is mainly due to the high operating pressure that must be used to maintain the electrical discharge. A widely used technique to lower the sputter gas pressure is to utilize magnetic fields to confine the electrical discharge to the region around the target (Fig. 2). Sputtering systems that utilize assemblies of magnets around the target are referred to as DC *magnetrons*. With these systems, the sputter gas pressure can be as low as 10^{-5} Torr and very high quality films can be produced at deposition rates that match those obtained by ►evaporation deposition techniques.

Unfortunately it is difficult to use DC systems and DC *magnetron* systems to sputter magnetic materials or insulators. For such targets, it is more common to use radiofrequency (RF) excitation to ionize the gas in the sputtering chamber (Fig. 3). A circuit is employed to match the ►impedance of the power supply to the *impedance* of the sputtering chamber. A blocking capacitor is placed in series with the target so that it is negatively biased during excitation. The sputter gas pressure is typically 1 mTorr. RF sputtering systems can also be fitted with magnet assemblies; such systems are referred to as RF ►magnetrons. A major disadvantage of RF sputtering is that substrate heating is more problematic than with DC *magnetron* systems.

Generally, sputtering systems are fitted with a shutter so that the target can be sputter cleaned before deposition. Other refinements include facilities for substrate biasing and for substrate sputter cleaning. Some sputtering systems are fitted with multiple targets so that different materials can be sputtered simultaneously or sequentially without breaking the vacuum.

For micro- and nanofluidic devices, sputtering is usually performed after channel fabrication. Areas that do not require sputter coating are masked off using a lift-off layer. This could be a specially fabricated photoresist layer, or it could just be the chromium mask left over from the channel etching step. The structured substrate is placed into the sputtering chamber where it is sputtered with the desired material. Then it is removed and the lift-off layer dissolved, leaving sputtered material in the appropriate areas. Subsequently the structure is bonded to a sealing layer so that the channel structure is enclosed.

Key Research Findings

Sputtering is a standard process in materials science and it has required fairly minor adaptation for its use in fluidic device fabrication. Hence, few papers specifically deal with sputtering for microfluidics, most authors mention sputtering as a technique employed in a rather brief manner. A non-exhaustive overview of different sputtering applications is given in Table 2. Many more metals, alloys, semiconductors and insulators can be sputtered than are listed in this table; however, they are beyond the scope of this article.

Sputtering is an excellent method for producing photolithographic mask blanks and for fabricating integrated electrodes, heating elements, sensors and catalysts. Sputtering can also be used to deposit sacrificial layers for nanochannel fabrication or for channel surface treatment

and modification. In addition to this, when microstructures are subjected to scanning electron microscopy (SEM) analysis, sputtering is often used to deposit a conducting layer prior to examination to prevent the structure from charging up when it is exposed to the electron beam.

Chromium is the most widely sputtered material for ►photomask fabrication. It sputters easily and it adheres well to glass. This high level of adhesion can be attributed to its ability to form a metal suboxide interface layer on glass. The exposed surface of the chromium is often oxidized to reduce its reflectivity. Aluminium is also sometimes used as a mask material, although it is more difficult to sputter and is has a higher reflectivity than oxidized Cr. This can be problematic for *photomask* applications.

On-chip electrodes have been fabricated from a number of metals including Al, Pt, Au, Indium Tin oxide (ITO)-Ag and Cu. Sometimes these electrodes have been used as low thermal mass integrated heating elements. The great versatility of sputtering is ideal for the creation of integrated on-chip sensors. These sensors range from simple thermocouples to pH sensors and even to multilayer oxide materials for giant magneto-resistance (GMR) sensors.

Sputtering has been used to incorporate a number of catalytic metals into microreactor devices. Examples include: Pt, Zr, Mo, Pd, Ru, Rh or alloys such as Pt-Ru. It is a convenient fabrication technique, although some researchers argue that the active surface area of the deposited catalyst is unsatisfactory. For many metals this problem can be overcome by sputtering using an oxygen-rich sputter gas rather than Ar alone. This produces a porous oxide deposit with a high surface area that can be reduced back to the metallic form after bonding. Alternatively, the catalytic metal can be co-sputtered with aluminium. The aluminium acts as an adhesion promoter and also forms an intermetallic oxide with the metal catalyst when the device is bonded. This method creates a robust and highly active catalyst.

Channel surface passification or modification can also be performed using sputtering. Examples include the deposition of SiO_2, SiC or even ►diamond like carbon (DLC). In addition to this, sputter deposited Ta has been used to promote ►anodic bonding for device fabrication.

Many sputtered metals do not adhere particularly well to typical device substrate materials such as silicon, glass and polymers. For example, noble metals such as Au can only rely on van der Waal's forces for adhesion and these forces

are relatively weak. Metals such as Cr, Al and Ti readily form a suboxide interface layer on glass and so they are often used as adhesion layers.

There is extensive knowledge of sputtering on Si and glass substrates that is available from the microelectronics and the electro-optics industries. Far less is known about sputtering onto more delicate substrates such as the polymers used for fluidic chip fabrication. Polymers are much more sensitive than glass and silicon to high temperatures and to being bombarded by charged particles and atoms. Conditions must be carefully optimized and the polymer substrate may even have to be protected by a layer of aluminium deposited by evaporation prior to sputtering. Great care must be taken when sputtering onto flexible polymers such as polydimethylsiloxane (PDMS), since bending may lead to cracking of the deposited film. This can be avoided by placing the polymer substrate onto a glass wafer or another rigid material. The adhesion of certain films to PDMS can be problematic. It has been found that ► plasma oxidation is sometimes helpful in improving film adhesion.

Sputtering is usually undertaken before the fluidic device is bonded and it is necessary to ensure that the deposited film does not interfere with the ► chip bonding process. This can be done by using a lift-off layer in the regions that must be clear of sputtered material. *Chip bonding* can have detrimental effects on the deposited film and this must be taken into account, especially where the device must be heated to a high temperature. After bonding, it is generally the case that catalysts deposited by sputtering must be activated before they can be used. This is often achieved by heating under a reducing atmosphere.

Future Directions for Research

Relatively few researchers in the field of micro- and nanofluidics have investigated the application of sputtering to their work. Hence, the potential of sputtering in device fabrication has been far from fully explored. In the future it is highly likely that sputtering techniques will play an important role in blurring the distinctions between electronic and fluidic devices. This will be driven by the desire to produce ever more sophisticated integrated devices with pumps, valves, electrodes, sensors, amplifiers and processors all placed on a single chip. The immense versatility of sputtering will lead to its use in the fabrication of devices with novel, nanostructured, multi-component materials. An infinite variety of composite nanomaterials can be deposited using sputtering. These materials can be engineered by: sputter etching of surfaces, sputtering using reactive sputter gases, sputtering with multicomponent targets (in combination or alternately to produce layers), by using angular dependence sputtering and by using oriented crystal substrates. Such materials will have extremely interesting catalytic and magneto-electro-optical properties and they will be utilized in many different areas of fluidics research. As can be seen from this brief introductory article, the combination of sputtering with micro- and nanofluidics is at a relatively primitive stage of development. Far more remains to be discovered.

Stability

Synonyms

Numerical stability

Definition

Stability is a desirable property of dynamic systems in general and numerical algorithms in particular. The precise definition of stability depends on the context, but it is generally related to the accuracy of the algorithm. It is sometimes observed that different ways of doing a single calculation yield different results as they have different levels of numerical stability. A numerical algorithm is called robust if it has good numerical stability.

In the context of ►Numerical Solution of Boltzmann Equationnumerical solution of partial differential equations, stability ensures that round-off and other errors in the calculation are not amplified to cause the calculation to blow up. An algorithm for solving an evolutionary (e. g., a time-dependent) ►partial differential equation is stable if the numerical solution at a fixed time remains bounded as the time step-size goes to zero. An important theorem in mathematics, the so-called Lax equivalence theorem, states that an algorithm converges if it is consistent and stable.

Stagnation Conditions

Definition

For a compressible flow, this is the thermodynamic state that would exist if a flow were brought to rest isentropically. In practice, this would correspond to the thermodynamic state of a very low-speed flow entering the nozzle inlet from an upstream combustion chamber or a pressurized reservoir. For this reason, stagnation conditions are also sometimes referred to as 'chamber' or 'reservoir' conditions.

Photopatterned materials; Cast-in-place polymeric media; In situ polymerized materials; Polymer monoliths; Cross-linked gels; Hydrogels

Definition

A stationary phase is a solid material, thin film, or gel that remains motionless relative to the flow of buffer, ions, or current in a microchannel during michrochip chromatography, electrochromatography, or electrophoresis.

Overview

Chromatographic separations frequently rely upon interactions between analytes in a flowing liquid or gas stream (or *mobile phase*), and a solid surface which remains motionless. In traditional forms of chromatography, the motionless solid surface, or *stationary phase*, might be porous particles of a polar material like silica (a *normal phase* chromatographic support), hydrophobically modified or coated silica (a *reversed phase* chromatographic support), or a thin polysiloxane film on the inner lumen of a capillary (for capillary gas chromatography).

These common forms of stationary phase are sometimes employed for miniaturized versions of chromatographic separations on microfluidic devices, although achieving uniform packing of porous particles in a planar chip can be difficult, typically requiring some form of on-chip frit. Furthermore, localizing particles to a single portion of a multifunctional device is challenging, requiring some form of on-chip valving or other strategy to isolate the chromatography column from the rest of the chip.

An alternative strategy which is sometimes employed is to fabricate a polymeric stationary phase *in situ*, often combined with photopatterning to localize the stationary phase in a particular region of the chip. As an example, phase separation polymerization using a variety of acrylate monomers, along with a photointiator, crosslinker, and porogenic solvent, can be used to define porous polymer monoliths within microchannels. In this approach, the monomers are initially soluble in the porogenic solvent, but as polymerization proceeds, the growing chains have decreased solubility, and eventually phase-separate or precipitate. Surface properties and pore size can be tailored by choice of monomer and solvent, with possibilities for hydrophobic, polar, or charged surfaces, and microscale or nanoscale pores. Polymerization can be initiated by flood illumination through a photomask, or using shaped laser light to localize monoliths to certain regions of the chip, with well-defined boundaries. Porous polymer monoliths created in this fashion have been used for on-chip liquid chromatography and electrochromatography of proteins, peptides, and other biomolecules, and are suitable for interfacing with mass spectrometry.

The term *stationary phase* can also be applied to a variety of crosslinked gels or hydrogels that can be fabricated within microchannels to act as sieving media for electrophoresis. Polyacrylamide gel is a typical stationary phase for electrophoretic separations, and has been used for sieving separations of native proteins and immunocomplexes, SDS-denatured proteins, and single- and double-stranded DNA. Sieving electrophoresis, particularly for DNA, is also frequently performed using semi-dilute solutions of non-crosslinked polymers. Crosslinked gels, like porous polymer monoliths, can be photpatterned *in situ* and localized to certain regions of the device with good spatial resolution, which can be an important advantage in complex, integrated microfluidic devices.

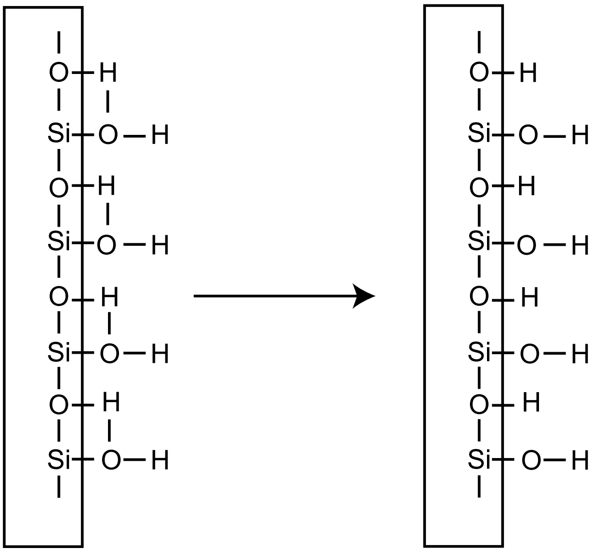
Synonym

Electroviscous effects

Definition

A forced ionic liquid flow generated by a pressure gradient in a microchannel induces an electrostatic field, and the current induced by the displacement of the heterogeneous charges in the flow is called the ► streaming current. Due to the electric neutrality of the fluid inside the microchannel, a conduction current, I_C, appears to equilibrate the ► streaming current, I_S. The physical and electrical properties of the fluid such as density, viscosity, electrical conductivity and permeability are influenced by concentrations of cations and anions. A forced ionic liquid flow with a surface potential induces a charge accumulation near the surface. Due to the concentration of charges the fluid viscosity near the surface is modified locally. This phenomenon of a change in apparent viscosity due to the



Streaming Current and Electroviscosity, Figure 1 Hydration and ionization of a fused silica surface by H_2O

presence of charges in an electrical field with a Lorentz force is also called ► electroviscosity.

Chemical and Physical Principles

Calculation of Streaming Current

► Streaming current and ► electroviscosity can only appear with an ionic fluid and a microchannel with a nonconductive inner surface such as fused silica. The surface charging mechanism with a liquid can have several origins [1]. One is the ionization and dissociation of a chemical group and another is ion adsorption, also called ion binding, on a surface which has a low charge or no charge initially. Whatever the wall charging mechanism, the final surface charge must be equilibrated by opposite sign charges accumulated in the fluid near the surface. The capacity of the wall to store charges is a function of its dielectric permittivity. For the purpose of this entry, the surface material is assumed to be fused silica (SiO_2). Water molecules hydrate the silica surface to create groups on the surface (Fig. 1). The physical mechanisms involved are the protonation and de-protonation of the SiO groups after hydration. The mechanism depends on the H^+ concentration given by the pH:

$$\mathrm{Si-O^-} + \mathrm{H^+} \longleftrightarrow \mathrm{Si-OH}\,, \tag{1a}$$

$$\mathrm{Si-OH} + \mathrm{H^+} \longleftrightarrow \mathrm{Si-OH_2^+}\,. \tag{1b}$$

If a pressure gradient is imposed on the fluid, a flow which contains charges appears and thus generates an electrostatic field due to the charge displacement. The electrostatic potential that is derived from this field is called the streaming potential. Without a pressure gradient, the fluid can be moved using an electrical field; hence an electro-osmotic flow appears. The fluid velocity profile which develops without the electric double layer (EDL) effect is parabolic; the velocity at the center of the microtube is maximum and null on the microtube surface. The charges in the fluid of opposite sign to that of the surface accumulate near the silica surface (SiO_2) and thus are transported at a lower speed than other charges far from the surface. These ion concentration laws are obtained by solving the Poisson–Boltzmann (PB) equation. Due to this differential transport phenomenon, an electric disequilibrium appears between the entrance and exit of the microtube in order to keep the total charge density constant. A current called a conduction current appears to counter the transport of charges by the fluid (streaming current). Without surface charges, no charge gradient appears in the cross-section; thus neither a streaming nor a conductive current appears. Considering that the Lorentz force (Eq. (2a)) applies on each charge, the balance between positive and negative charge is null at the center of the microtube and thus the resulting force is null. However, this disequilibrium induces a non-zero Lorentz force which has a maximum near the surface. This force decreases far from the surface as the excess charge density $\varrho(r)$ decreases. The fluid potential $\phi(r, z)$, written according to Eq. (2b), is a superposition of two potentials: the surface one $\psi(r)$ due to the EDL on the r-axis and the streaming one on the z-axis due to the differential transport phenomena of charges in the streaming field E_Z.

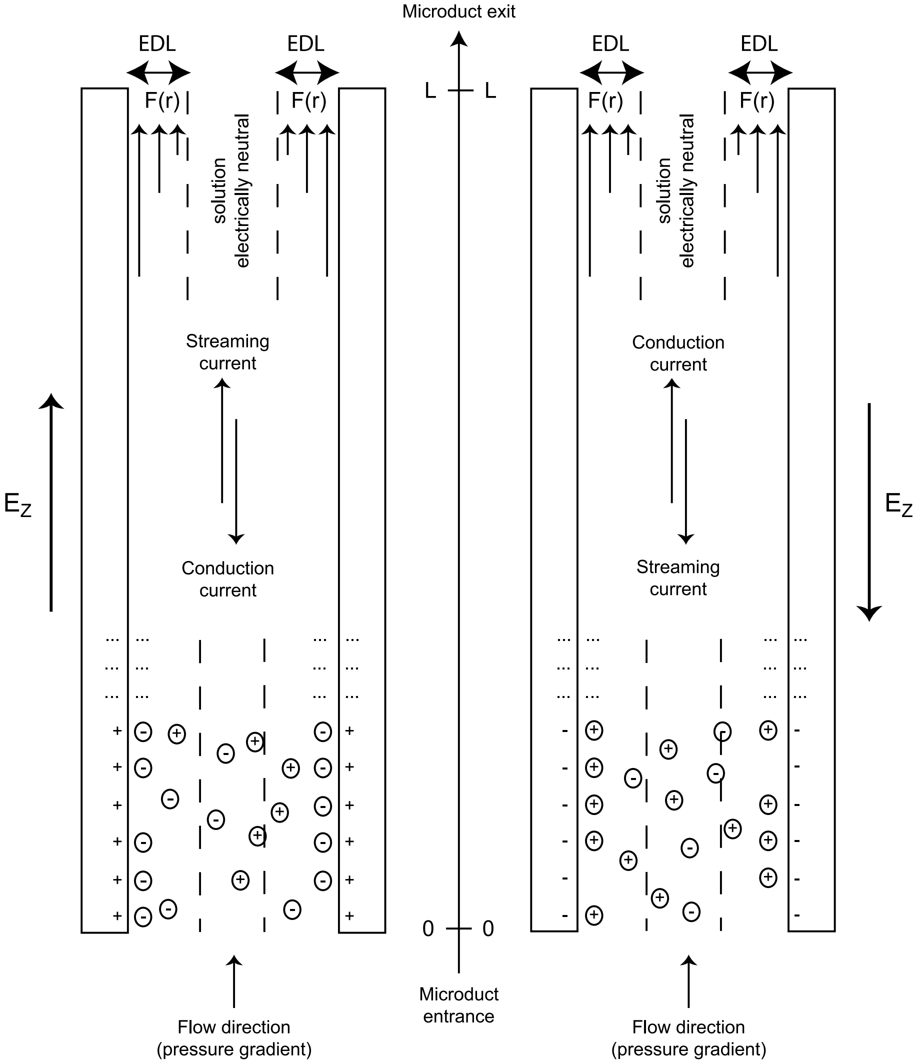
$$\boldsymbol{F}(r) = \varrho(r) E_Z \boldsymbol{e}_Z \tag{2a}$$

$$\phi(r, z) = \phi_0(r, z) - E_Z * z + \psi(r) \tag{2b}$$

$$E_Z = -\frac{\partial \phi(r, z)}{\partial z} \tag{2c}$$

The surface potential generates the charge gradient along the radius of the microtube according to an exponential law, whereas the streaming field induces a potential gradient along the microtube on the z-axis. As soon as ions are positioned radially, the pressure gradient induces a displacement on z. The total Lorentz force is thus on z. Its orientation is always in the direction of the flow. This phenomenon, in opposition to the fluid flow, occurs whatever the surface charge sign, as presented below:

- If the surface is negatively charged, positive charges are attracted near the surface of the microtube and thus a leak of these charges appears in the diffusive layer. The conduction current which characterizes the electron displacement is directed from the microtube



Streaming Current and Electroviscosity, Figure 2 Fluid charge distributions, electrostatic field orientations, force orientations and intensities for positive and negative surface charges

entrance to the exit in the direction opposite to that of the electrical field. The local force $F(r)$ which is based on the excess charge density (here positive charges: $+$e) is applied on a field E_Z oriented following $-\boldsymbol{e}_Z$ (from the exit to the entrance). $F(r)$ is therefore oriented along $-\boldsymbol{e}_Z$ and acts in opposition to the flow.

- If the surface is positively charged, negative charges are attracted near the surface of the microtube and thus a leak of these charges appears in the diffusive layer. The conduction current which characterizes the electron displacement is in the direction opposite to that of the electrical field from the microtube exit to the entrance. The local force $F(r)$ which is based on the excess charge density (here negative charges: $-$e) is applied on a field E_Z oriented along $\boldsymbol{e}_Z$ (from the entrance to the exit). $F(r)$ is therefore oriented parallel to $-\boldsymbol{e}_Z$ and also acts in the direction opposite to that of the flow.

The formulation used in this entry is based on the EDL theory detailed by Israelachvili [1]. The surface potential used for further calculations is denoted by ψ_0. The compact layer near the surface has a thickness of only a few atoms (about 1 nm) whereas the diffusive layer can reach 1 μm. The interfacial potential between these layers is called the zeta potential (ζ). In further computations we assume $\zeta \sim \psi_0$. Assuming a negatively charged surface, which is the case corresponding to our material, positive charges are attracted to the surface and there is a leak of negative charges. To calculate the local density of ions and co-ions, we need to make the chemical potential (μ_C)

balance on each species using the equations given below, where z is the ion valence, k_B the Boltzmann constant, T the average fluid temperature and e the proton charge:

$$\mu_C^i = ze\psi + k_B T \log n^i \,, \tag{3a}$$

$$n^i(r) = n_0 \exp\left(-i\frac{ze\Psi(r)}{k_B T}\right) . \tag{3b}$$

Considering that this potential is conserved, the chemical potential can be written for a radius and at the microtube center where the electrostatic potential is null: $\psi_{r=0} = 0$ where the fluid charge density is the bulk density (n_0). The ion concentration is given by

$$\varrho(r) = [n^+(r) - n^-(r)]ze \,, \tag{4a}$$

$$\varrho(r) = -2n_0 ze \sinh\frac{ze\Psi(r)}{k_B T} . \tag{4b}$$

where n^+ and n^- are respectively the positive and negative ion concentrations. The excess charge density is expressed as a function of the electrostatic potential.

The Poisson equation gives the relationship between the electrostatic potential $\psi(r)$ and the charge density $\varrho(r)$. In a circular geometry, the relation is

$$\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left(r\frac{\mathrm{d}\Psi(r)}{\mathrm{d}r}\right) = -\frac{4\pi}{\varepsilon\varepsilon_0}\varrho(r) \,, \tag{5a}$$

$$\frac{1}{\bar{r}}\frac{\mathrm{d}}{\mathrm{d}\bar{r}}\left(\bar{r}\frac{\mathrm{d}\bar{\Psi}(\bar{r})}{\mathrm{d}\bar{r}}\right) = -\frac{4\pi n_0 e^2 R^2}{\varepsilon\varepsilon_0 k_B T}\bar{\rho}(\bar{r}) . \tag{5b}$$

For further calculations we define nondimensional parameters such as $\bar{r}$, $\bar{\varrho}(\bar{r})$, $\bar{\Psi}(\bar{r})$:

$$\bar{r} = \frac{r}{R} \,, \tag{6a}$$

$$\bar{\varrho} = \frac{\varrho}{n_0 e} \,, \tag{6b}$$

$$\bar{\Psi} = \frac{e\Psi}{k_B T} \tag{6c}$$

$$\bar{\rho}(\bar{r}) = -2\sinh\bar{\Psi}(\bar{r}) \tag{7}$$

When Eq. (7) is included in Eq. (5b), the PB equation is obtained. κ is the electrokinetic length (usually called the Debye–Hückel length). The definition of δ depends on the geometry studied because whatever the geometry $\kappa = \delta R$ constitutes the right term of the equation before $\sinh(\bar{\Psi}(\bar{r}))$. In the literature, δ in planar geometry differs slightly from δ in circular geometry: $\delta_{circ} = \sqrt{4\pi}\,\delta_{plan}$. The boundary conditions for this nonlinear ordinary differential equation of second order are given below:

$$\frac{1}{\bar{r}}\frac{\mathrm{d}}{\mathrm{d}\bar{r}}\left(\bar{r}\frac{\mathrm{d}\bar{\Psi}(\bar{r})}{\mathrm{d}\bar{r}}\right) = \kappa^2\sinh\bar{\Psi}(\bar{r}) \,, \tag{8a}$$

$$\kappa = \delta R = \sqrt{\frac{8\pi n_0 z^2 e^2}{\varepsilon\varepsilon_0 k_B T}}R \,, \tag{8b}$$

$$\bar{r} = 0 \quad\Rightarrow\quad \frac{\mathrm{d}\bar{\Psi}(\bar{r})}{\mathrm{d}r} = 0 \,, \tag{8c}$$

$$\bar{r} = 1 \quad\Rightarrow\quad \bar{\Psi}(1) = \bar{\psi}_0 = \frac{e\psi_0}{k_B T} . \tag{8d}$$

The surface potential is related to the surface charge density through the charge balance, also known as the Grahame equation:

$$\sum_i \varrho_{0i} = \sum_i \varrho_{\infty i} + \frac{\sigma^2}{2\varepsilon\varepsilon_0 kT} \tag{9}$$

where σ is the charge density in $\mathrm{Cm^{-2}}$. ϱ is the volumic density of charges in $\mathrm{m^{-3}}$. Physically, the surface charge is constant for a given fluid while the surface potential is thereby a function of the charge fluid density. The glass–water surface potential is negative [2]. This is due to the H_3O^+ ion adsorption from the water dissociation. The authors performed measurements for glass surfaces with KCl solutions and show for a 3×10^{-3} M solution a surface charge of $-0.8\,\mu\mathrm{C\,cm^{-2}}$. For a higher pH of, say, 8.5, the measured surface charge reaches $-1.75\,\mu\mathrm{C\,cm^{-2}}$.

For example, with a 1 : 1 electrolytic solution ($z = 1$) with a concentration varying from 10^{-4} to $1\,\mathrm{mol\,l^{-1}}$ and a low surface charge of $0.2\,\mu\mathrm{C\,cm^{-2}}$, we obtain the relation between the surface charge and the surface potential function of the ion concentrations (C):

$$\sigma = \sqrt{8\varepsilon\varepsilon_0 k_B T\left(1000\left[\frac{C}{2}\right]\right)N_a}\sinh\frac{e\psi_0}{2k_B T} \tag{10}$$

where N_a is the Avogadro number, ε the relative fluid permittivity and ε_0 the absolute fluid permittivity.

To solve the PB equation we consider two zones in the microtube. Thus the hyperbolic sinus function is dissociated into two functions:

$$\bar{\Psi}(\bar{r}) \ll 1 \quad\Rightarrow\quad \sinh\left(\bar{\Psi}(\bar{r})\right) \approx \bar{\Psi}(\bar{r}) \,, \tag{11a}$$

$$\bar{\Psi}(\bar{r}) \gg 1 \quad\Rightarrow\quad \sinh\left(\bar{\Psi}(\bar{r})\right) \approx \frac{1}{2}e^{\bar{\Psi}(\bar{r})} . \tag{11b}$$

S

Equation (11a) is used for the central zone of the microtube for low potentials ($\psi_0 < 25$ mV or $\bar{\Psi}(1) < 1$) whereas Eq. (11b) is used for the zone near the surface with high surface potentials ($\psi_0 > 25$ mV or $\bar{\Psi}(1) > 1$).

Thus we build a potential function consisting of two branches matched at $\bar{r} = \beta$. Both functions are written $\bar{\Psi}_1(\bar{r})$ for $\bar{r} < \beta$ and $\bar{\Psi}_2(\bar{r})$ for $\bar{r} > \beta$. The matching condition is required for the function and their first derivate equality at $\bar{r} = \beta$. The boundary conditions for the potential function are given below:

$$\left[\frac{\mathrm{d}\bar{\Psi}_1(\bar{r})}{\mathrm{d}\bar{r}}\right]_{\bar{r}=\beta} = \left[\frac{\mathrm{d}\bar{\Psi}_2(\bar{r})}{\mathrm{d}\bar{r}}\right]_{\bar{r}=\beta} \tag{12a}$$

$$\bar{\Psi}_1(\beta) = \bar{\Psi}_2(\beta) \tag{12b}$$

$$\bar{r} = 0 \quad \Rightarrow \quad \frac{\mathrm{d}\bar{\Psi}_1(\bar{r})}{\mathrm{d}\bar{r}} = 0 \tag{12c}$$

$$\bar{r} = 1 \quad \Rightarrow \quad \bar{\Psi}_2(1) = \bar{\psi}_0 \tag{12d}$$

The continuity condition on the first derivative is used to access β which cannot be obtained analytically. At this stage it is necessary to solve the problem using a mathematical solver. The method for the solution of the ordinary differential equation is given by Levine et al. [3].

The momentum balance equation is applied for our situation with a volumic force due to the heterogeneous presence of charge excess. The geometry considered is a one-dimensional circular one with an incompressible liquid flow on the z-axis:

$$\frac{\mu}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left(r\frac{\mathrm{d}U_Z(r)}{\mathrm{d}r}\right) - \frac{\mathrm{d}P}{\mathrm{d}z} + F_Z = 0 \tag{13}$$

For the sake of simplicity we use the following notations. F_Z is expressed as a function of the excess charge density ($\varrho(r)$) and E_Z is the electrostatic field given by $E_Z = E_S/L$, where E_S is the electrical field:

$$P_Z = \frac{\mathrm{d}P}{\mathrm{d}z} \tag{14a}$$

$$F_Z = E_Z\varrho(r) \tag{14b}$$

$$\bar{U} = \frac{U_Z}{U_0} \tag{14c}$$

Thus we obtain the following ordinary differential equation to solve

$$\frac{1}{\bar{r}}\frac{\mathrm{d}}{\mathrm{d}\bar{r}}\left(\bar{r}\frac{\mathrm{d}\bar{U}(\bar{r})}{\mathrm{d}\bar{r}}\right) + K_1 - \frac{K_2\bar{E}_S}{\kappa^2}\frac{1}{\bar{r}}\frac{\mathrm{d}}{\mathrm{d}\bar{r}}\left(\bar{r}\frac{\mathrm{d}\bar{\Psi}(\bar{r})}{\mathrm{d}\bar{r}}\right) = 0 \tag{15a}$$

where K_1, K_2 and E_S are defined as

$$K_1 = \frac{P_Z R^2}{\mu U_0} \tag{15b}$$

$$K_2 = \frac{2n_0 e\xi R^2}{\mu U_0 L} \tag{15c}$$

$$\bar{E}_S = \frac{E_S}{\xi} \tag{15d}$$

K_1 is the classical force ratio between pressure and the viscous forces. With a difference of one coefficient, K_1 is the classical definition of the Poiseuille number.

Without the presence of the EDL, it is possible to relate K_1 to the wall shear stress by creating a force balance on the perimeter of the microtube. Thus we obtain the relation between the classical Poiseuille number (Po) and K_1 which is $K_1 = \mathrm{Po}/8$. With the EDL, an additional term must be accounted for. This is the first space integration of the EDL force in the cross-section:

$$P_Z = \frac{4\tau_W}{D} \tag{16}$$

Equation (15a) is transformed into

$$\frac{1}{\bar{r}}\frac{\mathrm{d}}{\mathrm{d}\bar{r}}\left(\bar{r}\frac{\mathrm{d}}{\mathrm{d}\bar{r}}\left(\bar{U} - \frac{K_2\bar{E}_S}{\kappa^2}\bar{\Psi}\right)\right) + K_1 = 0 \tag{17a}$$

then spatially integrated twice to obtain $\bar{U}(\bar{r})$ given by

$$\bar{U}(r) = \frac{K_1}{4}(1 - r^2) - \frac{K_2\bar{\xi}\bar{E}_S}{\kappa^2}\left(1 - \frac{\bar{\Psi}(r)}{\bar{\xi}}\right) \tag{17b}$$

The velocity profile is a function of the electrostatic potential function. For information, the reference velocity profile is given by

$$\bar{U}_{\mathrm{ref}}(\bar{r}) = 2(1 - \bar{r}^2) \tag{17c}$$

and will be used in the following sections for comparison. The electrostatic potential is solved as a function of $\bar{r}$ for both differential Eqs. (18a) and (18b) in the two separated zones:

$$\frac{1}{\bar{r}}\frac{\mathrm{d}}{\mathrm{d}\bar{r}}\left(\bar{r}\frac{\mathrm{d}\bar{\Psi}_1(\bar{r})}{\mathrm{d}\bar{r}}\right) = \kappa^2\bar{\Psi}_1(\bar{r}) \quad \forall\bar{r} \in [0, \beta] \tag{18a}$$

$$\frac{1}{\bar{r}}\frac{\mathrm{d}}{\mathrm{d}\bar{r}}\left(\bar{r}\frac{\mathrm{d}\bar{\Psi}_2(\bar{r})}{\mathrm{d}\bar{r}}\right) = \frac{\kappa^2}{2}e^{\bar{\Psi}_2(\bar{r})} \quad \forall\bar{r} \in [\beta, 1] \tag{18b}$$

The solution of Eq. (18a) can easily be obtained and is given below, where Bessel I_0 is the modified Bessel function of the first kind zero order:

$$\bar{\Psi}_1(\bar{r}) = \frac{\text{Bessel}\, I_0(\kappa\bar{r})}{\text{Bessel}\, I_0(\beta\kappa)} \tag{19}$$

The validity range for the integration of Eq. (18a) is the microtube cross-section ($\bar{r} \in [0, 1]$) and thus we obtain the solution for the assumption of low potentials (< 25 mV). This solution is called LP for 'low potentials':

$$\bar{\Psi}(\bar{r})_{\text{LP}} = \bar{\psi}_0 \frac{\text{Bessel}\, I_0(\kappa\bar{r})}{\text{Bessel}\, I_0(\kappa)} \tag{20}$$

It will be compared with the full solution for high potentials (HP) in the following sections.
According Levine et al. [3] in the case $P < 0$ the solution of Eq. (18b) is given by

$$\bar{\Psi}_2(\bar{r}) = \ln\left(\frac{-P}{\kappa^2\bar{r}^2\cos^2(Q + \frac{1}{2}\sqrt{-P}\ln\bar{r})}\right) \tag{21a}$$

where

$$P = \left[2 + \beta\kappa\frac{\text{Bessel}\, I(1, \beta\kappa)}{\text{Bessel}\, I(0, \beta\kappa)}\right]^2 - e^1\beta^2\kappa^2 \tag{21b}$$

and

$$Q = \cos^{-1}\left(\sqrt{\frac{-P}{e^{\psi_0}\kappa^2}}\right) \tag{21c}$$

The electrostatic potential variation is solved for both zones as defined by

$$\bar{\Psi}(\bar{r})_{\text{HP}} = \begin{cases} \bar{\Psi}_1(\bar{r}) = \dfrac{\text{Bessel}\, I_0(\kappa\bar{r})}{\text{Bessel}\, I_0(\beta\kappa)} \\ \quad \text{if } \bar{r} \in [0, \beta] \\ \bar{\Psi}_2(\bar{r}) = \ln\left(\dfrac{-P}{\kappa^2\bar{r}^2\cos^2(Q + \frac{1}{2}\sqrt{-P}\ln\bar{r})}\right) \\ \quad \text{if } \bar{r} \in [\beta, 1] \end{cases} \tag{22}$$

Thus it is possible to obtain the velocity profile as given by

$$\bar{U}(\bar{r})_{\text{HP}} = \begin{cases} \bar{U}_1(\bar{r}) = \dfrac{K_1}{4}(1 - \bar{r}^2) \\ \qquad - \dfrac{K_2\bar{\psi}^2\bar{E}_{\text{S}}}{\kappa^2}\left(1 - \dfrac{\bar{\Psi}_1(\bar{r})}{\bar{\psi}_0}\right) \\ \quad \text{if } \bar{r} \in [0, \beta] \\ \bar{U}_2(\bar{r}) = \dfrac{K_1}{4}(1 - \bar{r}^2) \\ \qquad - \dfrac{K_2\bar{\psi}^2\bar{E}_{\text{S}}}{\kappa^2}\left(1 - \dfrac{\bar{\Psi}_2(\bar{r})}{\bar{\psi}_0}\right) \\ \quad \text{if } \bar{r} \in [\beta, 1] \end{cases} \tag{23}$$

Now we need to determine $\bar{E}_{\text{S}}$ from the electrical charge balance inside the microtube.
A forced ionic liquid flow generated by a pressure gradient induces an electrostatic field E_{S}. The current induced by the charge displacement in the flow is called the electrostatic current I_{S}; its expression is

$$I_{\text{S}} = 2\pi \int_0^R U(r)\varrho(r) r\, \text{d}r \tag{24a}$$

After a classical nondimensioning of the governing equations on $U(r)$ and $\varrho(r)$, the expression of $\bar{I}_{\text{S}}$ is

$$\bar{I}_{\text{S}} = \frac{I_{\text{S}}}{U_0 R^2 n_0 e} = -4\pi \int_0^1 \bar{U}(\bar{r})\bar{\Psi}(\bar{r})\bar{r}\, \text{d}\bar{r} \tag{24b}$$

Applying the electric neutrality of the fluid inside the microtube, a conduction current (I_{C}) occurs in order to equilibrate the streaming current due to the charge displacement. The following equation gives the expression of the conduction current:

$$\begin{aligned} I_{\text{C}} &= \int_0^R 2\pi rme[n_+(r) + n_-(r)]\frac{E_{\text{S}}}{L}\, \text{d}r \\ &= \frac{E_{\text{S}}\lambda_0}{L}\int_0^R 2\pi r \cosh\bar{\Psi}(r)\, \text{d}r \end{aligned} \tag{25}$$

where λ_0 is the electrical fluid conductivity which can be calculated using

$$\lambda_0 = \text{F}^2 \sum z_i^2 \nu_i c_i \tag{26}$$

where ν_i is the ion mobility, c_i is the ion concentration, z_i is the charge and F is the Faraday constant.

Using a nondimensional form with Eq. (27c), we obtain Eq. (27a) where Σ_1 is a pure numerical integration:

$$\bar{I}_{\mathrm{C}} = \frac{I_{\mathrm{C}}}{\lambda_0 R \psi_0} = 2\pi \bar{E}_{\mathrm{S}} \bar{L} \Sigma_1 \tag{27a}$$

$$\Sigma_1 = \int_0^1 \bar{r} \cosh \bar{\Psi}(\bar{r})\, \mathrm{d}\bar{r} \tag{27b}$$

$$\bar{L} = \frac{L}{R} \tag{27c}$$

Using Eq. (28), the balance is written for both currents:

$$I_{\mathrm{S}} + I_{\mathrm{C}} = 0 \tag{28}$$

Thus we obtain $\bar{E}_{\mathrm{S}}$ which is given by

$$\bar{E}_{\mathrm{S}} = 2\frac{K_3}{\Sigma_1} \int_0^1 \bar{r}\bar{U}(\bar{r})\bar{\Psi}(\bar{r})\, \mathrm{d}\bar{r} = \frac{K_1 \Sigma_3}{\frac{2\Sigma_1}{K_3} + \frac{4K_2\bar{\psi}_0\Sigma_4}{\kappa^2}} \tag{29}$$

where K_3 is given by

$$K_3 = \frac{n_0 e L U_0}{\lambda_0 \psi_0} \tag{30}$$

and

$$\Sigma_3 = \int_0^1 \bar{r}(1-\bar{r}^2)\bar{\Psi}(\bar{r}) \tag{31}$$

$$\Sigma_4 = \int_0^1 \bar{r}\left(1 - \frac{\bar{\Psi}(\bar{r})}{\bar{\psi}_0}\right)\bar{\Psi}(\bar{r}) \tag{32}$$

Using the nondimensional electrostatic potential expression in the velocity profile expression, we obtain the Poiseuille number expression. K_3 is the nondimensional ratio between the convection current and the conduction current.

Electroviscosity

Theory

The net effect of the charge forces close to the wall is a diminished flow in the main flow axis. The fluid appears to exhibit an enhanced viscosity if its flow rate is compared with the flow without the EDL effects. This increase in apparent viscosity of a fluid is the ▶electroviscous effect [4–6].

To calculate ▶electroviscosity, we first define the volumic flow rate using

$$Q_{\mathrm{V}} = \int_0^R U(r) 2\pi r\, \mathrm{d}r \tag{33}$$

To use the previous results of the fluid velocity profile, we require a nondimensional form of the volumic flow rate:

$$Q_{\mathrm{V}} = 2\pi R^2 U_0 \int_0^1 \bar{r}\bar{U}(\bar{r})\, \mathrm{d}\bar{r} \tag{34}$$

The expression of the fluid velocity has already been calculated in the previous section (Eq. (23)). For calculation purposes, we use the following writing simplification ($i = 1$ if $\bar{r} < \beta$, $i = 2$ if $\bar{r} > \beta$):

$$\bar{U}_i(\bar{r}) = \frac{K_1}{4}(1-\bar{r}^2) - \frac{K_2\bar{\psi}_0\bar{E}_{\mathrm{S}}}{\kappa^2}\left(1 - \frac{\bar{\Psi}_i(\bar{r})}{\bar{\psi}_0}\right) \tag{35}$$

By replacing the fluid velocity expression, we extract the expression of the volumic flow rate:

$$Q_{\mathrm{V}} = 2\pi R^2 U_0 \left[\frac{K_1}{24} - \frac{K_2\bar{\psi}_0\bar{E}_{\mathrm{S}}}{\kappa^2}\int_0^1 \bar{r}\left(1 - \frac{\bar{\Psi}_i(\bar{r})}{\bar{\psi}_0}\right)\right] \tag{36}$$

The expressions of K_1 and K_2 (Eqs. (15b) and (15c)) are introduced into Eq. (36) to reveal the fluid viscosity:

$$Q_{\mathrm{V}} = \frac{\pi R^4}{12\mu}P_{\mathrm{Z}} - \frac{4\pi R^4 n_0 e \xi \bar{\psi}_0 \bar{E}_{\mathrm{S}}}{\mu L \kappa^2}\int_0^1 \bar{r}\left(1 - \frac{\bar{\Psi}_i(\bar{r})}{\bar{\psi}_0}\right) \tag{37}$$

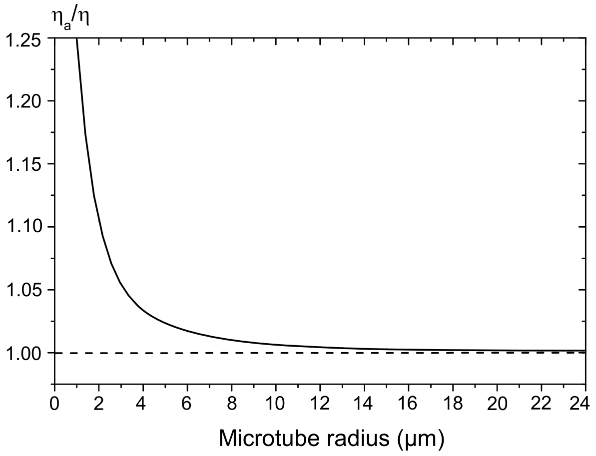
The apparent fluid viscosity (μ_{a}) can be deduced by assuming the classical relation between volumic flow rate and pressure drop:

$$Q_{\mathrm{V}} = \frac{\pi R^4}{12\mu_{\mathrm{a}}}P_{\mathrm{Z}} \tag{38}$$

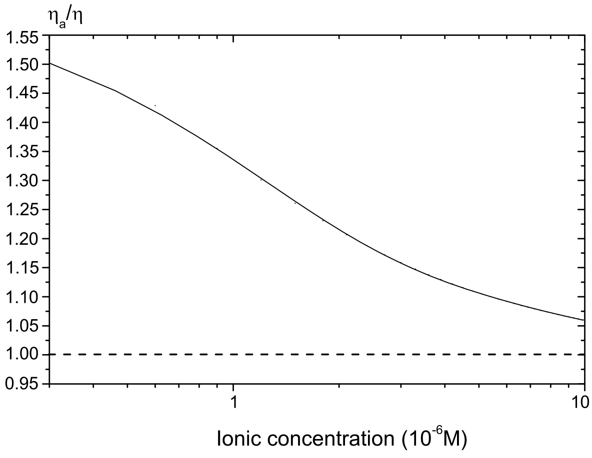
$$\frac{\mu_{\mathrm{a}}}{\mu} = \frac{1}{1 - \frac{32\bar{E}_{\mathrm{S}}(\bar{\psi}_0)^2\varepsilon\varepsilon_0}{\pi R^2 P_Z L}\int_0^1 \bar{r}\left(1 - \frac{\bar{\Psi}_i(\bar{r})}{\bar{\psi}_0}\right)} \tag{39}$$

Volumic flow rates which are identical are identified and enable us to find the ▶electroviscosity.

Equation (39) gives the ▶electroviscosity in a microtube with an inner charged surface at the potential ψ_0. The reduced forward volumic flow rate observed experimentally is interpreted as an increased apparent viscosity. Using the expressions of K_1, K_2, E_{S} and K_3 (respectively Eqs. (15b), (15c), (29) and (30)) it is possible to evidence that μ_{a}/μ is a function of neither the average fluid velocity (U_0) nor the pressure gradient (P_Z) but only a function of the microtube diameter and the electrokinetic parameters. The case of two parallel plates has been studied by Mala et al. [6] and will not be presented here. The ▶electroviscosity equation obtained differs slightly from Eq. (39) due to the geometry.



Streaming Current and Electroviscosity, Figure 3 Electroviscosity as a function of microtube radius for a pure deionized water flow with an electrical surface potential of 57 mV



Streaming Current and Electroviscosity, Figure 4 Electroviscosity as a function of fluid ionic concentration in a microtube with a diameter of 1 μm and an electrical surface potential of 40 mV

Example

Let us consider a capillary tube with a radius ranging from 1 to 24 μm, which corresponds to commercial fused silica microtubes used in gas chromatography. The fluid is pure deionized water with a total ionic concentration of 2×10^{-7} M and consequently an electrical conductivity of 4.1×10^{-7} S m^{-1}. The inner capillary surface is slightly charged at 50 μC m^{-2}, with a 1 : 1 electrolytic solution ($z = 1$). We obtain the relation between the surface charge and the surface potential function of the ion concentrations with Eq. (10). The surface potential (ψ_0) which is calculated by deduction is 57 mV.

Figure 3 presents the variation of the ►electroviscosity for a fluid flow of pure deionized water in a microtube with a radius ranging from 1 to 24 μm. The increase in ►electroviscosity in a microtube is not perceptible for diameters above 15 μm. Below 15 μm the increase becomes perceptible with a maximum of 25% for a microtube with a diameter of 2 μm. The model previously described and the mathematical assumptions are correct since the radius of the microtube is greater than the electrokinetic distance, which is about 1 μm for pure water. Experiments with microtubes smaller than the electrokinetic distance have not as yet been reported in the literature.

Figure 4 presents the variation of the ►electroviscosity for a KCl solution with an ionic concentration ranging from 3×10^{-7} to 10^{-5} M. As the ionic concentration increases, the electrokinetic distance ($1/\delta$) decreases according to Eq. (8b). The surface potential is constant at 40 mV and the diameter of the microtube is 1 μm. The largest electrokinetic distance is about 0.2 μm for the lowest ionic concentration based on two kinds of ions: K^+ and Cl^- for a total number charge (n_0). The ►electroviscosity is almost the classical fluid viscosity for solution concentrations higher than 10^{-5} M. For lower concentrations up to 3×10^{-7} M the apparent viscosity increases to reach +50% for a 3×10^{-7} M concentration, which is close to the ion concentration of pure water (total ion concentration of 2×10^{-7} M with H_3O^+ and OH^-).

Key Research Findings

The experimentally observed differences in the literature for fluid flow in microchannels can have many explanations. Some deviations can be rapidly explained by the use of microducts which have not been well calibrated. The four main effects proposed to explain these observed deviations are: the micropolar fluids theory, electrokinetic effects, heat viscosity dissipation and the wall continuity condition. Among all these effects electrokinetic flow has been more widely investigated in the literature; ion interaction with water is of great importance in biological and chemical applications for MEMS technology.

Electroviscous effects on fluid flow for ionic fluids in microchannels have been evidenced over the last decade experimentally [7–9] and are still a subject of widespread theoretical research [4, 10]. Ren et al. [5] found experimentally significant electroviscous effects for dilute solutions flowing through microchannels with hydraulic diameters of 14.1, 28.2 and 40.5 μm. They elaborated a model for a microchannel between two plates which considers the deficit of counterions and the surplus of co-ions outside the EDL. They obtain a nonzero electrical potential gradient and a net charge density near the middle plane of the microchannel. The highest fluid velocity and the transport

S

of the net charge at the center of the microchannel result in a higher streaming potential.

Subdynamic Regime

Definition

Laminar fluid flow regime in which inertial effects become negligible compared with frictional damping.
This regime exists at very low values of the Reynolds number, usually below $\mathrm{Re} \simeq 10$. In the true subdynamic

regime the character of the flow ceases to depend on the Reynolds number, the flowfield becomes self-similar. Microfluidic devices are rarely if at all employed in the subsonic regime – usually the inertial effects remain noticeable in them. The regime, however, served as a useful reference asymptotic state.

darren.hitt@uvm.edu

Synonyms

MEMS-nozzle; Microthruster; MEMS-thruster

Definition

The fundamental purpose of any nozzle is the acceleration of a flow field via the conversion of available pressure and/or internal energy into kinetic energy. For compressible fluids (gases), it is possible accelerate to the flow from subsonic to sonic speeds – and ultimately supersonic speeds – with sufficiently high inlet pressure ratios. Supersonic nozzles typically consist of three distinct regions: a subsonic converging portion at the inlet, followed by a 'throat' where the cross-sectional area is minimum, and finally a supersonic diverging section ('expander'). Micronozzles are uniquely defined by their small length scales (throat diameters typically below 100 μm) and the low Reynolds numbers of the flow ($Re < 1000$).

Overview

Perhaps the most frequent engineering application of nozzles is in propulsion systems for aircraft or spacecraft; however, other important applications exist as well (e. g., spray nozzles and fluid atomization). Initial acceleration of a flow at subsonic speeds occurs in the convergent section and, for sufficiently high pressure ratios and nozzle area contraction, it is possible to accelerate a flow to sonic conditions at the nozzle throat. The addition of a divergent section downstream of the throat enables further acceleration of the flow through supersonic expansion (i. e., a *de Laval* nozzle). It is the ability of the convergent–divergent nozzle to fully and efficiently extract pressure/internal energy from a low speed inlet flow and produce supersonic exit velocities that make it such a vital component in high-speed aerospace propulsion. In the present article, we shall restrict our focus to supersonic nozzle behavior within the context of propulsion physics and engineering.

In most aerospace propulsion applications, the combination of high speeds and moderate-to-large length scales result in very high Reynolds numbers – sufficiently large that viscous effects can be largely ignored and inviscid analyses employed as a first approximation. However, the importance of viscous effects in supersonic flows is emerging in light of recent trends within the aerospace community linked to the design of next-generation miniaturized spacecraft. Most commonly known as 'nano-sats' (The names 'micro-sats' and more recently 'pico-sats' are also used, and to a certain degree, they can be regarded as interchangeable with nano-sat. At present there exists no formalism to distinguish the specific mass range that defines a micro/nano/pico-sat other than being successfully smaller than each other), these spacecraft will feature masses < 20 kg and be capable of operating in distributed networks ('formation flying') and performing mission objectives not currently achievable with traditional satel-

S

lite architectures. Over the past decade, numerous and diverse micropropulsion initiatives for nano-sats have been undertaken by governments, industry, and academia throughout the world. The various approaches, all of which tend to have their unique benefits, have included both liquid/solid chemical propellants and electric propulsion concepts; many of these options require supersonic micro-nozzles as an integral part of the design. For the interested reader, a comprehensive survey of current micropropulsion concepts is given by Mueller [1].

As a result of the dramatically reduced size, nano-sats require miniaturized propulsion systems to provide the extremely low levels of thrust/impulse necessary for orbital maneuvering and precise station-keeping. With the characteristic length scales being considered for these new propulsion systems being on the order of microns to millimeters, the corresponding Reynolds numbers within the supersonic nozzles are $\mathrm{Re} \sim 10^2 - 10^3$ and hence viscous effects can no longer be ignored. The scenario of low Reynolds number, supersonic flow represents a *very unusual flow regime*, and one that has not been extensively examined in the fluid dynamics literature. In this regime, there is the usual thermo-fluidic complexity of a supersonic flow superimposed with subsonic viscous boundary layers extending from solid surfaces. At these low Reynolds numbers the viscous layer can occupy a sizable fraction of the divergent nozzle cross-section and, as a consequence, substantially impact the performance of the nozzle (e. g. thrust production). Aside from viscous forces, other important effects such as heat transfer and flow rarefaction may also be present on the micro-scale. The former becomes a concern as the thermal mass of the flow is reduced and the surface area-to-volume ratio increases on the micro-scale. The latter introduces additional complications since gas kinetic (non-continuum) effects begin to emerge as the characteristic length scales begin to approach molecular mean free paths.

In this article, we provide an overview of the various engineering issues and challenges surrounding the modeling, design and fabrication of micro-propulsion systems and supersonic micro-nozzles in particular. From this, it is our hope and intent that the reader will develop an appreciation for the unique aspects of supersonic nozzle behavior on the micro-scale.

Basic Methodology

Design Considerations and Specifications

Micro-Electro-Mechanical Systems (MEMS) techniques offer great potential in satisfying future mission requirements for the next generation of small scale spacecraft being designed by the aerospace community. Owing to the substantially reduced size, nano-sats have unique propulsion requirements, including extremely low thrust levels and/or extremely low minimum impulse requirements for orbital maneuvers and attitude control. Nanosatellites will be launched from Earth in a consolidated manner via a single rocket. Once in orbit, they will be subsequently deployed and operate in a distributed network performing simultaneous, multi-point observations and communication. The Magnetospheric Constellation (MagCon) is an example of one mission currently being designed by the NASA Goddard Space Flight Center (GSFC) that will utilize the unique characteristics of nano-satellites to monitor the Earth's magnetosphere. This type of space mission is not feasible with traditional satellite architectures. Nano-satellite technology demands highly accurate and extremely precise control of the spacecraft to maintain pattern formation. The primary method of attitude control is spin axis precession. In order to correct for perturbations such as solar radiation pressure or gravitational non-uniformities, the propulsion system must operate by firing low thrust, precise, and controlled impulse 'bits'. As a result of the spacecraft's reduced size and mass, the ability to perform spin axis precession and very small station-keeping maneuvers will require the development of radically new propulsion systems.

Supersonic Micro-Nozzles, Table 1 Design parameters for the NASA/GSFC MEMS-based monopropellant supersonic micro-nozzle.

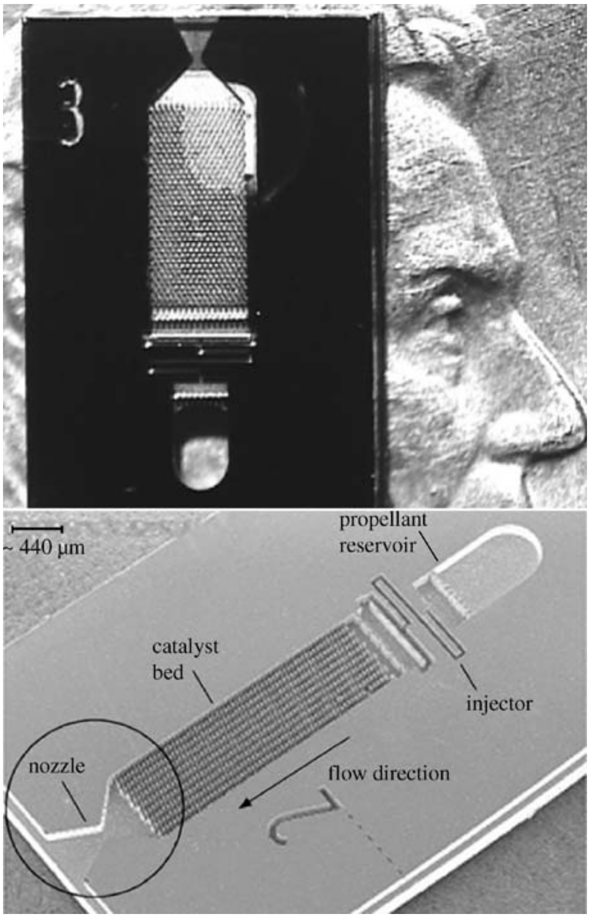
Design Parameter	Value/Range
Target Thrust Level	$10 - 500\ \mu\mathrm{N}$
Maximum Specific Impulse	180 sec
Specific Impulse Efficiency	80%
Steady State Inlet Pressure	250 kPa
Mass Flow Rate	~ 0.015 kg/sec
Throat Area	$9000\ \mu\mathrm{m}^2$
Expansion Ratio	6.22
Inlet Mach No.	0.05
Exit Mach No.	$2.5 - 3.0$
Reynolds Number	< 1000
Impulse Bit	$1 - 100\ \mu\mathrm{N}$ sec

As an illustrative example, NASA/GSFC has designed a prototype monopropellant micro-thruster, shown in Fig. 1, for the purpose of nano-satellite attitude control and station keeping maneuvers [2]. The supersonic micro-nozzle has been outlined in the figure for clarity. A listing of target design specifications for this prototype is given in Table 1. The NASA/GSFC prototype is based on catalytic decomposition of a liquid monopropellant; specifically

hydrogen peroxide H_2O_2 or hydrazine N_2H_4. Chemical-based propulsion schemes, on the whole, are attractive in several regards: they feature relatively high energy densities and efficiencies; the propellants can be stored at low pressures thus alleviating leakage concerns; and they offer the ability to throttle and control the rate of thrust production via transient operation.

Quasi-1D Flow Approximation and Analysis

A supersonic micro-nozzle consists of a micro-machined channel with a varying cross-sectional area $A(x)$, where the $+x$-direction coincides with the flow direction within the channel. Under the 'quasi-one-dimensional' (quasi-1D) flow approximation, all flow variables are assumed to vary only with the streamwise position x (and time if the flow field is unsteady). Variations across a given cross-section are considered negligible. Such an approximation is valid provided that the *rate of area variation* $\mathrm{d}A/\mathrm{d}x$ *is sufficiently small*. The quasi-1D model is, of course, only an approximation of an actual 3D flow; however, it greatly simplifies analyses and often yields surprisingly good results in predicting basic nozzle behavior. An overview of the quasi-1D nozzle model and its limitations can be found in most gas dynamics references (e. g., [3]).



Supersonic Micro-Nozzles, Figure 1 (Top) A photograph of the NASA/GSFC MEMS-based micro-thruster etched into a silicon wafer and placed on top of a US penny for purposes of scale. (Bottom) A Scanning Electron Microscopy (SEM) image of the NASA/GSFC micro-thruster with the converging-diverging supersonic micro-nozzle outlined for clarity. See [2] for details

The governing equations for the flow are obtained by one-dimensional approximations of conservation laws for mass, momentum and energy. Often the additional assumptions of inviscid, adiabatic flow are invoked and, as a consequence, the flow is regarded as isentropic throughout. From the conservation laws, one may derive an important relation between the cross-sectional area, the velocity and the local Mach number:

$$\frac{\mathrm{d}A}{A} = \left(\mathrm{M}^2 - 1\right)\frac{\mathrm{d}u}{u} \tag{1}$$

Here $\mathrm{M} = u/a$ is the Mach number and a is the isentropic speed of sound defined by

$$a^2 = \gamma RT \tag{2}$$

where T is the static temperature, R is the gas constant, and $\gamma = C_\mathrm{p}/C_\mathrm{v}$ is the ratio of the specific heats.

The area-velocity relation provides important insight regarding the behavior of a quasi-1D compressible flow in a channel of varying cross section. It states that for a subsonic flow ($\mathrm{M} < 1$) to increase velocity, a decrease in cross-sectional area is required. This is an intuitive and familiar result similar to incompressible flow theory. In contrast, acceleration of a supersonic flow ($\mathrm{M} > 1$), requires an increase in area: a counter-intuitive result when viewed from an incompressible flow perspective. This relation also indicates that sonic velocity ($\mathrm{M} = 1$) can only occur at a nozzle throat where the area is a minimum. It thus follows for a gas to expand from subsonic to supersonic velocities, it must flow through a convergent–divergent channel arrangement.

An alternative and extremely useful form of the area-velocity relation (1) can be derived for isentropic flow which relates the local Mach number to the local area,

$$\left(\frac{A}{A_*}\right)^2 = \frac{1}{\mathrm{M}^2}\left[\frac{2}{\gamma+1}\left(1 + \frac{\gamma-1}{2}\mathrm{M}^2\right)\right]^{\frac{\gamma+1}{\gamma-1}} \tag{3}$$

where A_* is the area of the nozzle throat where sonic conditions exist. For a prescribed nozzle profile $A(x)$, this 'area-Mach relation' yields the corresponding variation in

the Mach number along flow direction. Further, for isentropic flow, it can be shown that the local thermodynamic properties (T, p, ρ) may be uniquely determined by the local Mach number according to the following:

$$\frac{T_0}{T} = 1 + \frac{\gamma - 1}{2}\mathrm{M}^2 \tag{4}$$

$$\frac{p_0}{p} = \left(1 + \frac{\gamma - 1}{2}\mathrm{M}^2\right)^{\frac{\gamma}{\gamma-1}} \tag{5}$$

$$\frac{\rho_0}{\rho} = \left(1 + \frac{\gamma - 1}{2}\mathrm{M}^2\right)^{\frac{1}{\gamma-1}} \tag{6}$$

Here, the subscript "0" indicates the stagnation conditions $(\mathrm{M} \to 0)$ corresponding to a specific flow state. In practice, these are the conditions of the gaseous products of chemical decomposition or combustion that exist upstream of the nozzle inlet and, therefore, may be regarded as known states for the purposes of the nozzle modeling.

In summary, for a prescribed nozzle profile $A(x)$ and inlet conditions, the area-Mach relation (3) and isentropic flow relations (4)–(6) are sufficient to completely determine the nozzle flow field under the quasi-1D model.

Thrust and Impulse

The ultimate deliverable for a supersonic nozzle in a propulsion application is the production of thrust and impulse. A control volume analysis of the nozzle indicates that the thrust produced at any moment in time can be approximated by the exit conditions according to

$$\boldsymbol{F} = \int_{A_{\mathrm{exit}}} \rho \boldsymbol{u} \left(\boldsymbol{u} \cdot \boldsymbol{n}\right) \mathrm{d}A \approx \dot{m}\boldsymbol{V}_{\mathrm{exit}} \tag{7}$$

where $\dot{m} = \rho_{\mathrm{exit}} V_{\mathrm{exit}} A_{\mathrm{exit}}$ is the mass flow rate through the nozzle and $\boldsymbol{V}_{\mathrm{exit}}$ is the average velocity at the nozzle exit plane. For transient operation, the total impulse during a single firing cycle of the thruster is given by

$$\boldsymbol{I} = \int_0^{t_\mathrm{b}} \boldsymbol{F}\,\mathrm{d}t \tag{8}$$

where t_b is the total burn time or thrust duration of a single micro-nozzle firing. Under the quasi-1D approximation, all force generated is necessarily in the axial direction (i.e., thrust). In actual 2D or 3D flows, this will generally not be the case and there will be performance reductions resulting from transverse velocity components at the exit. Thus, exit flow alignment is yet another consideration that is part of the overall supersonic nozzle design.

Continuum vs. Rarefied Flows

The preceding discussion has implicitly assumed that the flow conditions are such that the continuum assumption remains valid within the micro-nozzle. The usual metric cited in arguing for (or against) the continuum assumption is the *Knudsen number* Kn, defined by $\mathrm{Kn} = \Lambda / L$ where Λ is the mean free path of the fluid particle and L is a characteristic length scale. For converging-diverging nozzles the throat dimension is commonly chosen as the characteristic length scale. An alternative version of the Knudsen number which is of particular use in investigating supersonic flows is given by

$$\mathrm{Kn} = \sqrt{\frac{\gamma\pi}{2}}\frac{\mathrm{M}}{\mathrm{Re}}\,.$$

While $\mathrm{Kn} \to 0$ is the formal requirement for a continuum flow, in practical terms gas flows for which Kn remains below a threshold value can be safely regarded as being within a continuum regime. The exact value of Kn at which rarefaction effects begin to appear remains a matter of some controversy and generally depends upon the specifics of the flow under consideration; however, $\mathrm{Kn} \sim 0.01 - 0.1$ is a representative range of values. At these and higher Kn numbers, the breakdown in the continuum assumption is first manifested at the boundaries with the appearance of velocity and (if applicable) thermal 'slip' wherein a discontinuity occurs between the flow and the solid boundary where they interact. Mathematically, these modified boundary conditions take the form:

$$u_{\mathrm{slip}} = \mathrm{Kn}\frac{\partial u}{\partial n} \qquad T - T_{\mathrm{wall}} = \mathrm{Kn}\frac{\partial T}{\partial n}$$

The flow within a typical converging/diverging supersonic micro-nozzle – and its plume – may span a wide range of Knudsen numbers encompassing continuum flow, highly rarefied flows and all intermediate states in between. A key determinant, however, rests with the value of the ambient back-pressure at the nozzle exit. For cases where there is very low back-pressures (e.g., low Earth orbit or space) a significant portion of the flow field may be influenced by rarefaction effects. Conversely, at more modest back-pressures (e.g., atmospheric operation) it may be that the flow field can safely be regarded as remaining within the continuum regime.

In most high-altitude or space applications, the nozzle flow will be under-expanded and the external plume will experience the greatest flow rarefaction. Depending on the circumstances, the rarefaction can be quite severe, extending beyond the slip regime and bordering on the free molecular regime. In such cases, modeling efforts require the use

of gas kinetic schemes such as Direct Simulation Monte Carlo (DSMC) or even Molecular Dynamics (MD). The discussion of these methods are beyond the scope of this article and the interested reader is encouraged to refer to the classic monograph by G. Bird [4]. It is important to note that, for supersonic flow, the level of accuracy required in the modeling of the plume region is really a 'matter of interest'. For example, if the interest lies in the chemical signatures of exhaust plumes or perhaps the interaction of the plume with a spacecraft's solid surfaces, then flow rarefaction cannot be ignored. On the other hand, if thrust production by the nozzle is the key item of interest, then the specifics of the supersonic plume are of no real import.

It is possible that the supersonic portion of the micro-nozzle may also experience some degree of rarefaction, depending on the specifics of the flow. However, the extent of the rarefaction is usually minor and, if needed, can be reasonably managed by augmenting a continuum model with slip boundary conditions to yield more precise estimates of thrust production.

Micro-Nozzle Geometry

Area Ratios and Physical Nozzle Dimensions

The driving constraint of a micro-nozzle design is the target thrust level, which is determined by the nozzle exit conditions (velocity, thermodynamic state, and area) as given by Eq. (7). It is important to note that there is not a unique flow state for a specific thrust, and thus other design constraints or conditions must be imposed in order to determine a specific solution. Such considerations might include: the ambient back-pressure at the nozzle exit, the maximum allowable size of the nozzle, or the maximum mass flow rate $\dot{m}$ that the system can deliver. For micro-nozzles that are components of miniaturized propulsion systems, size may be the overriding concern and hence the exit area may provide the necessary additional constraint. Once the desired nozzle exit conditions have been identified, the nozzle area expansion ratio (A/A_*) is fixed by the area-Mach relation (3); moreover, the values of all the remaining thermodynamic variables $(T/T_0,\ p/p_0,\ \rho/\rho_0)$ are fixed by the isentropic flow relations (4)–(6). Note that the state of the gaseous products of decomposition or combustion upstream of the nozzle inlet establishes the stagnation values T_0, p_0, and ρ_0.

As an illustrative example, the NASA/GSFC micro-nozzle described in [2] is designed to produce a thrust level in the range of $10-500\,\mu$N. This prototype featured a throat dimension of $90\,\mu$m and an exit area expansion ratio $A_{exit}/A_* \sim 6$ which produce an exit Mach number of ~ 3.4.

Nozzle Profile and 3D Effects

The idealized nozzle profile $A(x)$ is one which provides the required area expansion ratios for supersonic flow and, concurrently, aligns the flow in the axial direction at the nozzle exit. This flow alignment minimizes losses in thrust production associated with unwanted transverse velocity components. The traditional 'bell-shape' contoured nozzle accomplishes this task while maintaining isentropic flow conditions throughout the nozzle. Note that the profile of the isentropic bell nozzle cannot be obtained by quasi-1D theory. Rather, it is determined through the solution of expansion and compression wave propagation in the supersonic portion of the nozzle – typically this is done using the method of characteristics (e. g., [3]). While a bell-shape profile may be the ideal case, linear nozzles are also commonly used in thruster propulsion systems. A linear nozzle features a supersonic section with a fixed expansion rate $\mathrm{d}A/\mathrm{d}x$ characterized by a divergence angle θ. Linear nozzle designs are attractive primarily for their geometric simplicity and the associated advantages in the fabrication process. This has proven to be an important consideration for micro-scale fabrication of nozzles over the past decade; however, microfabrication techniques continue to improve and the likely future trend will be a return to the more efficient bell-shape nozzles.

Regardless of the profile, one key difference between micro-nozzles and their macro-scale counterparts is their inherent 3D nature. Owing to the method of microfabrication (see below) the nozzles are ducts with rectangular cross-sections. Conversely, all macro-scale nozzles are conical in nature and thus the flows are 2D aximsymmetric. The 3D nature of the flow can have substantial effects on the supersonic nozzle performance on the micro-scale.

Microfabrication Techniques

Many MEMS-based micro-nozzles are created from 2D planar patterns which are transferred to a substrate material (typically Si) via a photolithographic masking process. The nozzle is fabricated within the substrate by selectively removing the substrate material from unmasked regions; commonly this is accomplished via reactive ion etching (RIE) or 'deep' reactive ion etching techniques. Whereas the RIE method is acceptable for etching depths on the order of $10\,\mu$m, the DRIE method enables etching depths in excess of $100\,\mu$m. Chemical wet etching is also possible, but is becoming less common because of its inherent limitations compared to RIE techniques. An alternative approach, and one which is becoming more widely available, is the use of 'focused ion beams' (FIB) to mill out the pattern on the substrate. Regardless of the method, high precision is required in the fabrication

process to ensure proper geometry is produced, including smooth nozzle walls. The nozzle is typically sealed by bonding a cover surface (e. g., Pyrex to provide optical access) to the substrate. Often anodic bonding is used to produce a permanent bond which can withstand a wide range of operating temperatures. To date, there has been little effort experimentally to provide for thermal insulation of the nozzle within the substrate. This may be an important area for future work given the potential significance of heat transfer during nozzle operation, as will be described later.

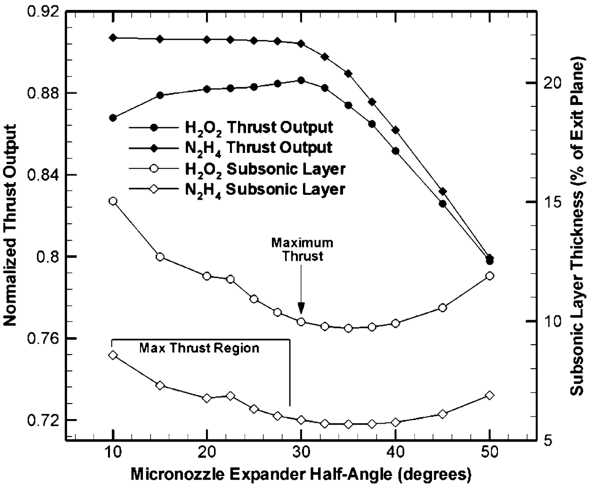
Key Research Findings

Steady Flow

Much of the current research is focused on examining the interaction of viscous forces and nozzle geometry in an effort to better understand and quantify performance characteristics. The majority of the research literature has dealt with 2D steady-state flow conditions. Given the experimental challenges associated with micro-scale supersonic flow interrogation, virtually all analyses have been computational in nature. While some experimental works have also been reported, most of these have reported only thrust measurements without corresponding flow field data.

Within the aerospace literature, Bayt and Breuer [5] were among the first to examine micro-nozzle flow and to identify the key role that viscous effects can play. In short, the low Reynolds numbers of these flows permit the growth of relatively thick viscous layers within the nozzle expander – these layers can occupy a significant portion of the nozzle exit, effectively restricting the flow and reducing thrust production. In an effort to mitigate the growth of viscous layers, propulsion researchers have considered increasing the expansion angle of the diverging section of the nozzle; however, as will be shown, doing so introduces geometric losses linked to increased non-axial exit velocity components.

The results that to follow are based on numerical simulations of the operation of the NASA/GSFC microthruster system described in [2]. While the data is somewhat case specific, the findings and issues that arise are germane to most micro-scale nozzles. Numerical models of monopropellant based supersonic flows have been developed for varying micro-nozzle geometries including linear and bell shaped expander sections. For the linear micro-nozzles, which will be of primary focus, expander half-angles have been examined within the range of $\theta = 10° - 50°$ (Fig. 2). For the present analysis, adiabatic nozzle walls are assumed. The supersonic flow field is characterized by Reynolds numbers typically less than 1000.



Supersonic Micro-Nozzles, Figure 2 Performance results for the NASA/GSFC supersonic microthruster nozzle with decomposed H_2O_2 and decomposed N_2H_4 as the working monopropellants. Thrust production, as shown on the left axis, has been normalized by the theoretical quasi-1D inviscid value. The percentage of the micro-nozzle exit plane occupied by the viscous subsonic layer is also shown on the right axis for both monopropellants of interest. Results are shown for expander half-angles ranging from 10° to 50°. Note that the expander angle exhibiting the maximum thrust production does not directly coincide with the minimum subsonic layer thickness. This is a direct result of the competing effects of viscous forces and micro-nozzle geometry. The optimum expander angle is the result of this trade-off

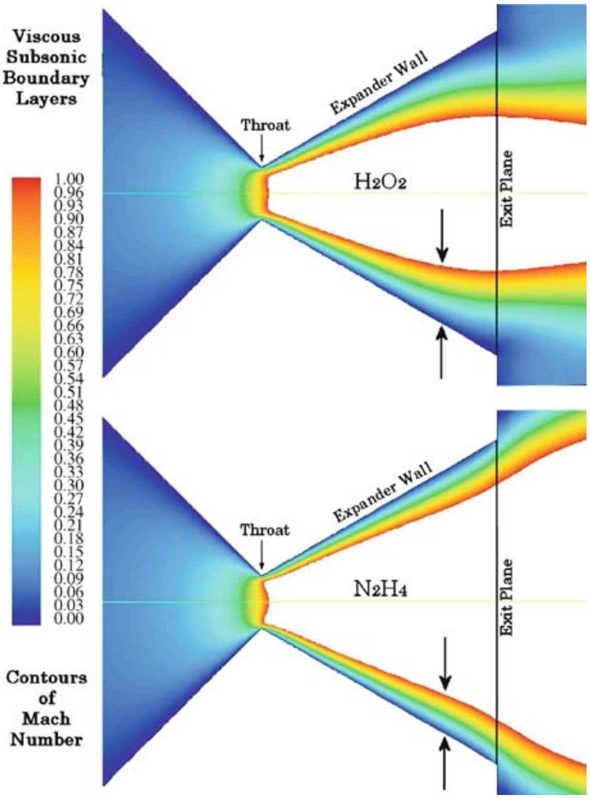
Referring to Fig. 2, a rapid and drastic reduction in thrust output is observed as the expander half-angle is increased above 30°. This is a direct consequence of expander geometry. For large expander angles, the flow follows the walls in the expander and thus a sizeable component of the velocity vector exits the nozzle in the transverse direction. This results in a significant reduction of axial momentum flux and a corresponding decline in thruster performance.

For small expander angles, transverse velocity components due to expander geometry are reduced, but at the expense of increased nozzle length in order to maintain the desired area expansion ratio. As the expander angle is decreased below 30°, viscous forces acting over the lengthened expander section begin to dominate nozzle performance. The subsonic layer acts to restrict the flow and reduce the effective exit area. Because the viscous boundary layer at the exit plane is subsonic, the ambient back-pressure conditions can communicate with the flow upstream within the nozzle expander near the walls. As a result, the flow inside the expander will respond in order to match ambient backpressure. The flow exiting the micro-nozzle is inherently underexpanded in a space environment and, as such, premature flow turning occurs via an

expansion fan originating within the nozzle. Thus, a portion of the exit momentum is vectored into the transverse direction which results in a further reduction in micro-nozzle performance. These factors combine to represent a performance trade-off between viscous and geometric effects as described further in Louisos and Hitt [6].

To provide additional insight into the nature of the viscous effects, the subsonic boundary layer in the nozzle expander can be examined. Fig. 3 shows the viscous subsonic boundary layer in the 30° expander half-angle for both decomposed H_2O_2 and decomposed N_2H_4. Forming at the throat, the viscous subsonic layer grows as the axial distance progresses towards the exit. The subsonic layer thickness also scales with the fluid viscosity, as is evident for the two different monopropellants shown in Fig. 3. The steady-state subsonic layer thickness at the nozzle exit has been quantified as a function of expander half-angle in Fig. 2. As the expander angle is decreased, the subsonic layer grows to occupy a larger percentage of the nozzle exit area, up to 15% for decomposed H_2O_2 and up to 8.5% for decomposed N_2H_4. For cases of smaller expansion angles, the corresponding length of the expander increases allowing the subsonic layer to grow as the flow moves further downstream. This scenario is directly responsible for the reduction in performance of the micro-nozzle at small divergence angles. For larger expander angles, the subsonic layer thickness again increases proportionally. Here the flow is forced to turn sharply at the throat as it enters the micro-nozzle expander section. The high speed bulk flow is unable to turn efficiently and a thick subsonic layer results near the wall boundary. However, owing to the low Reynolds number regime, no flow separation is observed.

It is clear that the interplay between viscous effects and micro-nozzle geometry is complex and must be fully understood for the efficient design of high-performance MEMS-based nozzles. In summary, with the flow conditions specified for the micro-thruster nozzle, trade-offs between the size of the subsonic layer and geometric losses due to non-axial flow components result in an optimal linear expander half-angle of approximately 30° with decomposed H_2O_2 as the monopropellant. This value is significantly larger ($2\times$) than half-angles of around 15° typically used in macro-scale conical thrusters [7]. While the N_2H_4 monopropellant thruster does not exhibit a distinct maximum thrust output corresponding to an optimal geometry, it is clear that the most effective half-angle is in the range of 25° and less.



Supersonic Micro-Nozzles, Figure 3 Visualization of the viscous subsonic boundary layer in the 30° half-angle micro-nozzle expander section as shown by Mach contours < 1.0 for both decomposed H_2O_2 (top) and decomposed N_2H_4 (bottom) at an inlet to exit pressure ratio of 10 : 1 across the micro-nozzle. Note that the size of the H_2O_2 subsonic layer is larger compared to the N_2H_4 subsonic layer owing to the fact that decomposed H_2O_2 has approximately a 38% greater viscosity over the operating temperature range within the micro-nozzle

S

Transient Flow

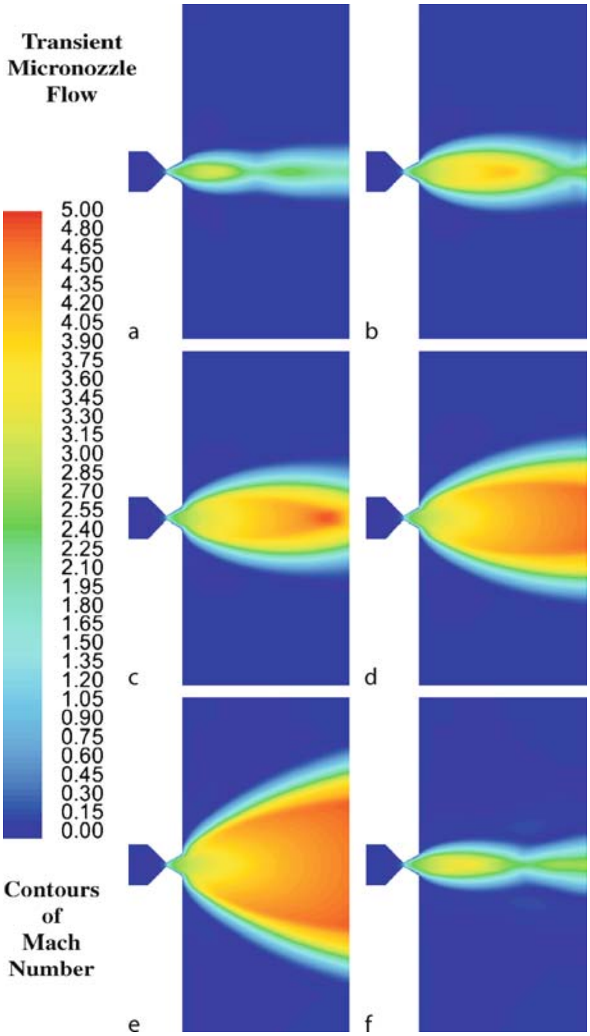
Supersonic micro-nozzles are intended to provide station keeping and attitude control for nano-sats. This is accomplished through the application of discrete impulse 'bits' resulting from the transient firing of the micro-thruster. The ability to precisely predict and control the impulse bit delivered during a firing is evidently of great importance from an operations standpoint. The thruster firing for a chemical-based system essentially involves three phases: start-up, a period of steady-state operation, and finally a shut-down sequence. Currently, typical micro-valve actuation of the propellant flow is on the order of milliseconds. Because of viscous effects on the micro-scale, the use of inviscid theory in determining flow actuation and micro-nozzle performance can lead to innaccurate predictions. This may be present in the form of 'residual' thrust and impulse resulting from the viscous impact on nozzle response. There has been little in the literature on transient operations. Here we describe results for a simulated firing of the NASA/GSFC micro-nozzle prototype.

Transient micro-nozzle simulations have been performed with divergence half angles ranging from $10-50°$ with decomposed H_2O_2 as the gas.

For a typical microthruster firing, the micro-valve is initially closed and there is no flow through the nozzle. As the valve opens, a pressure gradient is established across the nozzle and the corresponding mass flow through the nozzle begins to generate thrust. Initially the pressure ratio is small and the flow at the exit is over-expanded and thus free boundary shock reflection is observed in the exhaust plume. With elapsed time the micro-valve continues to open and the pressure gradient across the nozzle increases as does thrust production. The size of the exhaust plume increases in tandem. As the micro-valve opens to its maximum position the flow transitions from over-expanded through perfectly-expanded and finally to under-expanded flow at steady-state; at this point a sizable expansion fan develops at the nozzle exit. This sequence is then repeated, in reverse order, during the shut-down process of the micro-nozzle duty cycle. The flow field evolution at selected time steps is shown in Fig. 4. A single typical thruster firing, which includes start-up, steady-state, and shut-down occurs on the order of a few milliseconds.

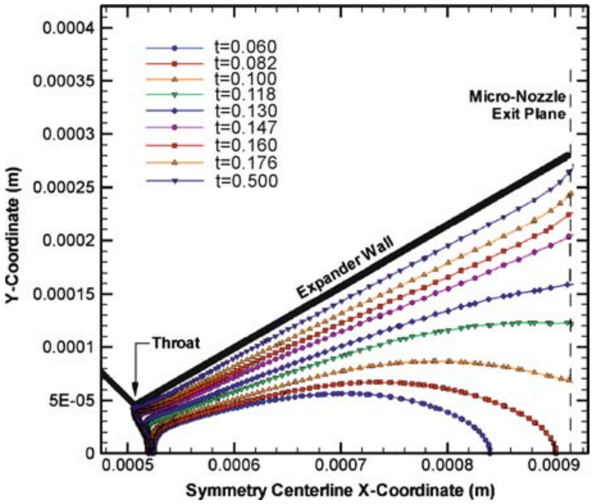
Numerical simulations of transient micro-nozzle flows have shown a lag in thrust production and performance response during the start-up sequence of the duty cycle [8]. For the reduced pressure gradient across the nozzle during start-up, viscous effects dominate and the flow throughout the entire expander section is subsonic. As the pressure gradient increases with time, the flow locally attains supersonic velocities in a region extending downstream from the throat, but then decelerates to subsonic speeds by the nozzle exit. This is seen in Fig. 5 which shows the extent of the viscous subsonic layer in the expander section at various times during the start-up process. As the micro-valve continues to open and larger pressure gradients are established, the flow is able to overcome viscous forces and establish wide-spread supersonic conditions in the expander section.

A finite time 'lag' is observed during the start-up which results from viscous effects. The lag in thrust production during start-up is most pronounced in the 10° and 50° expander half-angles owing to the fact that these geometries feature for the largest subsonic layers. It is interesting to note that the flow does *not* exhibit a lag in response to micro-valve closure during the shut-down sequence of the micro-nozzle [8]. Owing to the fact that viscous effects tend to reduce flow through frictional forces, the shut-down process is in fact facilitated by the existence of the subsonic layer. As the pressure ratio across the micro-nozzle is reduced during shut-down, the subsonic layer grows into the bulk of the flow field and thus promotes the reduction of thrust output. In this sense, viscous forces aid the shut-down sequence through dissipation.

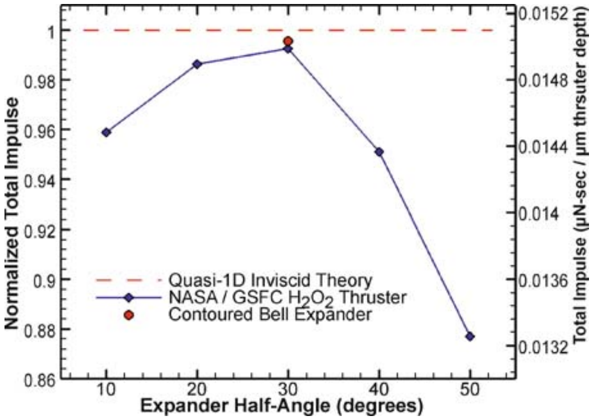


Supersonic Micro-Nozzles, Figure 4 The evolution in time of the micro-nozzle flow field as shown by Mach number contours for the 30° expander half-angle during transient operation of the microthruster. As the pressure ratio across the micro-nozzle increases during start-up, the exhaust plume grows in size and the flow transitions from over-expanded through perfectly expanded flow to under-expanded conditions. A typical microthruster firing is on the order of milli-seconds and the simulation depicted here has a total actuation time of 1.7 ms. The results normalized by the actuation time are characterized as follows; (**a**) $t^* = 0.16$ over-expanded start-up, (**b**) $t^* = 0.176$ over-expanded start-up, (**c**) $t^* = 0.188$ perfectly expanded start-up flow, (**d**) $t^* = 0.206$ under-expanded start-up, (**e**) $t^* = 0.5$ steady-state under-expanded, and (**f**) $t^* = 0.82$ over-expanded shut-down flow. As expected, free boundary shock reflection occurs in the case of over-expanded flow while an expansion fan can be seen near the exit of the micro-nozzle for under-expanded flow

The transient results can be summarized by examining the total impulse over one duty cycle for a single micro-nozzle



Supersonic Micro-Nozzles, Figure 5 Shown in the figure are transient sonic lines (M = 1) which indicate the maximum extent of the viscous subsonic layers from the micro-nozzle wall during the start-up sequence of the micro-nozzle. The time t has been normalized by the total actuation cycle time of 1.7 ms. Note that for $t < 0.082$ the flow is initially supersonic in the vicinity of the throat before viscous forces impede the flow and thus cause it to revert back to entirely subsonic conditions at the nozzle exit



Supersonic Micro-Nozzles, Figure 6 A plot of the total impulse generated during a single actuation cycle for a range of expander half-angles as compared to quasi-one-dimensional inviscid theory. Maximum total impulse occurs at a micro-nozzle half-angle of 30°. For expander half-angles < 30°, viscous effects are responsible for the reduction in performance while at larger expander angles, performance decreases as a result of significant transverse velocity components at the micro-nozzle exit. The bell contoured expander here initially has a 30° half-angle in the vicinity of the throat and the contoured walls align the flow along the nozzle axis. As anticipated, the contoured expander outperforms the linear nozzle owing to the straightening of the flow and lack of transverse velocity associated with the bell profile

firing. The results are shown in Fig. 6; also shown are the results from quasi-1D inviscid theory for comparison purposes. As expected, the total impulse from the simulations is less than that predicted by inviscid theory – this difference can be directly attributed to the integrated effect of viscous and geometrical losses incurred during the transient process. The 'optimal' angle for a linear micro-nozzle in the transient case is seen to be the same as for the steady-state operation.

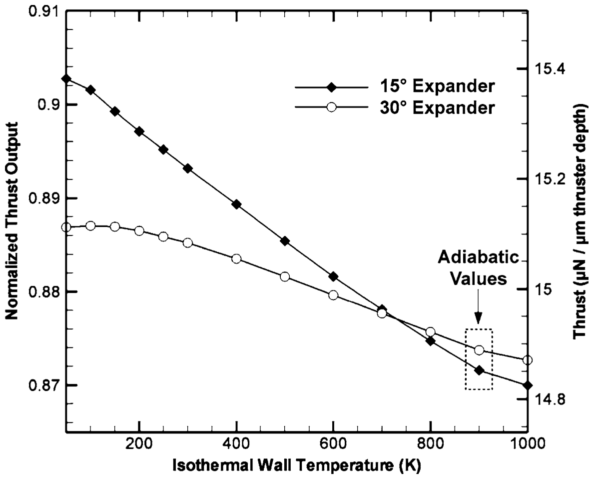
Heat Transfer Effects

Micro-nozzles are typically fabricated into much larger, thermally-conducting substrates. In an operational setting, these substrates will be thermally linked with the remainder of the spacecraft and will experience major temperature variations over a single orbit due to alternating day/night conditions. It is thus expected that significant heat transfer is possible between the micro-nozzle and the substrate and, in turn, may impact the flow. As a first approximation, one may argue that the substrate can be regarded as a thermal sink (or source) of constant temperature for the nozzle flow. This argument is based on a comparison of the relative thermal masses of the flow and a typical substrate; indeed, a lumped capacitance analysis of the NASA/GSFC micro-nozzle indicates that only a 5% temperature increase would be realized within the substrate under a typical firing sequence involving a 'cold' nozzle.

From a modeling perspective, then, a reasonable first-approximation of heat transfer effects is the imposition of isothermal boundary conditions on the micro-nozzle walls. The particular wall temperature would reflect the thermal state of the spacecraft as a whole based on its orbital location with respect to the Sun. To demonstrate the effect of heat transfer, we present findings obtained from numerical simulations of the NASA/GSFC linear micro-nozzle for expansion angles of 15° and 30° and isothermal wall temperatures ranging from 50 K to 1000 K. The thrust production (normalized with respect to quasi-1D inviscid theory) as a function of isothermal wall temperature is shown in Fig. 7. For comparison, the adiabatic results are also given. Cases with heat loss are seen to outperform comparable simulations with adiabatic walls. From a performance standpoint, as the wall temperature is increased the thrust output decreases and the subsonic layer grows non-linearly. A large subsonic layer has already been shown to greatly reduce micro-nozzle performance.

The observed effects of heat transfer on the flow in micro-nozzles is readily explained as follows. From compressible *Rayleigh flow* it is known that removing heat from a supersonic flow acts to accelerate the flow. At steady-state, the bulk of the flow in the micro-nozzle expander is super-

S



Supersonic Micro-Nozzles, Figure 7 Steady-state micro-nozzle performance including heat transfer through an isothermal wall. A reduced wall temperature is used to model heat losses from the flow field into the silicon micro-nozzle substrate acting as a thermal sink. As heat is removed from the expander, the supersonic flow is further accelerated, subsonic layer size is reduced, and performance as measured by thrust output increases. Note that the adiabatic results nearly coincide with the 900 K isothermal wall values as indicated

sonic and thus heat transfer acts to further accelerate the supersonic flow. Concurrently, as the flow is cooled, the exit density ρ increases. The overall effect is an increase in thrust. Heat extraction from the flow into the substrate increases performance from the subsonic layer point of view as well. For low nozzle wall temperatures, the local sonic velocity is diminished and the near-wall Mach number increases. This phenomena is the force driving the reduction in subsonic layer size for micro-nozzle flows with heat removal. In fact, with sufficient heat extraction from the flow, the subsonic layer can be reduced to the point where the competing effects of viscous forces and nozzle geometry cause the optimum expander half-angle to be shifted from 30° to a more traditional expander half-angle of 15°. This is demonstrated in Fig. 7 for isothermal wall temperatures less than ~ 700 K.

Non-Continuum Effects

Alexeenko et al. [9, 10] have performed non-continuum Direct Simulation Monte Carlo (DSMC) analyses of milli-/micro-nozzle flows in order to examine the influence of rarefaction effects on performance. The DSMC method is a statistical approach to the solution of the Boltzmann equation, the governing equation for rarefied gasdynamics. Their work has found that for Knudsen numbers of $\mathrm{Kn} \sim 0.1$, gas-surface interactions have a strong influence on the flow in both the converging and diverging sections of the nozzle. Owing to the fabrication process of MEMS devices, the surfaces have a significant degree of roughness at the molecular scale and thus result in inelastic diffusive collisons of a molecule with the surface. As such, a large portion of the flow remains subsonic along the nozzle expander walls. This causes an overall reduced Mach number at the nozzle exit and decreased thrust production. Comparisons have also been made between predicted velocity fields obtained by DSMC and Navier–Stokes continuum models for a supersonic converging-diverging micro-nozzle [9]. It was observed that the two solutions exhibit strong agreement within the micro-nozzle and that differences between the two methods were confined to the vicinity of the exhaust plume, specifically the corners of the nozzle exit. This is due to the rapid expansion of the gas and high flow rarefaction that is difficult to capture by continuum methods. Minor differences were reported in the size of the subsonic layers in the expander section owing to the difference in the wall boundary conditions (i. e., no-slip vs. slip). However, comparison of the velocity distributions along the nozzle centerline region shows only a small difference between the two methods.

Rarefied analyses of thermal coupling between the micro-nozzle with the surrounding substrate have also been reported [10]. In this work, steady low Reynolds number gas flows were again modeled by the DSMC approach and the substrate transient thermal response was governed by the heat conduction equation. It was shown that propulsive efficiencies of the micro-nozzle decreased with higher nozzle wall temperatures and vice versa. These results are in agreement with the continuum-based heat transfer results previously discussed.

Future Directions for Research

We close this article with a brief discussion concerning future research opportunities and needs for supersonic micro-nozzle flow within the context of micro-propulsion applications. In some instances preliminary work has been reported in various forms within the aerospace literature, however comprehensive and detailed studies have not yet appeared.

Conjugate Heat Transfer in Prototype Devices

As described previously, heat transfer from the micro-nozzle to its surroundings can have a significant impact on the supersonic flow within. Most of the studies to date, however, have been based on models featuring simplified and somewhat artificial thermal boundary conditions rather than a full conjugate heat transfer analysis with the domain surrounding the micro-nozzle. This shortcom-

ing is a consequence of incomplete knowledge of actual nano-sat propulsion system configurations, geometries and operating conditions. As experimental prototype nano-sats and propulsion systems begin to appear in greater numbers – and the design configurations and typical operating conditions start to take shape – more detailed heat transfer analyses will be warranted. Indeed, the solution of the conjugate heat transfer problem will be an important part in future design optimization process for supersonic micro-nozzles.

Three-Dimensional Geometric Effects

Much of the modeling efforts to date have focused on 2D planar geometries, owing largely to the 2D nature of patterning associated MEMS-based fabrication procedures. To a lesser degree, 2D modeling has also been invoked as a simplification to reduce computational resources required for numerical simulations. In reality, MEMS-based supersonic nozzles will have rectangular cross sections as a result of reactive ion etching or milling performed in the fabrication process. Further, the depth dimension may be substantially smaller than the nozzle width at the exit plane. One could posit that viscous boundary layer growth from the upper and lower boundaries of the nozzle will be of equal, if not greater, significance than the boundary layers studied in the 2D simulations. The presence of the upper and the lower boundaries also provides substantial, additional surface areas for heat loss from the nozzle flow and thus the consequences may well be more severe than those previously discussed in 2D models. In all, it is clear that there is a very real need for the pursuit of 3D models for the supersonic micro-nozzle flow. It is, however, also important to note that the additional computational resources required for full 3D simulations will be significant, particularly in cases of transient flows and flows with rarefaction.

Multiphase Flow

One unique aspect of supersonic micro-nozzles is the potential for the occurrence of multiphase flow, particularly in the expansion section. There are two primary mechanisms by which a liquid phase could be present within the flow. The first scenario would involve sufficiently high levels of heat loss through the nozzle walls resulting in gas condensation near the solid boundaries; this situation would most likely occur in the supersonic expansion section of the nozzle. The probable impact of condensation would be a reduction in thrust and micro-nozzle performance. A second scenario involves a multi-phase inlet that could be the result, for example, of incomplete chemical decomposition (catalysis) of a monopropellant or incomplete combustion of bi-propellants upstream of the nozzle (e. g., Hitt et al. [2]). Such problems could arise in chemical monopropulsion, for example, over time with degradation/fouling of catalysts in micro-reactors. In this case, the multiphase subsonic flow would likely affect the critical conditions required for sonic conditions to occur at the nozzle throat. Regardless of the particular scenario, there is a definite need for modeling efforts in this area – be it analytical, computational or both – to provide predictive capabilities for micro-nozzles under these multiphasic conditions.

Rarefaction Effects for Realistic Gases

Much of the micro-nozzle literature dealing with rarefied flows has focused on so-called 'cold gas' propulsion mechanisms. A cold-gas system features a single, inert gas (typically N_2) as a propellant and, consequently, offers a great modeling simplification for gas kinetic simulations utilizing DSMC or MD approaches. The fact that all molecules are identical within the flow simplifies the treatment of molecular collisions; in contrast, for multi-gas flows the treatment of collisions between molecules of different sizes and number densities becomes considerably more complicated. In practice, many propulsion schemes feature gas mixtures (e. g., decomposed H_2O_2 or decomposed N_2H_4 monopropellant schemes) and as such, there remains a significant void in the micro-nozzle literature concerning the effects of flow rarefaction in these cases.

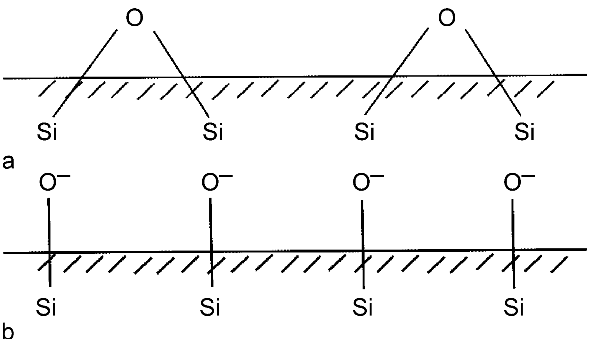
Definition

The surface-charge patterning technique is a surface chemistry process to make both positively charged and negatively charged patterns on a glass/silicon dioxide surface.

Overview

In microfluidic systems, liquid flow control is very challenging because of the large flow resistance. As such, electro-osmotic flow (EOF), a surface-driven flow phenomenon, is an alternative to pressure-driven flow (PDF), in order to overcome the flow resistance problem. Since the velocity of EOF depends on the surface charge of the channel wall, the surface-charge patterning technique has thus been developed to control liquid flow in a very confined space.



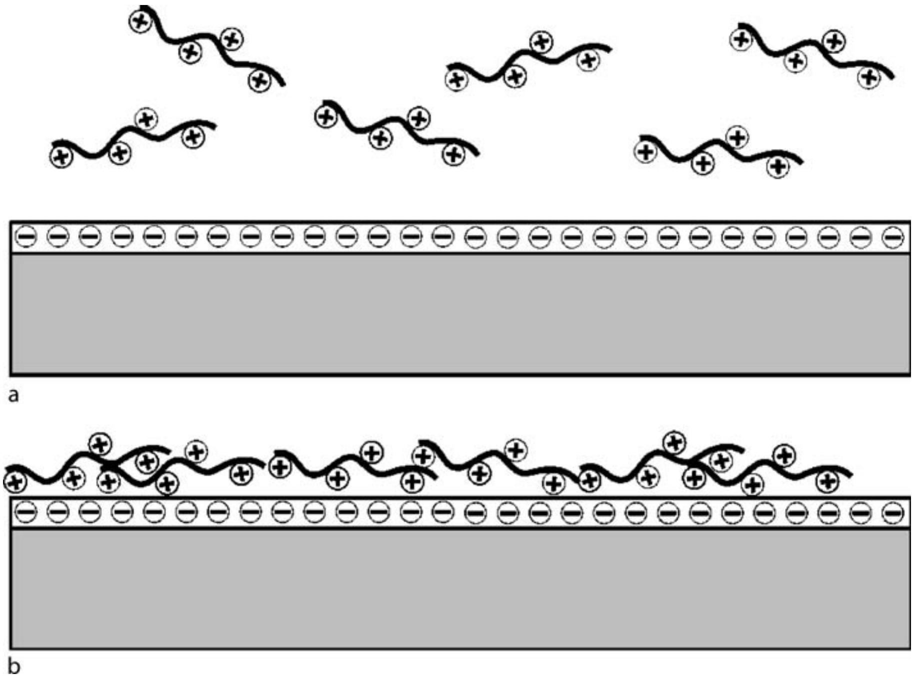
Surface-Charge Patterning Techniques, Figure 1 (**a**) Schematic chemical structure of a glass (or silicon dioxide) surface. (**b**) Glass surface carries negative charges in contact with aqueous solution

Surface Chemistry

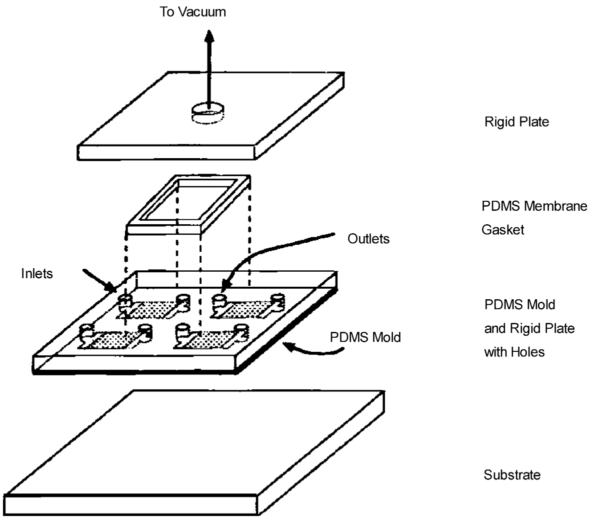
Glass (or silicon dioxide) naturally carries negative charges on its surface. When a glass surface is in contact with an aqueous solution, ionization occurs in the surface chemical group [1], leaving the chemical group with negative charges (Fig. 1). However, the surface charge density of such a natural process is low.

The surface-charge patterning technique can be considered as a two-step process. Firstly, the negative charges on the glass surface are enhanced by chemical processing with alkali and acid. The purpose is not only to make a negatively charged surface but also to prepare for the second step. In the second step, part of the glass surface, i. e. the pre-designed pattern, is masked by a very thin polymer coating or polymer structure. Then the whole glass surface is submerged in or flooded with a positively charged polymer solution called a polyelectrolyte. Owing to the glass surface and the polyelectrolyte having opposite charges, the polyelectrolyte is bound to the glass surface by electrostatic force, forming a thin polymer coating of the order of nanometers in thickness, as illustrated in Fig. 2. This binding process is termed an electrostatic self-assembly (ESA) process [2].

The positively charged patterning process in the second step can be accomplished by soft-lithography or photolithography. There exist several variations in soft-lithography but the principles are the same – to mask the pre-designed pattern on the glass surface [3, 4]. To illustrate the general idea, one soft-lithography technique which makes use of molding is presented, followed by a discussion of the photolithography technique.



Surface-Charge Patterning Techniques, Figure 2 Electrostatic self-assembly (ESA) process. (**a**) A glass substrate with negative charges on its surface is submerged in a positively charged polymer solution. (**b**) The polymer binds to the glass surface due to electrostatic attraction



Surface-Charge Patterning Techniques, Figure 3 Schematics of the setup for micromolding that creates polymer surface-charge pattern on a glass surface

Soft-Lithography with Micromolding

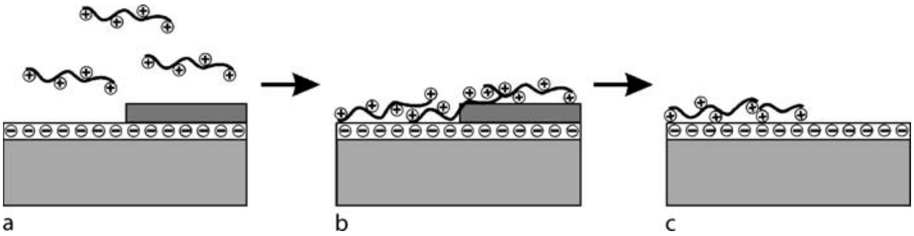
The mold used is made of a thin polydimethylsiloxane (PDMS) membrane attached to a rigid plate of glass as shown in Fig. 3 [4]. The plate has holes to introduce the polymer solution and to connect to vacuum. The valve to vacuum is closed while the polymer solution is applied at several inlets. The ESA process takes place on the glass surface when the capillaries are filled with the polymer solution. Finally, the vacuum is released and the mold is removed. As a result, a polymer which has the same pattern as the mold is obtained.

Photolithography with Lift-Off

Photolithography is a standard patterning technique in the fabrication process of integrated circuits (ICs) in the semiconductor industry. In fact, many silicon-based microfluidic devices are fabricated by photolithography. Photolithography is combined with the lift-off technique to make surface-charge patterns [5]. A photoresist (PR), a UV-curable polymer used in photolithography, is patterned on a glass substrate which is submerged in a polymer solution, as shown in Fig. 4a. The ESA process takes place (Fig. 4b). The unnecessary polymer is lifted off by removing the PR underneath. Finally, a pre-designed pattern containing both positive and negative charges is obtained.

Application in Microfluidics

The surface-charge patterning technique combined with EOF is, in principle, able to create numerous flow patterns



Surface-Charge Patterning Techniques, Figure 4 Schematics of surface-charge patterning by the photolithography method. (**a**) A glass substrate with patterned photoresist is submerged in a polymer solution. (**b**) ESA takes place. (**c**) The unnecessary polymer is lifted off by removing the photoresist underneath, leaving the desired surface-charge pattern

(**b**) A cross-section B–B' of the microchannel showing asymmetric patterns on top and bottom of the channel walls

at the microscale. In experiments, several simple flow patterns have been demonstrated, namely bi-directional shear flow (Fig. 5) [5, 6], out-of-plane vortex (Fig. 6) [6, 7] and in-plane vortex (Fig. 7) [8]. These basic flows are studied so that more complex flows can be understood and designed. A promising application is continuous mixing between two liquids or particle-laden liquids because liquid flow at the microscale is always laminar which does not favor mixing. It has already been demonstrated that the mixing efficiency can be significantly enhanced

Specific surface conductivity values are of the order $10^{-9} \sim 10^{-8}$ for water in glass capillaries.

Overview

Generally, surface conductivity usually is referred to the electrical conductivity through a thin liquid layer near the solid-liquid interface where there is a net charge accumulation due to the charged solid-liquid interface. Zeta potential is considered as an electrokinetic potential at the shear plane near a solid-liquid interface where the liquid velocity is zero. The zeta potential and the surface conductivity are very important interfacial electrokinetic properties to a huge number of natural phenomena, such as electrode kinetics, electrocatalysis, corrosion, adsorption, crystal growth, colloid stability and flow characteristics of colloidal suspensions and electrolyte solutions through porous media and microchannels. In electro-osmotic flow or pressure-driven flow through fine capillary tubes, the zeta potential and the surface conduction will critically influence the velocity or flow rate. In many cases, knowing the surface conductivity is a must in order to evaluate the zeta potential and other electrokinetic properties correctly. Measurement of the surface conductivity, therefore, is important in the studies of electrokinetic phenomena. Two methods to measure the surface conductivity, one involving pressure-driven flow, and the other electroosmotic flow, will be reviewed in this entry.

It is well-known that most solid surfaces carry electrostatic charges, i.e. an electrical surface potential. If the liquid contains a certain amount of ions (for instance, an electrolyte solution or a liquid with impurities), the electro-

S

static charges on the solid surface will attract the counterions in the liquid. The rearrangement of the charges on the solid surface and the balancing charges in the liquid is called the electrical double layer (EDL) [1–3]. Immediately next to the solid surface, there is a layer of ions which are strongly attracted to the solid surface and are immobile. This layer is called the compact layer, normally about several Angstroms thick. From the compact layer to the uniform bulk liquid, the net charge density gradually reduces to zero. Ions in this region are affected less by the electrostatic interaction and are mobile. This region is called the diffuse layer of the EDL. The thickness of the diffuse layer is dependent on the bulk ionic concentration and electrical properties of the liquid, usually ranging from several nanometers for high ionic concentration solutions up to several microns for pure water and pure organic liquids. The boundary between the compact layer and the diffuse layer is usually referred to as the shear plane. The electrical potential at the solid-liquid surface is difficult to measure directly. The electrical potential at the shear plane is called the zeta potential, ς, and can be measured experimentally [1–3]. In practice, the zeta potential is used as an approximation to the potential at the solid-liquid interface. The ion and electrical potential distributions in the electrical double layer can be determined by solving the Poisson–Boltzmann equation [1–3]. According to the theory of electrostatics, the relationship between the electrical potential ψ and the local net charge density per unit volume ρ_e at any point in the solution is described by the Poisson equation:

$$\nabla^2 \psi = -\frac{\rho_e}{\varepsilon} \tag{1}$$

where ε is the dielectric constant of the solution. Assuming the equilibrium Boltzmann distribution equation is applicable, which implies uniform dielectric constant, the number concentration of the type-i ion in a symmetric electrolyte solution is of the form

$$n_i = n_{io} \exp\left(-\frac{z_i e \psi}{k_B T}\right) \tag{2}$$

where n_{io} and z_i are the bulk ionic concentration and the valence of type-i ions, respectively, e is the charge of a proton, k_B is the Boltzmann constant, and T is the absolute temperature. The net volume charge density ρ_e is proportional to the concentration difference between symmetric cations and anions, via.

$$\rho_e = ze(n_+ - n_-) = -2zen_o \sinh\left(\frac{ze\psi}{k_B T}\right) \tag{3}$$

Substituting Eq. (3) into the Poisson equation leads to the well-known Poisson–Boltzmann equation.

$$\nabla^2 \psi = \frac{2zen_o}{\varepsilon} \sinh\left(\frac{ze\psi}{k_B T}\right) \tag{4}$$

When a liquid is forced through a capillary under an applied hydrostatic pressure, the ions in the diffuse layer (mobile part) of the EDL are carried towards the downstream end, resulting in an electrical current in the pressure-driven flow direction. This current due to the transport of charges by the liquid flow is called the streaming current. Corresponding to this streaming current, there is an electrokinetic potential called the streaming potential. This flow induced streaming potential is a potential difference that builds up along the capillary. This streaming potential acts to drive the ions in the diffuse layer of the EDL to move in the direction opposite to the streaming current, i. e., opposite to the pressure-driven flow direction. The action of the streaming potential will generate an electrical current called the conduction current. The conduction current will produce a liquid flow in the opposite direction to the pressure driven flow. The overall result is a reduced flow rate in the pressure drop direction.

The zeta potential can be determined from the measured pressure drop and the measured streaming potential along a single capillary tube. In absence of an applied electric field, when a liquid is forced through a channel under hydrostatic pressure, the excess counter-ions in the diffuse layer of the EDL are carried by the liquid to flow to the downstream, forming an electrical current, i. e., the streaming current. The streaming current is given by

$$I_s = \int_{A_c} v \rho_e \, dA_c \tag{5}$$

where A_c is the cross-section of the capillary, v is the local velocity of the liquid, and ρ_e is the local net charge density. For a liquid flowing through a cylindrical capillary tube of radius R at a steady state, the liquid local velocity $v(r)$ is given by the solution of the Poiseuille equation:

$$v(r) = \frac{\Delta P \left(R^2 - r^2\right)}{4\eta L} \tag{6}$$

where r is the radial variable measured from the central of the capillary, ΔP is the pressure drop along the capillary, η is the viscosity of the liquid, and L is the length of the capillary. The local net charge density $\rho_e(r)$ in Eq. (5) can be replaced by the Poisson equation, Eq. (1). Realizing that local net charge density $\rho_e(r)$ is not zero only in the EDL, i. e., only in a thin region near the channel wall, and that the EDL potential at the channel wall is approximated to

be the zeta potential ζ, one can show that the streaming current is given by:

$$I_s = -\frac{\varepsilon\zeta}{\eta}\pi R^2\frac{\Delta P}{L} \quad (7)$$

As explained above, the streaming potential generates a conduction current in the reversed direction. For a cylindrical capillary, the conduction current is given by:

$$I_c = \frac{\pi R^2 \lambda_b E_s}{L} \quad (8)$$

where λ_b is the bulk liquid electrical conductivity, and E_s is the streaming potential. At a steady state, the net electrical current should be zero, i. e., $I_s + I_c = 0$. Using this condition, one obtains the following:

$$\frac{E_s}{\Delta P} = \frac{\varepsilon\zeta}{\eta\lambda_b} \quad (9)$$

As seen from Eq. (9), by measuring the streaming potential and the pressure drop, and knowing the liquid properties, the zeta potential can be determined.

Generally, for a given solid-liquid system at a given temperature, the zeta potential is considered as a constant, this is because the nature of the material, its surface charge, and the nature and the concentration of the electrolyte determine the electrokinetic potential. However, early studies found that zeta potential determined from Eq. (9) depends on the size of the capillary tubes for the same solid material (the capillary wall) and the same liquid (with the same electrolyte concentration). This problem was solved later by considering the surface conduction, i. e., the electrical conduction through a thin layer at solid-liquid interface. Generally, the surface conduction is the excess conduction tangential to a charged surface, and originates from the excess counterions' concentrations in the EDL region near the solid-liquid interface [4]. Particularly in the cases of low bulk ionic concentrations, the surface conduction will have a significant contribution to the total conduction current through the capillary tube. Usually, the surface conductivity, λ_s, is considered as the conductivity of a sheet of material of negligible thickness, with a unit $\Omega^{-1}\mathrm{m}^{-1}$. Specific surface conductivity values are of the order $10^{-9} \sim 10^{-8}\Omega^{-1}\mathrm{m}^{-1}$ for water in glass capillaries. The surface conductivity is expected to have a significant effect on the zeta potential in capillaries smaller than 1 mm in diameter at concentrations below 1×10^{-3} M.

Briggs [5] suggested a simple procedure to correct Eq. (9). This method requires the measurement of the actual electrical resistance of the liquid in the capillary, R_{exp}, and the comparison of this value with calculated electrical resistance at high concentration, R_{cal}, where the surface conduction is expected to be negligible. The modified Eq. (9) becomes:

$$\frac{E_s}{\Delta P} = \frac{\varepsilon\zeta}{\eta\lambda_b}\frac{R_{exp}}{R_{cal}} \quad (10)$$

Briggs' method does not give explicit information on surface conduction. Two modern methods of determining the zeta potential and the surface conductivity will be summarized below.

Basic Methodology

Streaming Potential Method

Theory

Rutgers [6] was first to rigorously consider the *surface conductance* effect on the zeta potential and solved the problem of zeta potential dependence on capillary size. By considering the *surface conductance*, the conduction current for a cylindrical capillary is given by:

$$I_c = \frac{\pi R^2 E_s \lambda_b}{L} + \frac{2\pi R E_s \lambda_s}{L} \quad (11)$$

In the above equation, the first term accounts for the conduction through bulk liquid, and the second term accounts for the surface conduction. Using Eq. (7) and Eq. (11), and the steady state condition, $I_s + I_c = 0$, we have:

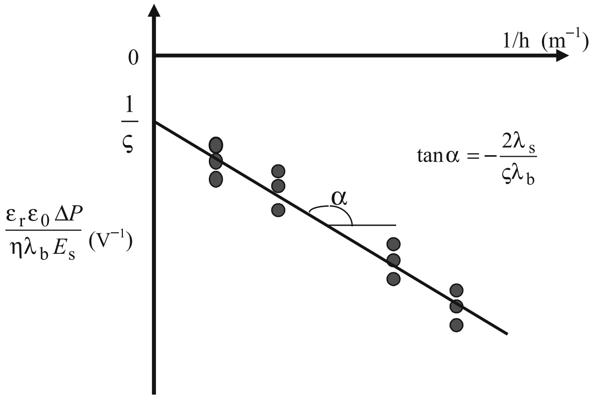
$$\frac{E_s}{\Delta P} = \frac{\varepsilon\zeta}{\eta(\lambda_b + 2\lambda_s/R)} \quad (12)$$

Realize $\varepsilon = \varepsilon_r\varepsilon_0$, where ε_r and ε_0 are the dielectric constant of the liquid and the permittivity of vacuum, respectively, the above equation can be rearranged into the following form:

$$\frac{\varepsilon_r\varepsilon_0\Delta P}{\eta\lambda_b E_s} = \frac{1}{\zeta} + \left(\frac{2\lambda_s}{\zeta\lambda_b}\right)\frac{1}{R} \quad (13)$$

For a given solid-liquid system, ε_r, η, λ_b, and ζ are constant. Equation (13) clearly shows that the term $\varepsilon_r\varepsilon_0\Delta P/\eta\lambda_b E_s$ is a linear function of $1/R$. If we plot $\varepsilon_r\varepsilon_0\Delta P/\eta\lambda_b E_s$ vs. $1/R$, as shown in Fig. 1, the intersection of the line given by Eq. (13) with the vertical axis is $1/\zeta$, and the slope of this line is $(2\lambda_s/\zeta\lambda_b)$. This implies that if one measures the pressure drop and the streaming potential of the same solid (capillary wall)-liquid system for different capillary radii, and plot the data according to Eq. (13), the zeta potential ζ and the surface conductivity λ_s can be determined from the intercept and the slope of the line.

S



Surface Conductivity Measurement, Figure 1 The linear relationship of $\varepsilon_r\varepsilon_0\Delta P/\eta\lambda_b E_s$ versus $1/h$ for a slit capillary (or $1/R$ for a cylindrical capillary) by using Eq. (14) (or Eq. (13)) to determine the Zeta potential and the surface conductivity by the streaming potential method

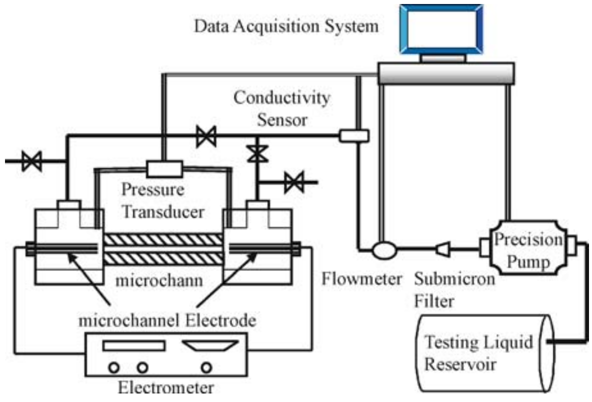
In additional to cylindrical capillary tubes, another type of capillary with a simple cross-section shape is the slit capillary, i. e., a channel formed between two parallel plates. For an electrolyte solution flowing through a slit capillary, it can be shown that, in analogy to Eq. (13),

$$\frac{\varepsilon_r\varepsilon_0\Delta P}{\eta\lambda_b E_s} = \frac{1}{\varsigma} + \left(\frac{2\lambda_s}{\varsigma\lambda_b}\right)\frac{1}{h} \tag{14}$$

where h is the height of the slit channel.

Experimental

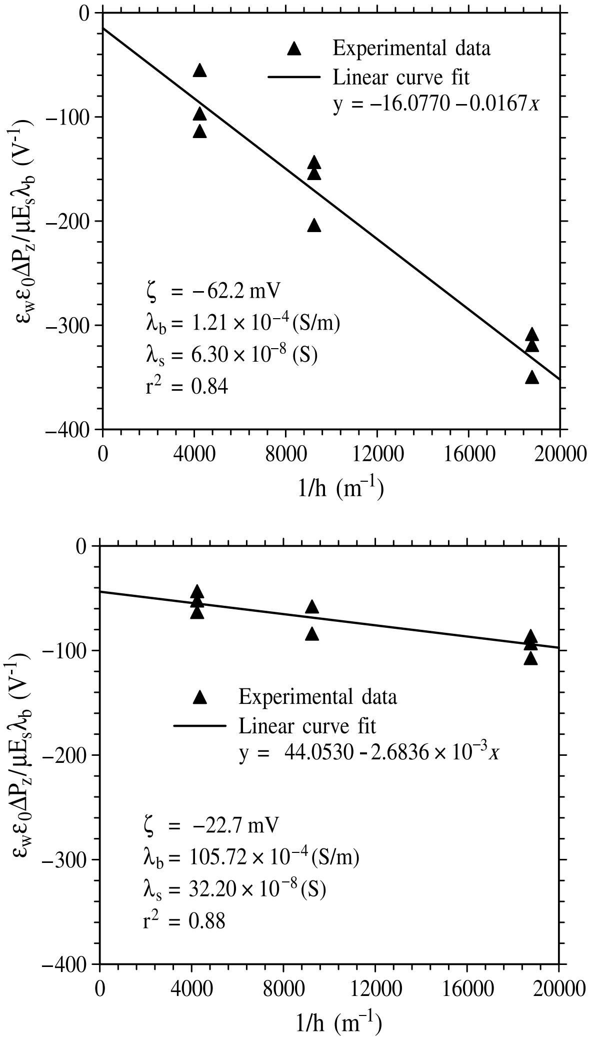
The key in the streaming potential method is to measure the streaming potential and pressure drop of the same solid-liquid system for different capillary radii. Figure 2 illustrates an experimental setup for such measurements [3, 7]. The capillary used in the test may be a single capillary tube or a bundle of capillary tubes of the same dimensions, or a slit channel formed between two parallel plates. The capillary tube is placed in a two-part symmetrical Plexiglas assembly to form a test cell as shown in Fig. 2. For a given capillary tube and a given electrolyte solution, the precision pump is set to maintain a constant flow rate. The pressure drop across the capillary tube is monitored and recorded by a differential pressure transducer (±0.5% FS accuracy, Validyne Eng. Corp.) and a computer data acquisition system. The flow was considered to have reached a steady state when the readings of the pressure drop do not change any more. Such a constant pressure drop value corresponds to the ΔP in Eq. (13) or (14). At this steady state, two electrodes (e. g., Ag/AgCl electrodes, Sensortechnik Meinsberg GmbH) and a high resistance electrometer (Keithley Instruments Inc.) are used to measure the streaming potential. The streaming potential measured at this steady state corresponds to the E_s in Eq. (13) or (14). It should be emphasized that such a streaming potential measurement should not last more than 60 or 100 s (depending on the electrolyte concentration and the flow rate) to avoid the polarization of the electrodes. In addition to the problem of electrode polarization, it should also be noted that there are no two identical electrodes due to the material and the manufacturing process. Therefore, in order to obtain more reliable and repeatable results, under the same flow rate, the flow is switched in an opposite direction after the previous streaming potential measurement. When the flow reaches the steady state again, the above described pressure drop and streaming potential measurement are repeated. Usually, for one flow rate, the operation described above should be repeated several times to ensure the repeatability and good average values of the pressure drop and the streaming potential. It is recommended to repeat the above measurements for several different flow rates.



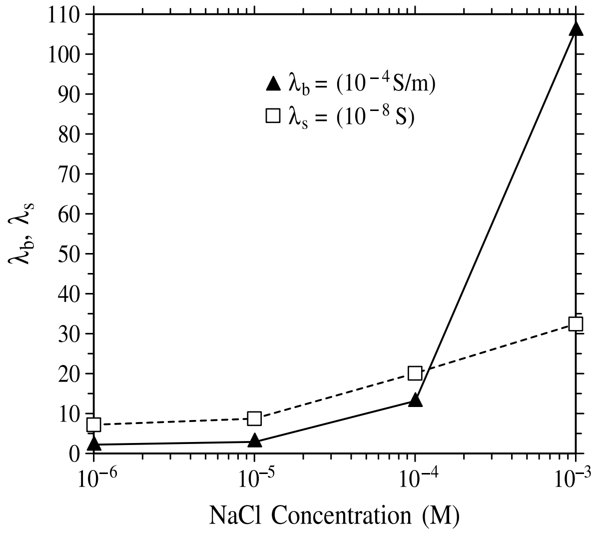
Surface Conductivity Measurement, Figure 2 Schematic of an experimental setup used for measurements of the streaming potential and the pressure across a capillary tube or a microchannel

As explained previously, in order to determine the zeta potential and the surface conductivity by using Eq. (13) or (14), one must measure the pressure drop and the streaming potential of the same solid-liquid pair for different capillary sizes. Therefore, the above-described measurements should be conducted for cylindrical capillary tubes with different radii or slit channels with different heights. Finally, by plotting $\varepsilon_r\varepsilon_0\Delta P/\eta\lambda_b E_s$ vs. $1/R$ (or $1/h$) as illustrated in Fig. 1, one can determine the zeta potential and the surface conductivity from the intercept and the slope of the best-fitted line to the experimental data points.

As an example, the results of glass surface-NaCl solution systems are re-plotted here [7] in Figs. 3 and 4. The measurements were done by using a slit channel formed by



Surface Conductivity Measurement, Figure 3 Experimental data for glass surface with (**a**) De-ionized Ultra-filtered water, and (**b**) 10^{-3} M aqueous NaCl solution



Surface Conductivity Measurement, Figure 4 Variation of the bulk conductivity and the surface conductivity with NaCl concentration

two parallel glass plates separated by two strips of a plastic shim of uniform thickness [7]. In Fig. 3, each data point represents an average value of several measurements as described above for the same channel height. For a given channel height the three data points represent the measurements for three different flow rates. Figure 4 shows the measured zeta potential and the surface conductivity as functions of the NaCl concentration. This method can also be used to study the effects of temperature, pH, different electrolytes and surfactants on zeta potential and surface conductivity.

It should be pointed out that Eq. (13) or (14) is derived on the basis of Eq. (6) (or the equivalent form for a slit channel), the solution of the classical Poiseuille equation. The Poiseuille equation, however, does not consider any EDL or electrokinetic (e. g., electro-viscous) effect on the liquid flow. For small capillaries, the electro-viscous effects on flow may be significant and have to be considered [3]. The Eq. (13) or (14) is no longer valid for small capillaries and may cause a significant error when used to evaluate the zeta potential and the surface conductivity [10]. Since the electro-viscous effect on flow is negligible for flow through a capillary with a hydraulic diameter larger than 50 μm, it is recommended that above-described method should be used with capillary tubes of a hydraulic diameter larger than 50 μm.

S

Electro-Osmosis Current Method

Within the diffuse layer of the EDL, the local net charge density, ρ_e, is not zero. If an electric field is applied such that it is tangential to the EDL, an electrical body force is exerted on the ions in the diffuse layer of the EDL. The ions will move under the influence of the applied electrical field to form a conduction current, pulling the liquid with them and resulting in an electro-osmotic flow. The liquid movement is carried through to the rest (beyond the EDL region) of the liquid in the channel by viscous force. This electrokinetic process is called electro-osmosis. The effect of the electrical force to generate the flow is dependent on the local net charge density within the liquid, which in turn is dependent on the electric double layer field and hence the zeta potential, ζ. On the other hand, the surface conduction will influence the bulk liquid's share of the applied electrical field and hence will influence the electro-osmotic flow. Therefore, electro-osmosis also depends on

both the zeta potential and the surface conductivity. The following will describe a method of determining both the zeta potential and the surface conductivity by measuring the electrical current in electro-osmotic flow through a capillary [8–10].

Zeta potential

Consider an electro-osmotic flow of an aqueous solution in a cylindrical capillary tube with a radius R as a fully-developed, one-dimensional flow at steady state. The momentum equation for such a case is given by [3]

$$-\eta \frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left(r\frac{\mathrm{d}u}{\mathrm{d}r}\right) = E_x \rho_\mathrm{e} \tag{15a}$$

Where r is the radial variable. The corresponding boundary conditions are:

$$r = 0: \quad \frac{\mathrm{d}u}{\mathrm{d}r} = 0; \qquad r = R: \quad u = 0 \tag{15b}$$

where u is the liquid velocity, η is the viscosity, E_x is the applied electrical potential gradient, and ρ_e is the local net charge density. In order to solve the above flow equation, the local net charge density $\rho_\mathrm{e}(r)$ must be known. The local net charge density $\rho_\mathrm{e}(r)$ can be determined by the Boltzmann equation:

$$\rho_\mathrm{e}(r) = ze(n_+ - n_-) = -2zen_0 \sinh\left(\frac{ze\psi(r)}{k_\mathrm{B}T}\right) \tag{3}$$

The EDL potential $\psi(r)$ can be determined by the solving the well-known Poisson–Boltzmann equation for cylindrical capillary:

$$\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left(r\frac{\mathrm{d}\psi}{\mathrm{d}r}\right) = \frac{2zen_0}{\varepsilon_\mathrm{r}\varepsilon_0}\sinh\left(\frac{ze\psi}{k_\mathrm{B}T}\right) \tag{16a}$$

with the following boundary conditions:

$$r = 0: \quad \psi = 0; \qquad r = R: \quad \psi = \varsigma \tag{16b}$$

Once the EDL potential $\psi(r)$ is known, the local net charge density $\rho_\mathrm{e}(r)$ is determined according to Eq. (3). Finally, the equation of motion, Eq. (15a), can be solved numerically to find the velocity $u(r)$. The average velocity can then be determined as follows:

$$u_\mathrm{av} = \frac{1}{A_\mathrm{cross}}\int_0^R u(r)\,\mathrm{d}A_\mathrm{cross} = \frac{2}{R^2}\int_0^R u(r)\cdot r\cdot \mathrm{d}r \tag{17}$$

where A_cross is the cross-section area of the capillary tube.

It should be realized from the above procedure that the velocity $u(r)$ and hence the average velocity u_av are implicit functions of the zeta potential, ζ (in the boundary condition, Eq. (16b)). If the average velocity can be measured directly, the zeta potential ζ can be determined by solving Eq. (17) by using an iterative technique. In this process, an initial guessing value of the zeta potential, ζ_guess, may be obtained by invoking the Debye–Huckel approximation, as described below.

The Debye–Huckel approximation assumes that the value of ψ is small ($\psi \leq 25$ mV) or the following approximation can be made:

$$\sinh\frac{ze\psi}{k_\mathrm{B}T} \approx \frac{ze\psi}{k_\mathrm{B}T} \tag{18}$$

If the above approximation can be made, the following exact solutions for the local net charge density distribution and the velocity profile can be obtained analytically:

$$\rho_\mathrm{DH}(r) = \zeta\frac{I_0(\kappa r)}{I_0(\kappa R)} \tag{19}$$

$$u_\mathrm{DH}(r) = \frac{\varepsilon_\mathrm{r}\varepsilon_0 E_x \zeta}{\eta}\left(1 - \frac{I_0(\kappa r)}{I_0(\kappa R)}\right) \tag{20}$$

where I_0 is the zero-order modified Bessel function of the first kind; and κ is the so-called Debye–Huckel parameter, defined by:

$$\kappa = \left(\frac{2z^2e^2n_0}{\varepsilon_\mathrm{r}\varepsilon_0 k_\mathrm{B}T}\right)^{1/2} \tag{21}$$

As shown in Eq. (17), the average velocity can be found by integrating the local velocity over the cross-section area of the capillary tube. Thus, with the Debye–Huckel assumption, ζ_DH can be expressed as an explicit function of the radius through the average velocity equation, such that if the average velocity is known, then the initial guess for the zeta potential ζ can be determined as

$$\varsigma_\mathrm{guess} = \varsigma_\mathrm{DH} = \frac{u_\mathrm{av}R^2\eta}{2\varepsilon\varepsilon_0 E_x}\left[\int_0^R r\left(1 - \frac{I_0(\kappa r)}{I_0(\kappa R)}\right)dr\right]^{-1} \tag{22}$$

Using this ζ_DH value as the initial guess for ζ_guess in Eq. (17) to calculate u_av, and comparing the result to the known (measured) value of u_av, a new ζ_guess is obtained. This procedure can be continued until the calculated and the known values of u_av converge.

Evaluation of the Specific Surface Conductivity

When considering the transport of an electrolyte solution, one must consider the motion of mobile ionic species in addition to the considerations of traditional fluid mechanics. The transport of ions in a capillary results in an electrical current. In electro-osmotic flow, the total current is a result of three physical processes:

1. the bulk conductivity of the electrolyte solution, resulting in a conduction current, $I_{\text{cond,bulk}}$;
2. the surface conductivity, resulting in a secondary conduction current, $I_{\text{cond,surf}}$; and,
3. the electro-osmotic flow, resulting in a convection current, I_{conv}.

Generally, the convection current is several orders of magnitude smaller than the other two components of the current. Neglecting the contribution of I_{conv} results in the following equation for the total current, I_{total}:

$$I_{\text{total}} = I_{\text{cond,bulk}} + I_{\text{cond,surf}} = \lambda_b A_{\text{cross}} \boldsymbol{E} + L_{\text{surface}} \lambda_s \boldsymbol{E} \tag{23}$$

For the case of a cylindrical capillary with an electrical field $\boldsymbol{E}$ applied in the axial direction only, I_{total} is given by:

$$I_{\text{total}} = \pi R^2 \lambda_b E_x + 2\pi R \lambda_s E_x \tag{24}$$

In general, the surface conductivity λ_s is unknown. Since the radius of the capillary tube, R, and the bulk liquid conductivity, λ_b, can be measured accurately, they can be treated as known, and E_x is applied electrical field strength and is known. Since the total current I_{total} can be measured, the above equation can be rearranged to solve for the surface conductivity, λ_s, such that:

$$\lambda_s = \frac{I_{\text{total}} - \lambda_b \pi R^2 E_x}{2\pi R E_x} \tag{25}$$

As seen from Eq. (25), by measuring the total current during a steady electro-osmotic flow, the bulk conductivity, the applied electrical field and the capillary size, the surface conductivity can be determined. Generally, this is a relatively simple method with a reasonable accuracy.

The above equation should be modified to account for the changes in ionic concentration within the double layer near the wall. The variation in ionic concentration is accounted for in the conduction current component by using the following equation:

$$I_{\text{cond,bulk}} = \int_A \lambda_b E_x \cosh \psi(r)\, dA \tag{26}$$

Thus, Eq. (25) becomes:

$$\lambda_s = \frac{I_{\text{total}} - \int_A \lambda_b E_x \cosh \psi(r)\, dA}{2\pi R E_x} \tag{27}$$

If ζ is known, the electrical field potential $\psi(r)$ can be determined by solving the Poisson–Boltzmann equation. The surface conductivity λ_s, therefore, can be determined by using the measured I_{total} and Eq. (27).

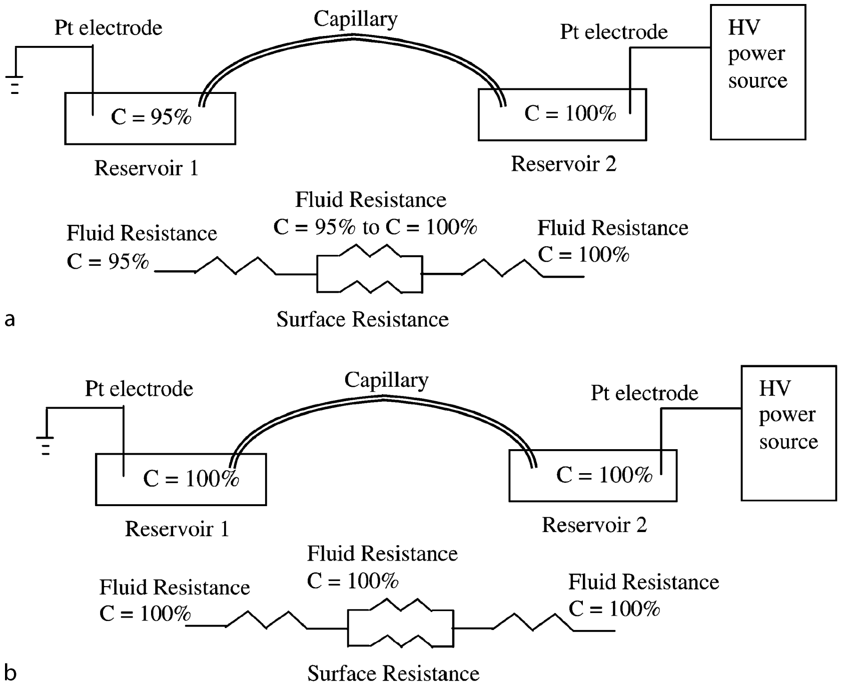
Experimental

The experimental set-up [8, 9] shown in Fig 5a can be used to measure the average velocity by monitoring the current in electro-osmosis. In the experiment, the reservoir 2 will be filled with an electrolyte solution at a desired concentration. The capillary tube and reservoir 1 will be filled with the same electrolyte solution at a concentration lower than the concentration in reservoir 2. For example, the capillary tube and reservoir 1 are filled with an electrolyte solution at a concentration that is 95% of the concentration in reservoir 2. Immediately after connecting the two reservoirs by the capillary tube, a voltage difference between the two reservoirs is applied by setting reservoir 1 at ground potential and reservoir 2 to a high voltage power supply unit (CZE1000R, Spellman, NY) via Platinum electrodes.

The applied electrical field results in an electro-osmotic flow in the capillary tube. During electro-osmosis, the higher-concentration electrolyte solution from reservoir 2 gradually displaces the lower-concentration electrolyte solution in the capillary tube (it can the opposite way depending on the polarity of the applied electrical field). As a result, the overall electrical resistance of the liquid and hence the current in the capillary tube changes, as illustrated in Fig. 5a. An L-DAS8 data acquisition chip (Kieffley) was used to record the voltage (kV) and current (μA) as a function of time (s). Once the lower-concentration solution in the tube is completely replaced by the higher-concentration solution from reservoir 2, the current will reach a maximum and constant value. The measured time for the current to reach such a plateau value is the time required for the solution from reservoir to travel through the entire capillary tube. The average velocity of the liquid flow can then be calculated by using:

$$u_{\text{av,exp}} = \frac{L}{\Delta t} \tag{28}$$

where L is the length of the capillary and Δt is the time required for the higher-concentration electrolyte solution to completely displace the lower-concentration electrolyte solution from the capillary tube.



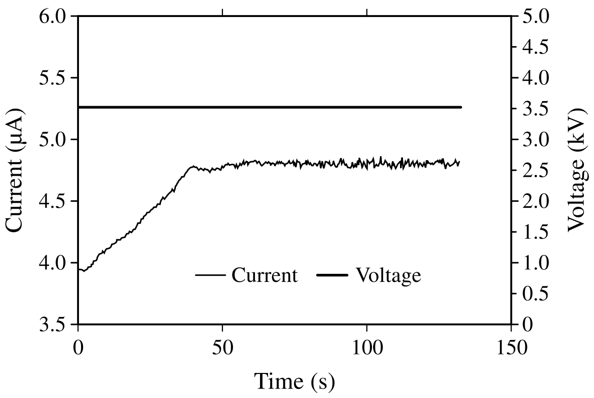
Surface Conductivity Measurement, Figure 5 Schematic diagram illustrating experimental set-up and varying resistances (**a**) for measuring the current variation and the complete displacement time of a two-concentration system; (**b**) for measuring the total current of a single concentration system

For the purpose of evaluating the specific surface conductivity, a second set of measurements using a similar set-up [8, 9], as shown in Fig. 5b, may be used to measure the total current, I_{total} during electro-osmosis. In these cases, reservoir 1, reservoir 2 and the capillary tube will be filled with an electrolyte solution of the same concentration.

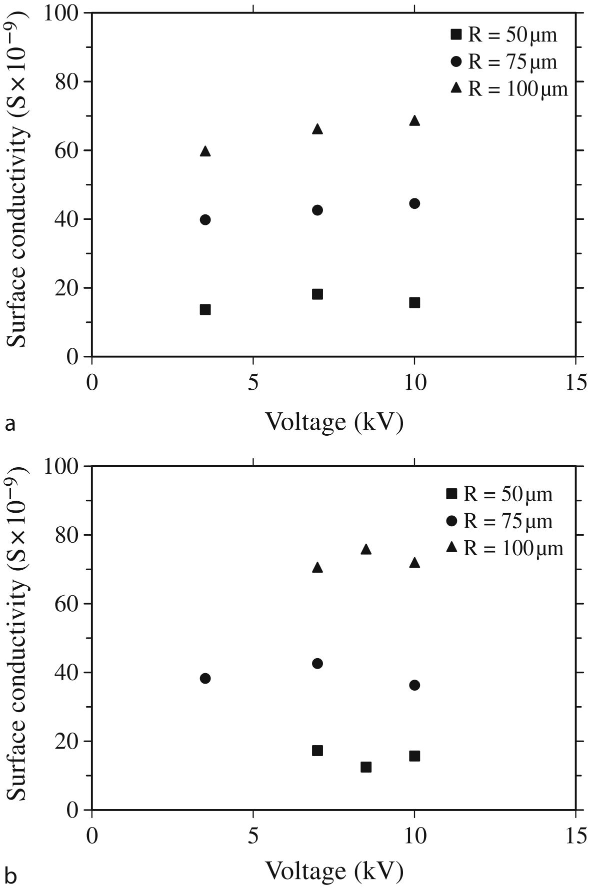
Key Research Findings

Generally, the value of specific surface conductivity depends on the molecules of the solid surface, the surface charge, and the electrokinetic properties of the liquid (e. g., type of ions, valance, the ionic concentration, pH). Typical values of specific surface conductivity are of the order $10^{-9} \sim 10^{-8}$ for water in glass capillaries.

The electroosmotic current method described in the above sections was used to evaluate the zeta potential and the surface conductivity for Polyamide coated silica capillary tubes with KCl solutions [8]. In the experiments, polyamide coated silica capillary tubes of various diameters (Polymicro Technologies Inc., Phoenix, AZ) were cut to 10 cm. lengths and connected to the reservoirs. The electrolyte solution was prepared by using KCl (Anachemia Science, Quebec) and deionized ultra filtered (DIUF) water (Fisher Scientific, Ontario). The amount of KCl was measured by using a precision scale (Mettler). The bulk liquid conductivity of the prepared solutions was measured using a high precision conductivity meter (Mettler Toledo). In the experiments, each measurement was repeated at least three times for a given set of conditions. All experiments were conducted at room temperature (22 °C).



Surface Conductivity Measurement, Figure 6 A typical result of current versus time for Set-up A. For the specific case of: capillary diameter $D = 100\,\mu\text{m}$, $E_x = 3500\,\text{V}/10\,\text{cm}$. KCl concentration in Reservoir 1 is $C_{95\%} = 0.95 \times 10^{-4}$ M. KCl concentration in Reservoir 2 is $C_{100\%} = 10^{-4}$ M



Surface Conductivity Measurement, Figure 7 Specific surface conductivity, λ_s versus the applied voltage and the capillary diameter, for a 10 cm long capillary tube, for: (**a**) $C = 10^{-4}$ M KCl; (**b**) $C = 10^{-3}$ M KCl

Figure 6 shows a typical variation of current versus time for a KCl solution with a 100 µm diameter silica glass capillary and an applied electrical field of 350 V/cm. The concentration in reservoir 2 is $C_{100\%} = 10^{-4}$ M, and the concentration in reservoir 1 is $C_{95\%} = 0.95 \times 10^{-4}$ M . Linear regression was used to smooth the experimental data and determine Δt. The current increases with time as the higher concentration ($C_{100\%}$) electrolyte solution displaces the lower concentration ($C_{95\%}$) electrolyte solution in the capillary. The increase in current continues until the capillary is completely filled with the $C_{100\%}$ electrolyte solution, at which time the current reaches a steady value, which continues until the applied voltage is removed.

The average velocity of the liquid during electro-osmosis is determined by Eq. (28). Using the measured average velocity data, the method described earlier can be used to calculate the zeta potential ζ. The measured total current for single-concentration systems is required to determine the specific surface conductivity λ_s according to Eq. (25). In a more rigorous treatment, using the measured total current and the determined zeta potential, the specific surface conductivity λ_s can be calculated by using Eq. (27). Figs. 7a and b are plots of λ_s versus the applied voltage and the capillary size for the two KCl concentrations, $C = 10^{-3}$ M and $C = 10^{-4}$ M, respectively. From the results, there is clearly a relationship between the size of the capillary and the specific surface conductivity. Comparing the λ_s values between Fig. 7a and b, λ_s appears to have no significant dependence on the ionic concentration. This may be understood as the K^+ and Cl^- are not the potential determining ions in this system and are not adsorbed on the solid surface.

Future Directions for Research

Surface conductance is important in micro- and nano-scale flow and transport processes, especially when the channel size is small and the ionic concentration of the bulk solutions (bulk liquid conductivity) is low. More experimental data of surface conductivity are needed for various liquid-microchannel systems. With the rapid development of nanofluidics, it is highly desirable to develop new theoretical models, experimental methods and the experimental data for surface conductance of nanochannels.

Definition

Generating surface tension gradients such as Marangoni stresses or discontinuities in surface energy, either through ►chemical patterning or ►topographical manipulation, facilitates the control of wettability of fluids upon that surface. Surface-directed microfluidics is the exploitation of this phenomenon to encourage fluid transport through capillary interactions upon a surface-modified platform. Consequently, the need for extraneous pumping components is eliminated. These techniques demonstrate a great capacity to automate fluid transport providing alternative manufacturing methods for microfluidic platform development.

Overview

The field of microfluidics promises the capacity to automate sophisticated laboratory analyses into a diminutive platform that can be implemented by a user with minimal analytical experience. Often an analogy is drawn towards the integrated circuit revolution which facilitated the automation of large-scale computation. Similarly, a great deal of optimism exists that microfluidics may have such an impact on chemistry, biology and medicine, resulting in a drastic decrease in the amount of expensive reagent or invasive fluid samples required while enabling higher degrees of throughput and ►parallelization.

Such microfluidic devices have been successfully developed. However, many microfluidic devices require multiple components to implement fluid transport. This article describes alternative platform design to mitigate the aforementioned problems resulting in a fully-autonomous micro-device capable of promoting capillary flow. An example of commercial microfluidic device exploiting capillarity includes the OneTouch® testing strip developed by LifeScan, Inc. The test strip imbibes micro-volumes of blood which is introduced to a blood glucose meter facilitating fast and accurate results. The autonomous nature of this inexpensive microfluidic device is very attractive with regard to point-of-care diagnostics. Furthermore, many more novel platform configurations and fabrication methods are currently being investigated resulting in stand-alone microfluidic systems. Specifically, spontaneous ►surface-directed capillary pumping of fluids with appropriate surface tension and viscosity is enabled by patterning energetic discontinuities or topographical features upon a surface.

However, before *surface-directed microfluidics* can be employed towards solving problems in chemistry, biology and medicine, a thorough understanding of the underlying physics must be established. This task becomes non-trivial as fluidic miniaturization results in dramatic changes to the fundamental physics manifested at small length scales. For example, mass transport within microfluidic devices is a challenge as viscous effects dominate at small length scales rather than inertial effects [1]. Consequently, utilizing scaling arguments through dimensional analysis, the nonlinear terms in the Navier-Stokes equations can be neglected in most microfluidic systems. Although the lack of inertia at small length scales seems to indicate analysis of microfluidic platforms is straightforward, quite the opposite is true. Other non-linear phenomena that may not be as familiar at the macro scale become apparent as surface area to volume ratios increase [1]. In particular, surface ►curvature and three-phase boundaries must be taken into account making the analysis of *surface-directed* flows substantially more difficult.

With regard to *surface-directed microfluidics*, patterning discontinuities in surface energetics results in deformation of the solid-liquid contact line. Such deformations

can either promote or impede capillary break-up. Consequently, discontinuous energetics serves as a mechanism to harness for autonomous fluid transport. Furthermore, other implications arise as a result of the capacity to manipulate interfacial *curvature* at the microscale. As the surface area to volume ratio experienced within microfluidic devices is rather substantial, the overall shape and stability of boundaries and interfaces can be dramatically affected by minute amounts of surface or fluid contaminants. Accordingly, *surface-directed microfluidic* devices warrant proper surface cleaning protocols, storage procedures and reagent preparation to ensure reproducible and reliable device function. Moreover, since reagents may necessarily contain surface-active components, adsorption dynamics may be an important factor in capillary pumping.

The breadth of this article seeks to address a review of fabrication techniques, characterization and analysis of microfluidic devices implementing the *surface-directed* approach. Furthermore, key research findings will be explicated along with aspects of this approach requiring future investigation. As a result, the methodology to implement the *surface-directed* approach will be established along with a suitable record of pertinent literature regarding this novel technique. However, before doing so, a brief diversion into the treatment of fluid physics for systems exhibiting high surface area to volume ratios may lend much insight in developing a robust understanding and appreciation of capillary-driven microfluidic flow.

Surface-Directed Capillary Physics

As previously mentioned, the analysis of microfluidic systems can be rather difficult for a variety of reasons. The direct implementation of the Navier-Stokes equations toward *surface-directed microfluidic* systems requires careful attention when considering the advection of the free surface and the associated curvature of this surface. Consequently, sophisticated computational fluid dynamics software packages are required for a comprehensive three-dimensional analysis of the fluid transport within *surface-directed microfluidic* devices. However, a time-consuming comprehensive analysis may be beyond the requirements of designing and manufacturing functional surface-directed microfluidic platforms. Consequently, empirical approximations and scaling arguments are commonly used in the characterization of microfluidics physics.

One common approach to treating capillary microfluidic phenomena entails equating the fluid volumetric flowrate to a ratio of pressure drop per resistance, R, in a fluid channel as developed by Washburn circa 1921 [2] where A_{cs} represents cross-sectional area of a fluid duct (assumed to be constant) and x represents the time-dependent location of the ► meniscus position.

$$A_{\mathrm{cs}}\frac{\mathrm{d}x}{\mathrm{d}t}=\frac{\Delta P}{R} \tag{1}$$

Considering capillary dynamics, the pressure drop term is often described by the Laplace equation, $\Delta P = 2\gamma H$, where γ represents liquid surface tension and H represents the mean *curvature* of the liquid-gas interface associated with all curves, C_i, passing through the surface. Furthermore, the character of a sufficiently smooth surface is through the invariant from differential geometry, the principal curvature of each curve, k_i. The the radii of curvature are the inverse of each principal curvature, $k_i = 1/r_i$. Considering the maximum and minimum ► radii of curvature at a point on a three-dimensional surface, the mean *curvature* can be calculated explicitly (see appendix for more thorough derivation of the mean *curvature* parameter).

$$H=\frac{1}{2}\left(\frac{1}{r_1}+\frac{1}{r_2}\right) \tag{2}$$

Curvature is usually assumed to follow geometries that can be fit to a circle (or sphere in the three-dimensional case) in the Laplace equation; this is not typically the case but usually results in a decent approximation. Further, for straight paths, r_2 can be considered as infinite and approximations can be made for r_1 [3].

$$r_1=\frac{h}{2\cos\theta_{\mathrm{I}}} \tag{3}$$

In Eq. (3), θ_{I} indicates the contact angle at the three-phase interface.

Moreover, resistance terms exist for common geometries such as rectangular ducts [4].

$$R_{\mathrm{D}}=\frac{12\mu x}{wh^3}\left[1-\frac{h}{w}\left(\frac{192}{\pi^5}\sum_{n=0,1,2}^{\infty}\frac{\tanh\frac{2n+1\pi w}{2h}}{(2n+1)^5}\right)\right]^{-1} \tag{4}$$

Here w represents channel width, h represents channel height and μ represents the viscosity of the fluid. In the case where $w \gg h$, the bracketed term can be neglected while maintaining sufficient accuracy through the approximation.

By substituting Eq. (3) into Eq. (2) and subsequently utilizing modified Eq. (2) and Eq. (4) with the general Washburn equation, one finds that capillary dynamics tend to follow

S

Eq. (5) with a general geometry-dependent characteristic length scale, L [1].

$$x \sim \left(\frac{\gamma L \cos\theta}{\mu} t\right)^{1/2} \tag{5}$$

Consequently, the time-dependent fluid front position in a *surface-directed microfluidic* device tends to be dependent on system geometry, intrinsic fluid properties, fluid-substrate interactions and the square root of time. This dependency has been derived theoretically and observed for a number of capillary-driven microfluidic systems such as the ▶v-groove geometry [5, 6]. Noting that the ratio γ/μ is a characteristic capillary velocity, U_c, enables the rearrangement $x \sim (U_c L \cos\theta t)^{1/2}$. This relation perhaps leads to a more tangible description of fluid specific capillary transport.

Outside of the capillary dynamics approach, scaling arguments and dimensionless analysis can provide valuable insight into fluid physics on the micro-/nanoliter scale. An exhaustive review of these approaches has been conducted for a variety of microfluidic techniques [1]. However, for this article, we will strictly consider scaling metrics and dimensionless numbers pertinent to the *surface-directed* approach.

First, we will consider perhaps the most often applied dimensionless number toward fluid transport, the Reynolds number. The Reynolds number is a measure of inertial to viscous forces [1] and is dependent upon fluid density ρ, and viscosity μ, as well as characteristic velocity U and the characteristic length scale L which can be written as follows.

$$\mathrm{Re} \equiv \frac{\rho L U}{\mu} \tag{6}$$

Characteristic length scales chosen depend on system geometry. For example, diameter is commonly chosen for cylindrical systems while the hydraulic diameter, $D_A = 4A/P$, may be chosen for Cartesian geometries (such as a microfluidic duct) in which A denotes cross-sectional area and P is the perimeter of the cross-section.

As mentioned earlier, the lack of turbulence in microfluidic devices indicates inertial effects are minimal. Consequently, viscous forces dominate. Reynolds numbers characteristic of microfluidic devices are generally on the order of $O(10^{-6})$ to $O(10)$ [1]. Furthermore, the transient time required to achieve this laminar flow goes according to $\tau \sim \rho L^2/\mu$. Consequently, one can see that flow in microfluidic devices tends to be rather devoid of turbulence.

Another relevant number in the analysis of microfluidic devices in general is the Péclet number; which yields the ratio of convective transport to diffusive transport where D represents the diffusion constant of a molecule within a particular fluid.

$$\mathrm{Pe} \equiv \frac{U}{D/L} \tag{7}$$

As already indicated, flow is laminar in microfluidic devices which results in great difficulty in attaining adequate mixing for chemical reaction processes. Scales for the general time ($\tau \sim w^2/D$) and length ($z \sim Uw^2/D$) to achieve mixing in a low Péclet number devices are known considering a channel of width w [1].

An additional dimensionless number particularly important to *surface-directed microfluidics* is the capillary number utilized to measure viscous to interfacial forces.

$$\mathrm{Ca} \equiv \frac{U}{\gamma/\mu} \tag{8}$$

Surface forces tend to be inherently important for capillary-driven microfluidic devices as surface area to volume ratios are rather high and surface tension-induced interfacial *curvature* is significant enough to promote capillary wicking. For chemically patterned devices depending on hydrophobic/hydrophilic confinement in particular, the capillary number must be sufficiently low (i. e. $\mathrm{Ca} \ll 1$) in order to maintain fluid confinement within intricate geometry implying $\Delta P \leqslant \gamma/w$ [1].

The above analyses lend insight into the behavior of fluids within *surface-directed microfluidic* devices. Now that an intuitive framework of the fluid physics within microfluidic platforms has been established, the contemplation of successful platform fabrication techniques and their associated applications is worthy of consideration.

Basic Methodology

Several approaches exist to manufacture *surface-directed microfluidic* platforms. Examples of relevance to this article include the *chemical patterning* of regions exhibiting drastic and abrupt disparity in surface energies and the manipulation of surface topography to influence mean *curvature*. Furthermore, some alternative techniques will be discussed as potential applications to *surface-directed microfluidics* such as thermal actuation and passive gate fabrication with coatings that enable contact angle mediation via photochemical reactions or the presence of water.

Chemical Patterning

The concept of *chemical patterning* generally involves the deposition of hydrophobic 'curbs' upon an other-

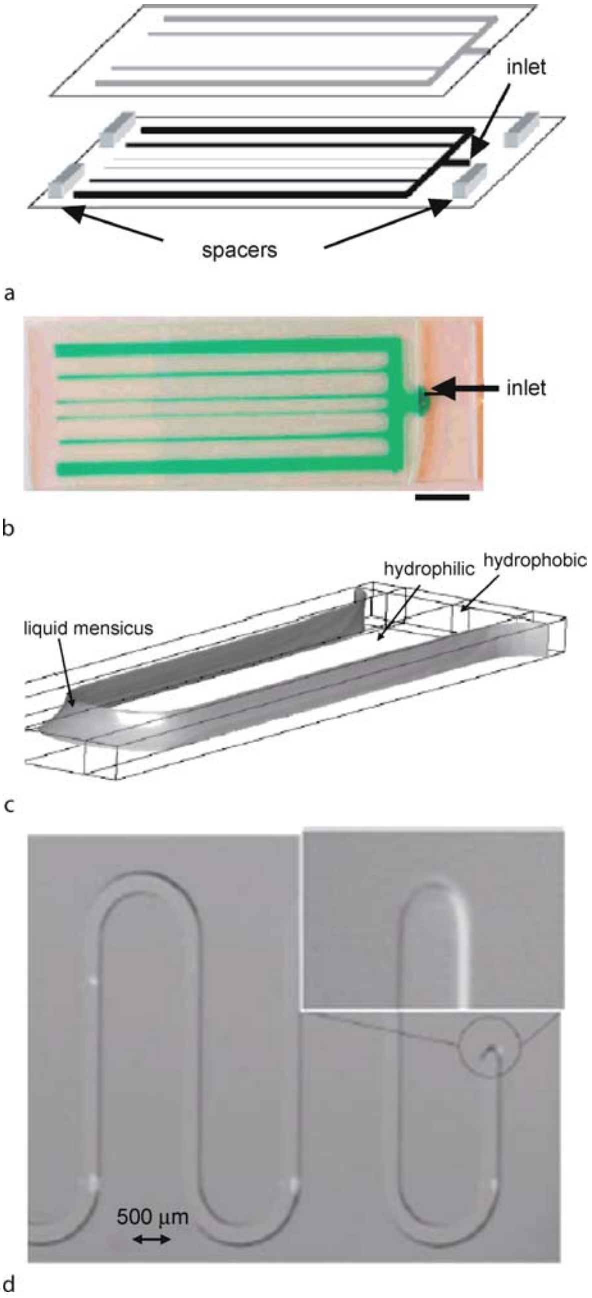
wise hydrophilic substrate. Consequently, capillarity can be exploited to promote autonomous fluid transport eliminating the requirement to integrate pumping equipment into the microfluidic platform.

Initial investigations focused on the relationship between fluid morphology and surface energy. Gau et al. investigated the shape instability that liquids undergo when an appropriate amount of liquid is adsorbed on a hydrophobic surface patterned with hydrophilic microstripes [7]. Hydrophilic stripes were deposited via thermal vapor deposition of MgF_2 (stripe thickness $\sim 20\,\text{nm}$) upon hydrophobic silicone rubber or thiolated gold substrates. The patterned surface was then exposed to sufficiently humid air and cooled to force the condensation of liquid upon the surface. The results indicate that initially, water adsorbs forming a structure with a cylindrical cross-section; however, when an adequate amount of water is adsorbed, instability can occur resulting in bulge formation. This instability is quite different from the classical Rayleigh instability; rather it is a bifurcation in two different morphologies of constant mean *curvature* [7]. A linear stability analysis indicates that the cylinder is locally stable so long as the wavelength of the shape deformation λ, exceeds a critical value λ_c, based upon the hydrophilic path width a and advancing contact angle θ.

$$\lambda_c = \left[\frac{\frac{\pi}{2}}{\theta^2 - \left(\frac{\pi}{2}\right)^2}\right]^{1/2} \frac{\theta}{\sin\theta} a \tag{9}$$

Consequently, Gau suggests that it is in fact feasible to build two-dimensional microfluidic devices through *chemical patterning* techniques.

These results were also independently confirmed by other groups [8]. Darhuber et al. developed disparities in hydrophilicity on a [001]-oriented p-type doped silicon wafers coated with a ► self-assembled monolayer of octadecyl-trichlorosilane (OTS). In all of the studies [7, 8], the experimental results were found to be in good agreement with theoretically determined surface morphology through the ► surface evolver software package. The surface evolver software package is an interactive tool to study the equilibrium surface shapes of liquids subject to surface tensions and other energies under various constraints. The surface evolver evolves the surface toward minimal energy by a gradient descent method. The surface evolver software package is a powerful tool for the theoretical investigation of static surface structures of *surface-directed microfluidics* enabling the determination of surface curvature and quantification of the Laplace pressure. Most often, gravity can be neglected in the surface evolver analysis as indicated by the low Bond number experienced in microfluidic devices (i. e. Bo $\ll$ 1). Specifically, the Bond number is a measure of body forces (i. e. gravity) per surface forces (i. e. capillarity) where $\Delta\rho$ indicates



Surface-Directed Capillary Flow Systems, Figure 1 *Surface-directed microfluidic* device fabricated via sol gel processing (**a**) with a demonstration of the configuration of device and (**b**) the implementation of the device with colored fluid for visualization [9]. (**c**) Computational fluid dynamic representation of the fluid front of a device fabricated with a patterned bottom substrate and indiscriminately hydrophobic top substrate. (**d**) The implementation of the device with an unpatterned top substrate [11]

the change in density across a surface, g is the gravitational constant, L is a characteristic length of the capillary cross-section and γ is the surface tension of the fluid.

$$\mathrm{Bo} \equiv \frac{\Delta \rho g L^2}{\gamma} \tag{10}$$

These findings were later extended towards the development of autonomous microfluidic platforms employing *surface-directed* fluid transport. Several studies indicate that microfluidic platforms can be manufactured by chemically patterning substrates in combination with correspondingly patterned (or in some cases unpatterned) lids in a parallel plate arrangement [9–11]. Figure 1 demonstrates the approach utilized to develop such devices. Figures 1a and b demonstrate the configuration of a device fabricated with hydrophobic commodity polymers patterned on both bottom and top substrates with a hydrophilic silica sol gel material [9]. Figure 1c exhibits the fluid front, determined through computational fluid dynamics, of a device (Fig. 1d) where the bottom substrate is composed of a hydrophilic borosilicate wafer patterned with hydrophobic plasma-polymerized hexafluoropropene barriers developed photolithographically. The top substrate in Figs. 1c and d is indiscriminately hydrophobic.

Results from the development of these parallel plate *surface-directed microfluidic* have resulted in optimal device geometry recommendations. The optimal aspect ratio, defined as width per height of the device, has been determined through free energy considerations [3]. To ensure spontaneous capillary flow, the aspect ratio must follow Eq. (11) which indicates that the height of the device b, must always be less than the width of the device a, and the capacity to promote fluid flow is subject to the magnitude of the advancing contact angle of the hydrophilic path. The development of Eq. (11) follows arguments based upon the ▶Laplace pressure drop associated with interfacial *curvature* [3].

$$\frac{b}{a} \leqslant \cos\theta \tag{11}$$

Consequently, as the advancing contact angle increases towards the 90° limit for spontaneous flow, the capacity of the device to promote capillary flow diminishes drastically.

Furthermore, devices have been developed demonstrating reactions and passive valves with *self assembled monolayers* of OTS via either multi-stream laminar flow or photolithography [9, 10]. The pressure sensitive valves were demonstrated with silane solutions and water with trace amounts rhodamine-B for visualization purposes. The maximum pressure experienced based on capillarity was determined for these devices dependent upon device geometry, liquid surface tension γ and the advancing contact angle for the non-polar hydrophobic region θ_N [9, 10].

$$\Delta P_{\mathrm{MAX}} = \frac{2\gamma}{b} \sin\left(\theta_{\mathrm{N}} - \frac{\pi}{2}\right) \tag{12}$$

Furthermore, an application requiring a large interfacial surface area is demonstrated with an acidified gas and phosphate buffer neutralization in the presence of indicator. This investigation also presents conditions for critical width and curve radius that fluid can make under spontaneous flow conditions [10]. Furthermore, through energy minimization considerations, Lam et al. independently derive and demonstrate Eq. (11) is in excellent agreement between theoretical and experimental results [9]. Consequently, Eq. (11) can be derived through an alternative but equally valid approach.

An additional method regarding the fabrication of *surface-directed microfluidic* devices entails chemically pattering plasma polymerized hexafluoropropene coating photolithographically upon a hydrophilic borosilicate wafer [11]. Consequently, such a drastic differential in wettability is established that only one patterned substrate is required and can be coupled with a hydrophobic top substrate. The advantage of this approach is that it eliminates the tedious necessity for proper alignment for top and bottom substrates. The investigators of this approach present a theoretical model to predict fluid front position versus time based upon a conservation of momentum approach and discuss the similarities between their model and an analogous model derived for cylindrical capillaries.

$$\frac{\mathrm{d}^2\left(x^2\right)}{\mathrm{d}t^2} + \frac{12\mu}{\rho a^2}\frac{\mathrm{d}\left(x^2\right)}{\mathrm{d}t} + \frac{2\gamma\left[2a - b\left(\cos\theta_1 + \cos\theta_2\right)\right]}{\rho a b} = 0 \tag{13}$$

In this relation, x denotes the fluid front position as a function of time t, system architecture a and b, and intrinsic material properties including contact angles of the fluid upon the hydrophilic and hydrophobic materials θ_1 and θ_2, respectively. The solution to this second order ordinary differential equation with respect to *meniscus* position squared can be solved relatively easy through numerical techniques. The solution determined by the investigators of this approach is in excellent agreement with experimental results [11]. Furthermore, the investigators demonstrated that confluent monolayers of cells could be cultured in their apparatus and proteins could be selectively adsorbed upon the device surface [11]. Consequently, the *surface-directed* approach may be advantageous for appli-

cations requiring uninhibited gas exchange such as tissue engineering.

Lastly, the *surface-directed* approach is not without limitations. Due to the inherent simplicity associated with these devices, flow control and mixing become an issue. Moreover, paths with bifurcations pose a challenge to flow control as fluid does not discriminate between paths to flow across. Specifically, preferentially controlling which path a particular fluid travels across is difficult, at best. In addition, flow within microfluidic devices tends to be laminar rendering turbulent mixing is difficult to achieve, at best [1]. However, one may be able to overcome this predicament by strategically patterning resistance upon the device surface although this has yet to be employed within a two-dimensional chemically patterned platform.

Although much work still exists before chemically patterned devices provide novel solutions to problems in chemistry, biology and medicine, many of the reports discussed are encouraging regarding the capacity of *surface-directed microfluidic* devices to support autonomous chemical processes.

Topographical Manipulation

An alternative paradigm to facilitating capillary wicking via the *surface-directed* technique includes deliberately manipulating the topography of a device to control interfacial *curvature*. This approach to *surface-directed microfluidics* generally exploits the fact that capillary-based flow can occur where the corners meet as a consequence of the diminishing *radius of curvature* at the intersection [12]. However, for this flow to occur spontaneously, the Concus-Finn condition must be fulfilled considering the advancing contact angle θ, as well as the corner half-angle α [13].

$$\theta < \frac{\pi}{2} - \alpha \tag{14}$$

This technique has been rigorously studied for the determination of equilibrated liquid morphology on structured surfaces such as rectangular channels and in *v-grooves* [5, 6]. In the case of rectangular channels, a map has been constructed enabling the a priori determination of ultimate liquid morphology based upon the contact angle of the substrate and aspect ratio of the duct cross-section [14]. Figure 2 illustrates this morphological dependency on fluid properties and system architecture. The associated syntax addresses features characteristic of each morphological regime. Results were calculated theoretically with the surface evolver software package and were found to be in good agreement with experimental results investigated through AFM [14].

Furthermore, the *v-groove* morphology has been thoroughly investigated and relations for capillary dynamics have been developed [5, 6]. Several alcohols with γ/μ ratios ranging from 46 – 970 cm/s were studied in grooves of varying geometry machined into a copper substrate. Figure 3a illustrates the groove geometry while Fig. 3b demonstrates the experimental platform used to conduct the studies [5, 6]. Two models were developed characterizing the capillary dynamics. The first model considers a hydrodynamic approach where the driving force is a result of pressure drop across a curved interface. The second model depends strictly upon the total interfacial energy change while neglecting the shape of the curved interface. In both cases, flow was demonstrated to always follow a relation of the following form where $K(\alpha, \theta)$ is a geometric parameter dependent on system geometry and contact angle.

$$x = K(\alpha, \theta)\, h_0 \frac{\gamma}{\mu} t^{1/2} \tag{15}$$

The results of these analyses demonstrate that the three-phase contact line location follows the square root of time. Coumarin fluorescent dye was utilized in small quantities to develop sufficient contrast of the three-phase line under UV irradiation for the comparison of experimental data to the models. The investigators of this approach conclude that exhaustive solutions to the capillary flow model can be realized; however, approximations via Eq. (15) can be employed for sufficiently accurate predictive models [5, 6].

As demonstrated through the referenced literature, *topographical manipulation* provides the capacity to induce capillary wicking through interfacial *curvature* modulation. As a result, one can exploit techniques such as photolithography, chemical etching and even three-dimensional machining to produce features promoting *curvature* management. Consequently, the approach of *topographical manipulation* is yet another straightforward but viable technique to produce *surface-directed* fluid transport.

Flow Modulation Techniques

As already established in previous sections, the *surface-directed* approach to microfluidic system fabrication produces autonomously functioning devices with little rigor associated regarding implementation. This is a direct implication of the fact that the driving force for flow exploits capillary interactions producing spontaneous capillary flow. However, an unwanted artifact resulting from the inherent simplicity of these devices is that flow modu-

lation is particularly difficult. This drawback is especially hindering for systems requiring the controlled introduction and the selective guidance of fluids across intricate geometry. This section intends to introduce several techniques that have been or could be employed to guide fluids in specific directions.

One such mechanism to control flow directionality or rate includes manipulating ►thermocapillary shear stresses at the liquid air interface upon a substrate with a temperature gradient to facilitate fluid transport [15]. This technique has been demonstrated through patterning a SiO_2 wafer with hydrophobic strips of octadecyltrichlorosilane and coupling this substrate with a heater array to induce temperature gradients [15]. The driving force for such thermocapillary induced flow is through local heating that can reduce the liquid surface tension producing *thermocapillary shear stress* [15].

$$\tilde{\tau} \cdot \hat{n} = \nabla \gamma = \frac{\partial \gamma}{\partial T} \nabla T \qquad (16)$$

For liquids, $\partial \gamma / \partial T$ is essentially temperature independent indicating that the driving force is ∇T. This affect induces fluid transit from warmer areas to cooler areas of a substrate. Figure 4 demonstrates the capacity to control fluid progression utilizing this technique. As demonstrated, fluid can be directionally guided down required pathways and even across 90° angles. Furthermore, models have

been developed with a lubrication equation approach and found to be in good agreement with the experimental results [15].

Other techniques provide the potential to produce wettability modulation upon chemically patterned substrates. For example, ▶contraphilic polyurethane materials exist exhibiting an 83° contact angle when dry but a 108° contact angle in the presence of water [16]. The proposed mechanism is that amide inter/intramolecular hydrogen bonding occurs in the dry and moderately hydrophilic state while surface-confined amide-water hydrogen bonding releases semifluorinated groups yielding a more hydrophobic surface when wet [16]. This mechanism has been found to be reversible and could potentially serve as method to design passive gates between aqueous and nonaqueous solutions. This material could also be utilized to selectively pattern regions to impede fluid flowrate.

Another example of a coating technique presenting a feasible solution to developing wettability modulation includes employing light sensitive compounds such as spiropyrans. These photoisomerizable compounds can undergo an 11 − 14° reversible decrease in contact angle when light is switched from the visible region to ultraviolet [17]. This photocapillary modulation technique could be utilized to control the *Laplace pressure*, and therefore the flowrate, in a microfluidic channel coated with spiropyran compounds. Consequently, the field of flow modulation in *surface-directed microfluidics* is currently wide-open for investigation. Novel flow control methods are a necessity before integrating complex reaction processes into an on-chip format.

Key Research Findings

As demonstrated within this review, the *surface-directed microfluidics* approach offers a simple method for fabrication and implementation of micro-analytical systems. This burgeoning field offers great opportunity to resolve problems associated with more complicated microfluidic systems. Though this approach is rather new, several findings have already been established which may be of particular importance to investigators initiating research in this field. From a fluid physics perspective, rigorous solutions to the Navier–Stokes equations are not immediately realizable as a consequence of the poor understanding of ▶slip velocities associated with boundary conditions in microfluidic systems. However, alternative approaches towards developing dynamic flow models indicate *meniscus* position progresses according to the square root of time and is dependent upon fluid/substrate properties and system geometry as demonstrated in Eq. (5). Interestingly, Mann et al. [5, 6] found that a dynamic contact angle was not required to fit their experimental data to theoretical predictions. Furthermore, *surface-directed microfluidic* platforms can adequately be characterized as exhibiting low Reynolds, Péclet, capillary and Bond number flow. Subsequently, flow in *surface-directed* devices tends to be rather laminar with transport being dominated by diffusion with surface forces out-competing body forces such as gravity, respectively.

Chemical patterning and *topographical manipulation* techniques have successfully produced autonomous devices for fluid transport. In some cases, reaction processes have been integrated within these devices. However, this field is ripe with opportunity regarding the implementation of *surface-directed* platforms towards developing platforms that conduct reactive and diagnostic analyses. Preliminary diversion into theory has provided some relations that can be utilized for intelligent device optimization; however, a great deal of investigation needs to be addressed before a comprehensive understanding of device function is established.

Surface-directed microfluidic devices are inherently simple. Consequently, flow modulation is a concern. Methods have been employed to gain more control over flow such as mechanical actuation and thermocapillary induction. Moreover, material coatings provide the potential for the development of flowrate impediment and passive gate introduction through contraphilism or light-mediation.

Future Directions for Research

The *surface-directed microfluidics* approach presents a manufacturing methodology involving minimal rigor. Furthermore, *surface-directed* devices are devoid of extraneous mechanical/electrical components which can lead to component malfunction and overall device failure. As a consequence of the inherent simplicity of *surface-directed microfluidic* devices, implementation of the platform is straightforward and requires limited analytical experience. However, before wide-scale deployment of *surface-directed microfluidic* devices can be realized, a more comprehensive understanding of the underlying physics needs to be conducted. Certain phenomena play a larger role in fluid physics as liquid samples approach the nanoliter scale. For example, long-ranged inter-molecular interactions, thermal fluctuations such as capillary waves and the influence of the molecular structure of the fluid all inherit a greater capacity to affect fluid physics as surface area to volume ratios decrease. To realize greater degrees of *parallelization* and high-throughput, a better theoretical framework is a necessity regarding microfluidics as a whole encompassing the

(**f**)–(**i**) Dodecane drop propelled through a 1000 μm wide intersection (elapsed time = 104 s). (**j**)–(**l**) Dodecane drop thermally guided across a 90° angle in a 1000 μm wide intersection (elapsed time = 164 s) [15]

surface-directed technique. Lastly, fluid sample pretreatment techniques are of great consideration to ensure reproducible and reliable function of devices as only minimal amounts of contaminants are required to influence capillary dynamics in *surface-directed* devices. A comprehensive literature review exists as a basis for microfluidic sample pretreatment [18]; however, these findings need to be extended to the *surface-directed* approach to enhance platform reliability. Addressing such concerns may expedite the application of the *surface-directed microfluidics* towards current problems in chemistry, biology and medicine.

Appendix

Considering a Monge surface of area A_o in Cartesian coordinates, $\xi\,(t,x,y)$, the change in free energy required to curve this surface with respect to a flat surface with a reference free energy, Ω_0, at a constant composition and temperature is as follows.

$$\Omega - \Omega_0 = \int_{A_o} [p]\,\xi\,(t,x,y)\,\sqrt{a}\,\mathrm{d}x\,\mathrm{d}y + \int_{A_o} \sqrt{a}\,\mathrm{d}x\,\mathrm{d}y \quad \text{(a)}$$

Where $[p]$ is the pressure drop (ΔP) across the interface and the a is a geometrical parameter.

$$a = \sqrt{1 + \left(\frac{\partial \xi}{\partial x}\right)^2 + \left(\frac{\partial \xi}{\partial y}\right)^2} \quad \text{(b)}$$

Considering that the surface $\xi\,(t,x,y)$ is arbitrary and the associated derivatives are small, the free energy function is simplified.

$$\Omega - \Omega_0 = \int_{A_o} [p]\,\xi\,\mathrm{d}x\,\mathrm{d}y + \int_{A_o} \gamma \left[1 + \frac{1}{2}\left(\frac{\partial \xi}{\partial x}\right)^2 + \frac{1}{2}\left(\frac{\partial \xi}{\partial y}\right)^2\right] \mathrm{d}x\,\mathrm{d}y \quad \text{(c)}$$

Let δ be the variational operator and consider that $\xi\,(t,x,y)$ and the derivatives of $\xi\,(t,x,y)$ are equal to zero on the boundary, ∂A_o , over which the variation function is determined. Moreover, it is implicitly assumed that $\delta\,[p] = 0$

and $\delta\gamma = 0$.

$$\delta\Omega = \int_{A_o} [p]\,\delta\xi\,dx\,dy + \int_{A_o} \gamma \left[\frac{\partial \xi}{\partial x}\frac{\partial \delta\xi}{\partial x} + \frac{\partial \xi}{\partial y}\frac{\partial \delta\xi}{\partial y} \right] dx\,dy \tag{d}$$

Utilizing integration by parts on the second integral further simplifies the variation in free energy.

$$\delta\Omega = \int_{A_o} [p]\,\delta\xi\,dx\,dy - \int_{A_o} \gamma \left[\frac{\partial^2 \xi}{\partial x^2} + \frac{\partial^2 \xi}{\partial y^2} \right] \delta\xi\,dx\,dy \tag{e}$$

Because A_o is arbitrary and $\delta\xi$ is small, but an otherwise arbitrary variation, an explicit pressure drop dependence becomes apparent.

$$0 = [p] - \gamma \left[\frac{\partial^2 \xi}{\partial x^2} + \frac{\partial^2 \xi}{\partial y^2} \right] \tag{f}$$

Furthermore, in comparison with the Laplace pressure, $\Delta P = 2\gamma H$, the mean curvature of the Monge surface can be reconstructed leading directly to the result in Eq. (2).

Definition

Surface chemistry is of great importance in micro/nano-fluidic devices, especially in the case of miniaturized and integrated systems, owing to the high surface-area-to-volume ratio. Surface properties play a vital role in a number of microfluidic devices through hydrophobic and electrostatic interactions. Protein and cell adhesion at surfaces can occur because of hydrophobic and electrostatic interactions, which is undesirable in bioanalytical applications. Control of surface properties is thus an indispensable prerequisite in microfluidic systems. The approach generally adopted is to modify the surface chemistry of the device to make it more useful for various applications.

Overview
